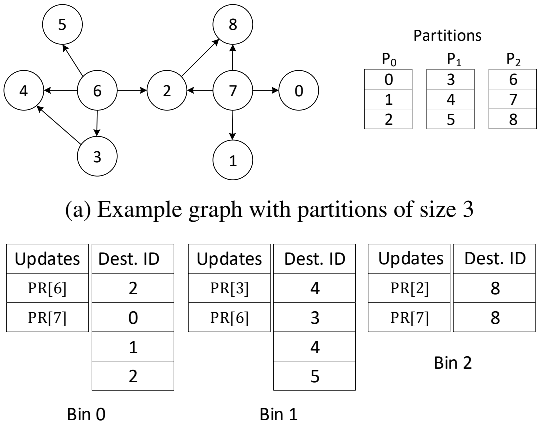
Before beginning PageRank computation, each partition calculates the offsets (address in bins where it must start writing from) into all *update_bins* and *destID_bins*. Our scattering strategy dictates that the partitions write to bins in the order of their IDs. Therefore, the offset for a partition P_i into any given bin is the sum of the number of values that all partitions with ID $< i$ are writing into that bin. For instance, in fig. 2, the offset of partition P_2 into *update_bins*[0] is 0 (since partitions P_0 and P_1 do not write to bin 0). Similarly, its offset into *update_bins*[1] and *update_bins*[2] is 1 (since P_1 writes one update to bin 1 and P_0 writes one update to bin 2). Offset computation provides each partition fixed and disjoint locations to write messages. This allows PCPM to parallelize partition processing without the need of locks or atomics.



(a) Example graph with partitions of size 3

(b) Bins store update value and list of destination nodes

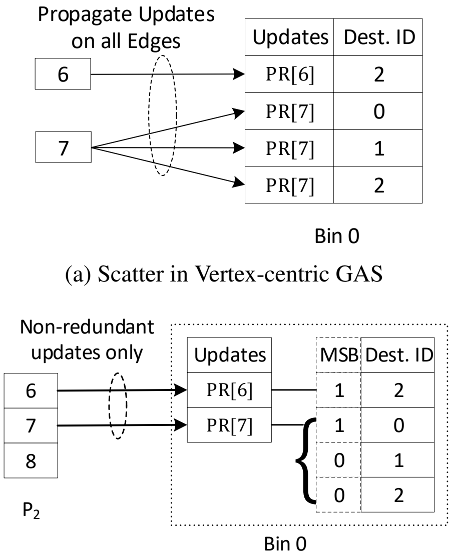
Figure 2: Graph Partitioning and messages inserted in bins during scatter phase

Note that since the destination node IDs written in the first iteration remain unchanged over the course of algorithm, they are written only once and reused in subsequent iterations. The reuse of destination node IDs along with the specific system optimizations discussed in section 3.2 and 3.3 enables PCPM to traverse only a fraction of the graph during scatter phase. This dramatically reduces the number of DRAM accesses and *gets rid of the inherent sub-optimality of GAS model.*

3.2 Partition-Centric Update Propagation

The unique abstraction of PCPM naturally leads to transmitting a single update from a node to a neighboring partition. In other words, even if a node has multiple neighbors in a partition, it inserts only one update value in the corresponding *update_bins* during scatter phase (algorithm 2). Fig. 3 illustrates the difference between Partition-Centric and Vertex-centric scatter for the example graph shown in fig. 2a.

PCPM manipulates the Most Significant Bit (MSB) of destination node IDs to indicate the range of nodes in a partition that use the same update value. In the *destID_bins*, it consecutively writes IDs of all nodes in the neighborhood of same source vertex and sets the MSB of first ID in this range to 1 for demarcation (fig. 3b). Since MSB is reserved for this functionality, PCPM supports graphs with upto 2 billion nodes instead of 4 billion for 4 Byte node IDs. However, to the best of our knowledge, this is enough to process most of the large publicly available datasets.



(a) Scatter in Vertex-centric GAS

(b) Scatter in PCPM

Figure 3: PCPM decouples *update_bins* and *destID_bins* to avoid redundant update value propagation

The gather phase starts only after all partitions are processed in the scatter phase. PCPM gather function sequentially reads updates and node IDs from the bins of the partition being processed. When gathering partition P_i, an update value $PR[v]$ should be applied to all out-neighbors of v that lie in P_i. This is done by checking the MSB of node IDs to determine whether to apply the previously read update or to read the next update, as shown in algorithm 2. The MSB is then masked to generate the true ID of destination node whose partial sum is updated.

Algorithm 2 describes PCPM based PageRank computation using a row-wise partitioned CSR format for adjacency matrix A. Note that PCPM only writes updates for *some* edges in a node's adjacency list, specifically the first outgoing edge to a partition. The remaining edges to that partition are *unused*. Since CSR stores adjacencies of a node contiguously, the set of first edges to neighboring partitions is interleaved with other edges. Therefore, we have to scan all outgoing edges of each vertex during scatter phase to access this set, which decreases efficiency. Moreover, the algorithm can potentially switch bins for each update insertion, leading to random writes to DRAM. Finally, the manipulation of MSB in node indices introduces additional data dependent branches which hurts the performance. Clearly, CSR adjacency matrix is not an efficient data layout for graph processing using PCPM. In the next section, we propose a PCPM-specific data layout.

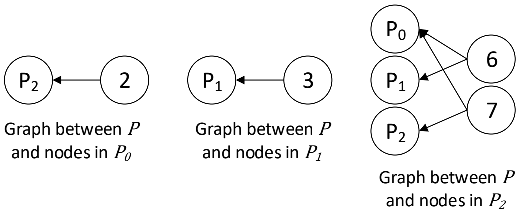
Algorithm 2 PageRank iteration in PCPM using CSR format. Writing of *destID_bins* is not shown here.

```
$q \rightarrow$ partition size, $P \rightarrow$ set of partitions
for all $p \in P$ do in parallel                                  ▷ Scatter
    for all $v \in p$ do
        $prev\_bin \leftarrow \infty$
        for all $u \in N_o(v)$ do
            if $\lfloor u/q \rfloor \neq prev\_bin$ then
                insert $PR[v]$ in $update\_bins[\lfloor u/q \rfloor]$
                $prev\_bin \leftarrow \lfloor u/q \rfloor$
$PR[:] \leftarrow 0$
for all $p \in P$ do in parallel                                  ▷ Gather
    while $destID\_bins[p] \neq \emptyset$ do
        pop $id$ from $destID\_bins[p]$
        if $MSB(id) \neq 0$ then
            pop $update$ from $update\_bins[p]$
        $PR[id \ \& \ bitmask] \mathrel{+}= update$
for all $v \in V$ do in parallel                                  ▷ Apply
    $PR[v] \leftarrow \frac{(1-d)/|V| \ + \ d \times PR[v]}{|N_o(v)|}$
```

3.3 Data Layout Optimization

In this subsection, we describe a new bipartite Partition-Node Graph (PNG) data layout that brings out the true Partition-Centric nature of PCPM. During the scatter phase, PNG prevents unused edge reads and ensures that all updates to a bin are streamed together before switching to another bin.

We exploit the fact that once *destID_bins* are written, the only required information in PCPM is the connectivity between nodes and partitions. Therefore, edges going from a source to all destination nodes in a single partition can be *compressed* into one edge whose new destination is the corresponding partition number. This gives rise to a bipartite graph G' with disjoint vertex sets V and P (where $P = \{P_0, \ldots, P_{k-1}\}$ represents the set of partitions in the original graph), and a set of directed edges E' going from V to P. Such a transformation has the following effects:



P2
2
Graph between P and nodes in P0
P1
3
Graph between P and nodes in P1
P0
P1
P2
6
7
Graph between P and nodes in P2

Figure 4: Partition-wise construction of PNG $G'(P,V,E')$ for graph $G(V,E)$ (fig. 2a). $|E'|$ is much smaller than $|E|$.

1. $Eff_1 \rightarrow$ the unused edges in original graph are removed
2. $Eff_2 \rightarrow$ the range of destination IDs reduces from $|V|$ to $|P|$.

The advantages of Eff_1 are obvious but those of Eff_2 will become clear when we discuss the storage format and construction of PNG.

The compression step reduces memory traffic by eliminating unused edge traversal. However note that scatters to a bin from source vertices in a partition are still interleaved with scatters to other bins. This can lead to random DRAM accesses during the scatter phase processing of a (source) partition. We resolve this problem by *transposing* the adjacency matrix of bipartite graph G'. The rows of the transposed matrix represent edges grouped by destination partitions which enables streaming updates to one bin at a time. This advantage comes at the cost of random accesses to source node values during the scatter phase. To prevent these random accesses from going to DRAM, we construct PNG on a per-partition basis i.e. we create a separate bipartite graph for each partition P_i with edges between P and the nodes in P_i (fig. 4). By carefully choosing q to make partitions *cacheable*, we ensure that all requests to source nodes are served by the cache resulting in *zero random DRAM accesses*.

Eff_2 is crucial for *transposition* of bipartite graphs in all partitions. The number of offsets required to store a transposed matrix in CSR format is equal to the range of destination node IDs. By reducing this range, Eff_2 reduces the storage requirement for offsets of each matrix from $O(|V|)$ to $O(|P|)$. Since there are $|P|$ partitions, each having one bipartite graph, the total storage requirement for edge offsets in PNG is $O(|P|^2)$ instead of $O(|V| \times |P|)$.

Although PNG construction looks like a 2-step approach, we actually merge *compression* and *transposition* into a single step. We first scan the outgoing edges of all nodes in a partition and individually compute the in-degree of all the destination partitions while discarding unused edges. A prefix sum of these degrees is carried out to compute the offsets array for CSR matrix. The same offsets can also be used to allocate disjoint writing locations into the bins of destination partitions. In the next scan, the edge array in CSR is filled with source node IDs completing both *compression* and *transposition*. PNG construction can be easily parallelized over all partitions to accelerate the pre-processing effectively.

Algorithm 3 shows the pseudocode for PCPM scatter phase using PNG layout. Unlike algorithm 2, the scatter function in algorithm 3 does not contain data dependent branches to check and discard unused edges. Using PNG provides drastic performance gains in PCPM scatter phase with little pre-processing overhead.

Algorithm 3 PCPM scatter phase using PNG layout

```
$G'(P,V,E') \rightarrow$ PNG, $N_i^p(p') \rightarrow$ in-neighbors of partition $p'$ in bipartite graph of partition $p$
**for all** $p \in P$ **do in parallel**                ▷ **Scatter**
    **for all** $p' \in P$ **do**
        **for all** $u \in N_i^p(p')$ **do**
            **insert** $PR[u]$ into $update\_bins[p']$
```

3.4 Branch Avoidance

Data dependent branches have been shown to have significant impact on performance of graph algorithms [14] and PNG removes such branches in PCPM scatter phase. In this subsection, we propose a branch avoidance mechanism for the PCPM gather phase. Branch avoidance enhances the sustained memory bandwidth but does not impact the amount of DRAM communication.

Note that the **pop** operations shown in algorithm 2 are implemented using pointers that increment after reading an entry from the respective bin. Let $destID\_ptr$ and $update\_ptr$ be the pointers to $destID\_bins[p]$ and $update\_bins[p]$, respectively. Note that the $destID\_ptr$ is incremented in every iteration whereas the $update\_ptr$ is only incremented if $MSB[id] \neq 0$.

To implement the branch avoiding gather function, instead of using a condition check over $MSB(id)$, we add it directly to $update\_ptr$. When $MSB(id)$ is 0, the pointer is not incremented and the same update value is read from cache in the next iteration; when $MSB(id)$ is 1, the pointer is incremented executing the **pop** operation on $update\_bins[p]$. The modified pseudocode for gather phase is shown in algorithm 4.

3.5 Weighted Graphs and SpMV

PCPM can be easily extended for computation on weighted graphs by storing the edge weights along with destination IDs in *destID_bins*. These weights can be read in the gather phase and applied to the source node value before updating the destination node. PCPM can also be extended to generic SpMV with non-square matrices by partitioning the rows and columns separately. In this case, the outermost loops in scatter phase (algorithm 3) and gather phase (algorithm 4) will iterate over row partitions and column partitions of A, respectively.

Algorithm 4 Branch Avoiding gather function in PCPM

```
$PR[:] = 0$
**for all** $p \in P$ **do in parallel**                ▷ **Gather**
    $\{destID\_ptr,\ update\_ptr\} \leftarrow 0$
    **while** $destID\_ptr < size(destID\_bins[p])$ **do**
        $id \leftarrow destID\_bins[p][destID\_ptr{+}{+}]$
        $update\_ptr \mathrel{+}= MSB(id)$
        $id \leftarrow id\ \&\ bitmask$
        $PR[id] \mathrel{+}= update\_bins[p][update\_ptr]$
```

4 Comparison with Vertex-centric GAS

The Binning with Vertex-centric GAS (BVGAS) method allocates multiple bins to store incoming messages ($(update, destID)$ pairs). If bin width is q, then all messages destined to $v \in [i*q, (i+1)*q)$ are written in bin i. The scatter phase traverses the graph in a Vertex-centric fashion and inserts the messages in respective bins of the destination vertices. Number of bins is kept small to allow insertion points for all bins to fit in cache, providing good spatial locality. The gather phase processes one bin at a time as shown in algorithm 5, and thus, enjoys good temporal locality if bin width is small.

Algorithm 5 PageRank Iteration using BVGAS

```
$q \rightarrow$ bin width, $B \rightarrow$ no. of bins
**for** $v \in V$ **do**                              ▷ **Scatter**
    $PR[v] = PR[v]/|N_o(v)|$
    **for all** $u \in N_o(v)$ **do**
        **insert** $(PR[v], u)$ into $bins[\lfloor u/q \rfloor]$
$PR[:] = 0$
**for** $b = 0$ to $B-1$ **do**                       ▷ **Gather**
    **for all** $(update, dest)$ in $bins[b]$ **do**
        $PR[dest] = PR[dest] + update$
**for all** $v \in V$ **do**                          ▷ **Apply**
    $PR[v] = \frac{(1-d)}{|V|} + d \times PR[v]$
```

Unlike algorithm 5, in our BVGAS implementation, we write the destination IDs only in the first iteration. We also use small cached buffers to store updates before writing to DRAM. This ensures full cache line utilization and reduces communication during scatter phase [5].

Irrespective of all the locality advantages and optimizations, BVGAS inherently suffers from redundant reads and writes of a vertex value on all of its outgoing

Table 2: List of model parameters

Original Graph $G(V,E)$		PNG layout $G'(P,V,E')$	
n	no. of vertices ($\lvert V \rvert$)	k	no. of partitions ($\lvert P \rvert$)
m	no. of edges ($\lvert E \rvert$)	r	compression ratio ($\lvert E \rvert / \lvert E' \rvert$)

Architecture		Software	
c_{mr}	cache miss ratio for source value reads in PDPR	d_v	sizeof (updates/PageRank value)
l	sizeof (cache line)	d_i	sizeof (node or edge index)

edges. This redundancy manifests itself in the form of BVGAS' inability to utilize *high locality* in graphs with optimized node labeling. PCPM on the other hand, uses graph locality to reduce the fraction of graph traversed in scatter phase. Unlike PCPM, the Vertex-centric traversal in BVGAS can also insert consecutive updates into different bins. This leads to random DRAM accesses and poor bandwidth utilization. We provide a quantitative analysis of these differences in the next section.

5 Analytical Evaluation

We derive performance models to compare PCPM against conventional Pull Direction PageRank (PDPR) and BVGAS. Our models provide valuable insights into the behavior of different methodologies with respect to varying graph structure and locality. Table 2 defines the parameters used in the analysis. We use a synthetic kronecker graph [28] of scale 25 *(kron)* as an example for illustration purposes.

5.1 DRAM Communication

We analyze the amount of data exchanged with main memory per iteration of PageRank. We assume that data is accessed in quantum of one cache line and BVGAS exhibits full cache line utilization. Since destination indices are written only in the first iteration for PCPM and BVGAS, they are not accounted for in this model.

PDPR: The pull technique scans all edges in the graph once (algorithm 1). For a CSR format, this requires reading n edge offsets and m source node indices. PDPR also reads m source node values that incur cache misses generating $mc_{mr}l$ Bytes of DRAM traffic. Outputting new PageRank values generates nd_v Bytes of writes to DRAM. The total communication volume for PDPR is:

$$PDPR_{comm} = m(d_i + c_{mr}l) + n(d_i + d_v) \tag{2}$$

BVGAS: The scatter phase (algorithm 5) scans the graph and writes updates on all outgoing edges of the source node, thus communicating $(n+m)d_i + (n+m)d_v$ Bytes. The gather phase loads updates and destination node IDs on all the edges generating $m(d_i + d_v)$ Bytes of read traffic. At the end of gather phase, nd_v Bytes of new PageRank values are written in the main memory. Total communication volume for BVGAS is therefore, given by:

$$BVGAS_{comm} = 2m(d_i + d_v) + n(d_i + 2d_v) \tag{3}$$

PCPM with PNG: Number of edge offsets in bipartite graph of each partition is k. Thus, in the scatter phase (algorithm 3), a scan of PNG reads $(k \times k + {}^{m}\!/_{r})d_i$ Bytes. The scatter phase further reads n PageRank values and writes updates on ${}^{m}\!/_{r}$ edges. The gather phase (algorithm 4) reads m destination IDs and ${}^{m}\!/_{r}$ updates followed by n new PageRank value writes. Net communication volume in PCPM is given by:

$$PCPM_{comm} = m\left(d_i\left(1 + \frac{1}{r}\right) + \frac{2d_v}{r}\right) + k^2 d_i + 2nd_v \tag{4}$$

Comparison: Performance of pull technique depends heavily on c_{mr}. In the worst case, all accesses are cache misses i.e. $c_{mr} = 1$ and in best case, only cold misses are encountered to load the PageRank values in cache i.e. $c_{mr} = {}^{nd_v}\!/_{ml}$. Assuming $k^2 \ll n \ll m$, we get $PDPR_{comm} \in [md_i, m(d_i + l)]$. On the other hand, communication for BVGAS stays constant. With $\theta(m)$ additional loads and stores, $BVGAS_{comm}$ can never reach the lower bound of $PDPR_{comm}$. Comparatively, $PCPM_{comm}$ achieves optimality when for every vertex, all outgoing edges can be compressed into a single edge i.e. $r = {}^{m}\!/_{n}$. In the worst case when $r = 1$, PCPM is still as good as BVGAS and we get $PCPM_{comm} \in [md_i, m(2d_i + 2d_v)]$. Unlike BVGAS, $PCPM_{comm}$ achieves the same lower bound as $PDPR_{comm}$.

Analyzing equations 2 and 3, we see that BVGAS is profitable compared to PDPR when:

$$c_{mr} > \frac{d_i + 2d_v}{l} \tag{5}$$

In comparison, PCPM offers a more relaxed constraint on c_{mr} (by a factor of ${}^{1}\!/_{r}$) becoming advantageous when:

$$c_{mr} > \frac{d_i + 2d_v}{rl} \tag{6}$$

The RHS in eq. 5 is constant indicating that BVGAS is advantageous for low locality graphs. With optimized node ordering, we can reduce c_{mr} and outperform BVGAS. On the contrary, $r \in [1, {}^{m}\!/_{n}]$ in the RHS of eq. 6 is a function of locality. With an optimized node labeling, r also increases and enhances the performance of PCPM. Fig. 5 shows the effect of r on predicted DRAM communication for the *kron* graph. Obtaining an optimal nodel labeling that makes $r = {}^{m}\!/_{n}$ might be very difficult or even impossible for some graphs. However, as can be observed from fig. 5, DRAM traffic decreases rapidly for $r \leq 5$ and converges slowly for $r > 5$. Therefore, a node reordering that can achieve $r \approx 5$ is good enough to optimize communication volume in PCPM.

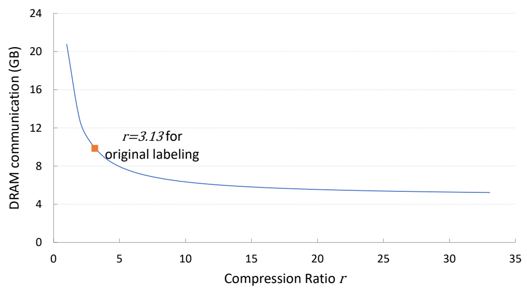


Figure 5: Predicted DRAM traffic for *kron* graph with $n = 33.5$ M, $m = 1070$ M, $k = 512$ and $d_i = d_v = 4$ Bytes.

5.2 Random Memory Accesses

We define a random access as a non-sequential jump in the address of memory location being read from or written to DRAM. Random accesses can incur latency penalties and negatively impact the sustained memory bandwidth. In this subsection, we model the amount of random accesses performed by different methodologies in a single PageRank iteration.

PDPR: Reading edge offsets and source node IDs in pull technique is completely sequential because of the CSR format. However, all accesses to source node PageRank values served by DRAM contribute to potential random accesses resulting in:

$$PDPR_{ra} = O(mc_{mr}) \tag{7}$$

BVGAS: In scatter phase of algorithm 5, updates can potentially be inserted at random memory locations. Assuming full cache line utilization for BVGAS, for every l Bytes written, there is at most 1 random DRAM access. In gather phase, all DRAM accesses are sequential if we assume that bin width is smaller than the cache. Total random accesses for BVGAS are then given by:

$$BVGAS_{ra} = O\left(\frac{md_v}{l}\right) \tag{8}$$

PCPM: With the PNG layout (algorithm 3), there are at most k bin switches when scattering updates from a partition. Since there are k such partitions, total number of random accesses in PCPM is bound by:

$$PCPM_{ra} = O(k * k) = O(k^2) \tag{9}$$

Comparison: BVGAS exhibits less random accesses than PDPR. However, $PCPM_{ra}$ is much smaller than both $BVGAS_{ra}$ and $PDPR_{ra}$. For instance, in the *kron* dataset with $d_v = 4$ Bytes, $l = 64$ Bytes and $k = 512$, $BVGAS_{ra} \approx 66.9$ M whereas $PCPM_{ra} \approx 0.26$ M.

Although it is not indicated in algorithm 5, the number of data dependent unpredictable branches in cache bypassing BVGAS implementation is also $O(m)$. For every update insertion, the BVGAS scatter function has to check if the corresponding cached buffer is full (section 4). In contrast, the number of branch mispredictions for PCPM (using branch avoidance) is $O(k^2)$ with 1 misprediction for every destination partition (p') switch in algorithm 3. The derivations are similar to random access model and for the sake of brevity, we do not provide a detailed deduction.

6 Experimental Evaluation

6.1 Experimental Setup and Datasets

We conduct experiments on a dual-socket Ivy Bridge server equipped with two 8-core Intel Xeon E5-2650 v2 processors@2.6 GHz running Ubuntu 14.04 OS. Table 3 lists important characteristics of our machine. Memory bandwidth is measured using STREAM benchmark [25]. All codes are written in C++ and compiled using G++ 4.7.1 with the highest optimization -O3 flag. The memory statistics are collected using Intel Performance Counter Monitor [40]. All data types used for indices and PageRank values are 4 Bytes.

Table 3: System Characteristics

Socket	no. of cores	8
	shared L3 cache	25MB
Core	L1d cache	32 KB
	L2 cache	256 KB
Memory	size	128 GB
	Read BW	59.6 GB/s
	Write BW	32.9 GB/s

We use 6 large real world and synthetic graph datasets coming from different applications, for performance evaluation. Table 4 summarizes the size and sparsity characteristics of these graphs. *Gplus* and *twitter* are follower graphs on social networks; *pld*, *web* and *sd1* are hyperlink graphs obtained by web crawlers; and *kron* is a scale 25 graph generated using Graph500 Kronecker generator. The *web* is a very sparse graph but has high locality obtained by a very expensive pre-processing of node labels [6]. The *kron* graph has higher edge density as compared to other datasets.

Table 4: Graph Datasets

Dataset	Description	# Nodes (M)	# Edges (M)	Degree
gplus [12]	Google Plus	28.94	462.99	16
pld [27]	Pay-Level-Domain	42.89	623.06	14.53
web [6]	Webbase-2001	118.14	992.84	8.4
kron [28]	Synthetic graph	33.5	1047.93	31.28
twitter [19]	Follower network	61.58	1468.36	23.84
sd1 [27]	Subdomain graph	94.95	1937.49	20.4

6.2 Implementation Details

We use a simple hand coded implementation of algorithm 1 for PDPR and parallelize it over vertices with static load balancing on the number of edges traversed. Our baseline does not incur overheads associated with similar implementations in frameworks [35, 30, 37] and hence, is faster than framework based programs [5].

To parallelize BVGAS scatter phase (algorithm 5), we give each thread a fixed range of nodes to scatter. Work per thread is statically balanced in terms of the number of edges processed. We also give each thread distinct memory spaces corresponding to all bins to avoid atomicity concerns in scatter phase. We use the Intel AVX non-temporal store instructions [1] to bypass the cache while writing updates and use 128 Bytes cache line aligned buffers to accumulate the updates for streaming stores [5]. BVGAS gather phase is parallelized over bins with load balanced using OpenMP dynamic scheduling. The optimal bin width is empirically determined and set to 256 KB (64K nodes). As bin width is a power of 2, we use bit shift instructions instead of integer division to compute the destination bin from node ID.

The PCPM scatter and gather phases are parallelized over partitions and load balancing in both the phases is done dynamically using OpenMP. Partition size is empirically determined and set to 256 KB. A detailed design space exploration of PCPM is discussed in section 6.3.2.

All the implementations mentioned in this section execute 20 PageRank iterations on 16 cores. For accuracy of the collected information, we repeat these algorithms 5 times and report the average values.

6.3 Results

6.3.1 Comparison with Baselines

Execution Time: Fig. 6 gives a comparison of the GTEPS (computed as the ratio of giga edges in the graph to the runtime of single PageRank iteration) achieved by different implementations. We observe that PCPM is $2.1-3.8\times$ faster than the state-of-the-art BVGAS implementation and upto $4.1\times$ faster than PDPR. BVGAS achieves constant throughput irrespective of the graph structure and is able to accelerate computation on low locality graphs. However, it is worse than PDPR for high locality (*web*) and dense (*kron*) graphs. PCPM is able to outperform PDPR and BVGAS on all datasets, though the speedup on *web* graph is minute because of high performance of PDPR. Detailed results for execution time of BVGAS and PCPM during different phases of computation are given in table 5. PCPM scatter phase benefits from a multitude of optimizations to achieve a dramatic $5\times$ speedup over BVGAS scatter phase.

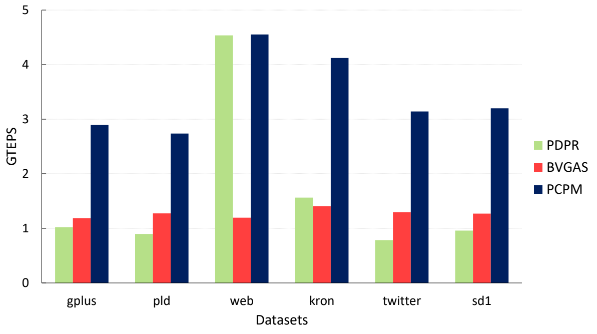

Figure 6: Performance in GTEPS. PCPM provides substantial speedup over BVGAS and PDPR.

Table 5: Execution time per iteration of PageRank for PDPR, BVGAS and PCPM

	PDPR	BVGAS			PCPM		
Dataset	Total Time(s)	Scatter Time(s)	Gather Time(s)	Total Time(s)	Scatter Time(s)	Gather Time(s)	Total Time(s)
gplus	0.44	0.26	0.12	0.38	0.06	0.1	0.16
pld	0.68	0.33	0.15	0.48	0.09	0.13	0.22
web	0.21	0.58	0.23	0.81	0.04	0.17	0.21
kron	0.65	0.5	0.22	0.72	0.07	0.18	0.25
twitter	1.83	0.79	0.32	1.11	0.18	0.27	0.45
sd1	1.97	1.07	0.42	1.49	0.24	0.35	0.59

Communication and Bandwidth: Fig. 7 shows the amount of data communicated with main memory normalized by the number of edges in the graph. Average communication in PCPM is $1.7\times$ and $2.2\times$ less than BVGAS and PDPR, respectively. Further, PCPM memory traffic per edge for *web* and *kron* is lower than other graphs because of their high compression ratio (table 6). The normalized communication for BVGAS is almost constant and therefore, its utility depends on the efficiency of pull direction baseline.

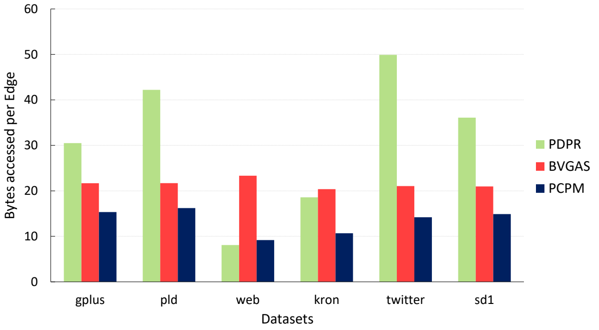

Figure 7: Main memory traffic per edge. PCPM communicates the least for all datasets except the *web* graph.

Note that the speedup obtained by PCPM is larger than the reduction in communication volume. This is because by avoiding random DRAM accesses and unpredictable branches, PCPM is able to efficiently utilize the available DRAM bandwidth. As shown in fig. 8, PCPM can sustain an average 42.4 GB/s bandwidth compared to 33.1 GB/s and 26 GB/s of PDPR and BVGAS, respectively. For large graphs like *sd1*, PCPM achieves $\approx 77\%$ of the peak read bandwidth (table 3) of our system. Although both PDPR and BVGAS suffer from random memory accesses, the former executes very few instructions and therefore, has better bandwidth utilization.

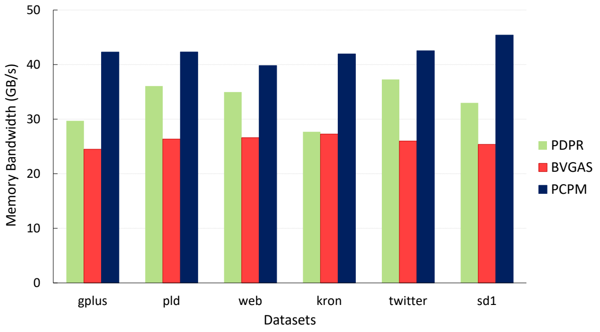

Figure 8: Sustained Memory Bandwidth for different methods. PCPM achieves highest bandwidth utilization.

Table 6: Locality vs compression ratio r. GOrder improves locality in neighbors and increases compression

		Original Labeling		GOrder Labeling	
Dataset	#Edges in Graph (M)	#Edges in PNG (M)	r	#Edges in PNG (M)	r
gplus	463	243.8	1.9	157.4	2.94
pld	623.1	347.7	1.79	166.7	3.73
web	992.8	118.1	8.4	126.8	7.83
kron	104.8	342.7	3.06	169.7	6.17
twitter	1468.4	722.4	2.03	386.2	3.8
sd1	1937.5	976.9	1.98	366.2	5.29

The reduced communication and streaming access patterns in PCPM also enhance its energy efficiency resulting in lower μJ/edge consumption as compared to BVGAS and PDPR, as shown in fig. 9. Energy efficiency is important from an eco-friendly computing perspective as highlighted by the Green Graph500 benchmark [16].

Effect of Locality: To assess the impact of locality on different methodologies, we relabel the nodes in our graph datasets using the GOrder [39] algorithm. We refer to the original node labeling in graph as *Orig* and GOrder labeling as simply *GOrder*. *GOrder* increases spatial locality by placing nodes with common in-neighbors closer in the memory. As a result, outgoing edges of the nodes tend to be concentrated in few partitions which increases the compression ratio r as shown in table 6. However, the *web* graph exhibits near optimal compression ($r = 8.4$) with *Orig* and does not show improvement with *GOrder*.

Table 7 shows the impact of *GOrder* on DRAM communication. As expected, BVGAS communicates a constant amount of data for a given graph irrespective of the labeling scheme used. On the contrary, memory traffic generated by PDPR and PCPM decreases because of reduced c_{mr} and increased r, respectively. These observations are in complete accordance with the performance models discussed in section 5.1. The effect on PCPM is not as drastic as PDPR because after r becomes greater than a threshold, PCPM communication decreases slowly as shown in fig. 5. Nevertheless, for almost all of the datasets, the net data transferred in PCPM is remarkably lesser than both PDPR and BVGAS for either of the vertex labelings.

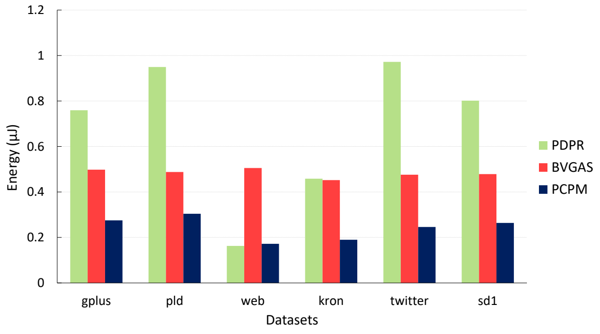

Figure 9: DRAM energy consumption per edge. PCPM benefits from reduced communication and random memory accesses.

Table 7: DRAM data transfer per iteration (in GB). PDPR and PCPM benefit from optimized node labeling

	PDPR		BVGAS		PCPM

sd1	65.1	23.8	37.8	37.8	26.9	15.6

6.3.2 PCPM Design Space Exploration

Partition size represents an important tradeoff in PCPM. Large partitions force neighbors of each node to fit in fewer partitions resulting in better compression but poor locality. Small partitions on the other hand ensure high locality random accesses within partitions but reduce compression. We evaluate the impact of partition size on the performance of PCPM by varying it from 32 KB (8K nodes) to 8 MB (2M nodes). We observe a reduction in DRAM communication volume with increasing partition size (fig. 10). However, increases partition size beyond what cache can accommodate results in cache misses and a drastic increase in the DRAM traffic. As an exception, the performance on *web* graph is not heavily affected by partition size because of its high locality.

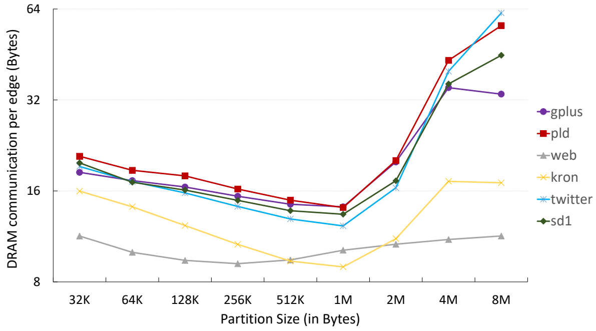

Figure 10: Impact of partition size on communication volume. Very large partitions result in cache misses and increased DRAM traffic.

The execution time (fig. 11) also benefits from communication reduction and is penalized by cache misses for large partitions. Note that for partition sizes > 256 KB and <= 1 MB, communication volume decreases but execution time increases. This is because in this range, many requests are served from the larger shared L3 cache which is slower than the private L1 and L2 caches. This phenomenon decelerates the computation but does not add to DRAM traffic.

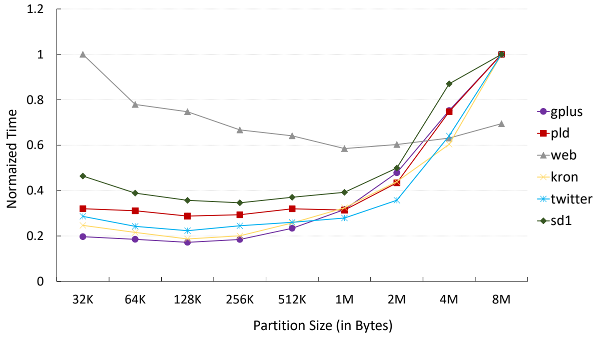

Figure 11: Impact of partition size on execution time.

Table 8: Pre-processing time of different methodologies. PNG construction increases the overhead of PCPM

Dataset	PCPM	BVGAS	PDPR
gplus	0.25s	0.1s	0s

twitter	0.7s	0.27s	0s
sd1	0.95s	0.32s	0s

6.3.3 Pre-processing Time

We assume that adjacency matrix in CSR and CSC format is available and hence, PDPR does not need any pre-processing. Both BVGAS and PCPM however, require a beforehand computation of bin size and write offsets incurring non-zero pre-processing time as shown in table 8. In addition, PCPM also constructs the PNG layout. Fortunately, the computation of write offsets can be easily merged with PNG construction (section 3.3) to reduce the overhead. The pre-processing time also gets amortized over multiple iterations of PageRank.

7 Conclusion and Future Work

In this paper, we formulated a Partition-Centric Processing Methodology (PCPM) that perceives a graph as a set of links between nodes and partitions instead of nodes and their individual neighbors. We presented several features of this abstraction and developed data layout and system level optimizations to exploit them.

We conducted extensive analytical and experimental evaluation of our approach. Using a simple index based partitioning, we observed an average 2.7× speedup in execution time and 1.7× reduction in DRAM communication volume over state-of-the-art. In the future, we will explore edge partitioning models [21, 8] to further reduce communication and improve load balancing for PCPM.

Although we demonstrate the advantages of PCPM on PageRank, we show that it can be easily extended to generic SpMV computation. We believe that PCPM can be an efficient programming model for other graph algorithms or graph analytics frameworks. In this context, there are many promising directions for further exploration. For instance, the streaming memory access patterns of PNG enabled PCPM are highly suitable for High Bandwidth Memory (HBM) and disk-based systems. Exploring PCPM as a programming model for heterogenous memory or processor architectures is an interesting avenue for future work.

PCPM accesses nodes from only one graph partition at a time. Hence, G-Store's smallest number of bits representation [18] can be used to reduce the memory footprint and DRAM communication even further. Devising novel methods for enhanced compression can also make PCPM amenable to be used for large-scale graph processing on commodity PCs.

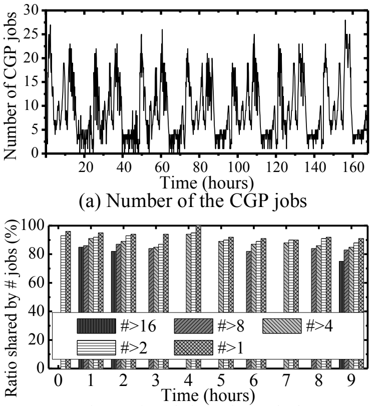
Abstract

With the fast growing of iterative graph analysis applications, the graph processing platform has to efficiently handle massive *Concurrent iterative Graph Processing* (CGP) jobs. Although it has been extensively studied to optimize the execution of a single job, existing solutions face high ratio of data access cost to computation for the CGP jobs due to significant cache interference and memory wall, which incurs low throughput. In this work, we observed that there are strong spatial and temporal correlations among the data accesses issued by different CGP jobs because these concurrently running jobs usually need to repeatedly traverse the shared graph structure for the iterative processing of each vertex. Based on this observation, this paper proposes a correlations-aware execution model, together with a core-subgraph based scheduling algorithm, to enable these CGP jobs to efficiently share the graph structure data in cache/memory and their accesses by fully exploiting such correlations. It is able to achieve the efficient execution of the CGP jobs by effectively reducing their average ratio of data access cost to computation and therefore delivers a much higher throughput. In order to demonstrate the efficiency of the proposed approaches, a system called CGraph is developed and extensive experiments have been conducted. The experimental results show that CGraph improves the throughput of the CGP jobs by up to 2.31 times in comparison with the existing solutions.

1 Introduction

In the past decade, iterative graph analysis has become increasingly important in a large variety of domains [7, 26], which need to iteratively handle the graph round by round until convergence. Due to the increasing need of analyzing graph-structured data (e.g., social networks and web graphs), many iterative graph algorithms run as concurrent services on a common platform. These *Concurrent iterative Graph Processing* (CGP) jobs are usually executed on the same graph simultaneously so as to analyze it for various information. For example, facebook [2] uses Giraph [13] to handle a large number of CGP jobs (such as the variants of pagerank [21], SSSP [20], and k-means [16]) daily over the same graph (or its different snapshots) to provide various information for different products, respectively. Figure 1(a) gives the number of the CGP jobs traced over a large social network and shows that more than 20 CGP jobs may be submitted to the common platform to concurrently analyze the same graph in an iterative way at the peak time.



(a) Number of the CGP jobs

(b) Ratio of shared graph data

Figure 1: Information traced on a social network

Many systems are recently proposed to support large-scale graph analytics. They try to fully utilize high sequential memory bandwidth [17, 22, 23], improve data locality [11, 28, 31, 32], spare the redundant data accesses [6, 25], and reduce the memory consumption [29, 30], etc. Despite of these research efforts, there is a major challenge for the efficient execution of the CGP jobs. When a massive number of CGP jobs are running on the same underlying graph using the existing systems, each individual CGP job separately accesses the shared graph structure along different graph paths, resulting in repeatedly loading of the same data into the cache at different time by different jobs. They suffer from expensive data

[*]Corresponding Author: Xiaofei Liao

access overhead due to the factors such as serious cache interference and limited bandwidth. As the result of high ratio of data access cost to computation in graph algorithm, the current graph processing systems experience low throughput. This paper investigates whether and how we can improve the throughput of the CGP jobs.

In practice, the CGP jobs usually need to repeatedly traverse the shared graph and iteratively process each vertex for their own purpose. It suggests that there are a large number of intersections among the graph structure data being accessed by these jobs in each iteration, which we call the *spatial correlation* of data accesses. In addition, the partition of the shared graph structure may need to be accessed by multiple jobs within a short time interval, which we call the *temporal correlation* of data accesses. These two correlations indicate that there exist significant redundant data storing and accessing cost in the jobs, which leaves us good opportunities to reduce these unnecessary costs and improve the throughput.

Based on the observation, we propose a data-centric *Load-Trigger-Pushing* (denoted by LTP) model to improve the throughput of CGP jobs by fully exploiting the correlations of their data accesses. It decouples the graph structure data from the vertex state associated with each job. Within each iteration, the graph structure partitions shared by multiple CGP jobs are streamed into the cache and trigger the related jobs to concurrently process the data, followed by vertex state pushing for convergence. In this way, many accesses to the shared graph partitions can be amortized by multiple CGP jobs through handling them along a common order. The consumption of cache/memory is also reduced since a single copy of the graph structure data is used to serve multiple jobs at the same time. It indicates higher throughput thanks to much lower data access cost. To further improve the throughput, a core-subgraph based scheduling algorithm is designed to maximize cache utilization by judiciously arranging the loading order of the partitions.

We conducted the extensive experiments with our system CGraph and compare its performance with those of three cutting-edge graph processing systems, i.e., CLIP [6], Nxgraph [11], and Seraph [29, 30]. Experimental results show that CGraph improves the throughput of the CGP jobs by up to 3.29 times, 4.32 times, and 2.31 times over CLIP, Nxgraph, and Seraph, respectively.

The remainder of this paper is organized as follows. Section 2 discusses the the motivation of this work. Section 3 outlines our approach, followed by experimental evaluation in Section 4. Section 5 gives a survey of related work. Finally, we conclude this paper in Section 6.

2 Problem Presentation and Motivation

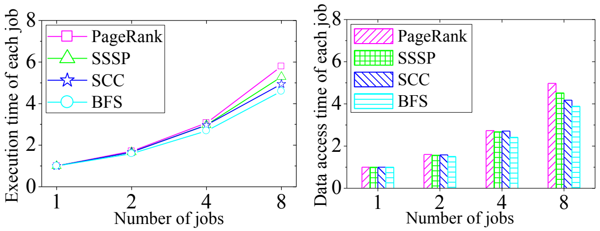
A common characteristic of an iterative graph processing job is that the operations are usually operated on two types of data: graph structure data and vertex state data. The graph structure data contains the edges between vertices and the information associated with each edge, whereas the vertex state data (e.g., ranking scores for PageRank [21], the distances from the source vertex for SSSP [20]) is computed by its tasks in a parallel way within each iteration and typically consumed in the next iteration. The graph structure data always occupies a majority of the memory, as compared with the vertex state data (i.e., job-specific data), and its proportion varies from 71% to 83% for different datasets [30]. As evaluated in Figure 1, the graph structure data is usually shared by multiple CGP jobs. However, in existing graph processing systems, these CGP jobs handle the shared graph in an individual manner along different graph paths, incurring low throughput for many redundant accesses to the shared graph and cache interference.

2.1 Data Access Problems of the CGP Jobs

In order to investigate the level of the inefficiency of the individual data accessing manner of the CGP jobs, we conducted the benchmark experiments to evaluate the execution time of different number of CGP jobs over Seraph [29, 30] on uk-union [3]. The hardware platform and benchmarks are the same as those described in Section 4.

From Figure 2(a), we made two observations. First, the concurrent way performs better than the sequential way of executing the jobs one by one. As observed in the experiments, it is because that the execution time of graph processing job is dominated by the data access cost and the CPU is always underutilized. Seraph is able to utilize the CPU in a better way by concurrently executing the jobs and also allowing them to share the in-memory graph structure data for less average data access cost. When there are eight jobs, the total execution time of the concurrent execution way is about 60% of the sequential way. Note that the total execution time of the concurrent way is the maximum value of these jobs' execution time, while it is the sum of those of all jobs for the sequential way. Second, the average execution time of each job, however, is significantly prolonged as the number of jobs increases. It is almost doubled when the number of jobs increases from four to eight, because of higher data access cost for each vertex processing.

Figure 2(b) shows the average data access time of the jobs over Seraph when the number of jobs increases. We can observe that the increment of the number of jobs leads to the significant rise of data access cost. It is because that the shared graph partitions are handled by the CGP jobs in an individual manner along different graph paths. As the number of the CGP jobs increases, more copies of the same data need to be created and loaded into the cache by the jobs at different time. Thus, more redundant data accesses are issued by the CGP jobs and



(a) Average execution time (b) Average data access time

Figure 2: Normalized performance of each CGP job over Seraph against that of the sequential way

it also incurs more serious cache interference due to the fact that more redundant data are stored into the cache for different jobs at different time. It eventually leads to low system throughput, since the data accessing cost typically represents a major proportion of the total execution time for an iterative graph algorithm.

Take Figure 3 as an example and assume that the cache can only store a partition for the CGP jobs. With the existing solutions, the SSSP job may firstly access partition 1 and then partition 2, whereas the PageRank job may firstly access partition 2 and then partition 1. Besides, the processing of each partition is various for different jobs, making their accesses more irregular. As a result, the partition 1 and partition 2 need to be repeatedly loaded into the cache. It leads to serious contention among the jobs for the data access channel, the cache and so on.

2.2 Correlations between the CGP Jobs

It is common that a set of CGP jobs involve in the analysis of the same graph. Figure 1(b) shows the ratios of a graph shared by different number of CGP jobs at various time sampled from the real trace. We discover that there are strong temporal and spatial correlations between the data accesses of the CGP jobs due to the repeated traverse of the graph shared by them. It indicates that many redundant accesses are issued by the CGP jobs and much cache space is also wasted to store several copies of the same graph structure data for the jobs at different time.

As described in Figure 1(b), the intersections of the set of graph partitions to be handled by different CGP jobs in each iteration are large (more than 75% of all active partitions on average). This is called the *spatial correlation*. However, the CGP jobs in existing systems access the shared graph partitions in different order individually, inducing much redundant overhead. Ideally, these CGP jobs should consolidate the accesses to the shared graph structure and store a single copy of the shared data in the cache to serve multiple CGP jobs at the same time.

In addition, some graph partitions may be accessed by multiple CGP jobs (may be more than 16 jobs) within a short time duration. This is called the *temporal correlation*. The traced results show that the number of CGP jobs to access each partition is skewed at any time. The current solutions, e.g., *Least Recently Used* (LRU) algorithm, may load the infrequently-used data into the cache when it is needed. It not only incurs the cost to load the data, but also swaps out the frequently-used data. A better solution should take into account the temporal correlations, e.g., the usage frequency of the graph partitions, when loading them into the cache.

These observations motivate us to develop a solution for efficient use of cache/memory and the data access channel to achieve a higher throughput by fully exploiting the spatial/temporal correlations discussed above.

3 Our Proposed Approach

Although we have identified the correlations between the CGP jobs, there are still several challenges that need to be tackled in order to exploit them. First, the shared vertices and edges may be individually handled by different jobs along different graph paths. Second, the CGP jobs have different properties (e.g., the rounds for convergence and the submission time), which reduce the chance of sharing the accesses to the graph structure data within a short time interval. For example, some graph structure partitions may be accessed by some jobs (e.g., PageRank) much more frequently than the others (e.g., BFS). Besides, the CGP jobs that share the same graph structure may be put into execution at different time. Third, it is a non-trivial task to design an efficient partition-loading order that can achieve a high cache utilization ratio.

Thus, we propose a data-centric *Loading-Trigger-Pushing* (LTP) model to fully exploit the spatial/temporal correlations between the CGP jobs, aiming to minimize the redundant accessing and storing cost of the shared graph structure data. In our LTP model, the shared graph is divided into a set of partitions. These partitions are loaded into the cache in sequence and in the same order for all jobs, where each partition is concurrently handled by the related CGP jobs. By such means, the accessing and storing of most graph structure partitions can be shared by multiple CGP jobs, thus significantly reducing the data access cost. When loading the graph partitions, a scheduling algorithm is further developed to specify the loading order of graph partitions (as well as the related job-specific data). The scheduler aims to maximize the cache utilization by fully exploiting the temporal correlations among the jobs' data accesses.

3.1 Data-centric LTP Execution Model

Assume that the data for an iterative graph algorithm is expressed as $D = (V, S, E, W)$, where V is the set of vertices, S is the set of states for the vertices, E is the set of edges, W is the set of weights associated with the edges. In our LTP model, the data of each job is decoupled as the graph structure data, i.e., $G = (V, E, W)$, and job-specific vertex states, i.e., S, where $G = \cup_i G^i$ is shared by different jobs and G^i is the i^{th} partition of the graph G. Each job has its own S, and repeatedly updates its S through its processing iterations until the calculated results converge. The processing of each iteration is divided into three stages: graph loading, parallel trigger, and pushing stage, which are formalized as follows.

Graph Loading. In each iteration, the shared graph structure partitions, e.g., G^i, are sequentially loaded for the CGP jobs along an order. It performs the following operation to load a graph partition: $L^i \leftarrow L(G^i, \cup_{j\in J} S^i_j)$, where $L(*)$ denotes an operator that loads the data specified in the parameter list "*" into the cache, J is the job set, S^i_j denotes the states of the vertices in G^i associated with the j^{th} job, and L^i is the data loaded into the cache. $S_j = \cup_i S^i_j$ is the set of vertex states related to the j^{th} job. In this way, it only needs to load a copy of each shared graph partition, e.g., G^i, for multiple CGP jobs and the partitions are also loaded for these jobs along a common order to provide opportunity to the sparing of redundant accesses by fully utilizing the correlations of these jobs.

Trigger and Parallel Execution. For each loaded graph partition G^i, the related CGP jobs, which are the jobs that need to process the vertices in the partition G^i and have not yet obtained the convergent results, are triggered to concurrently execute the following operator: $S^{i_{new}} \leftarrow \cup_{j\in J} T_j(G^i, S^i_j)$. The function $T_j(G^i, S^i_j)$ denotes the specific graph processing operations performed by the activated job j on the loaded data (i.e., G^i and S^i_j) towards its own objectives. Its outputs (denoted by $S^{i_{new}}_j$) are the new states related to the vertices in G^i and are associated with the j^{th} job. $S^{i_{new}}$=$\cup_{j\in J} S^{i_{new}}_j$ is the new vertex states that are related to the vertices in G^i for all CGP jobs. When the processing of G^i is finished for all related jobs, the next partition then can be loaded. By such means, it enables multiple jobs to regularly and concurrently process the set of shared graph partitions for their own goals along the same order and efficiently share the accesses to them for lower overhead.

State Pushing. If a job, e.g., j, has processed all its active partitions in an iteration, its new calculated results, i.e., S^{new}_j=$\cup_i S^{i_{new}}_j$, at this iteration are pushed for the state synchronization between the vertices of its different partitions (stored in its own job-specific space) for convergence. Then, the job starts a new iteration. Note that a CGP job will move to the next iteration once it has processed all active partitions in its current iteration and therefore different CGP jobs may be in different iterations of their graph processing. For example, BFS [10] may only need to handle a few active partitions in each iteration, while other algorithms, e.g., PageRank [21], may have to go through all partitions to complete an iteration.

Figure 3 gives an example to illustrate the LTP model. In this example, the graph in Figure 4(a) is divided into two partitions, which need to be handled by two jobs, i.e., a PageRank job and a SSSP job. The graph structure data is stored in the global space and is shared by these two CGP jobs, while the job-specific space is provided for each CGP job to store its own vertex states. It can load the two partitions along the order of partition 1 then 2. When the partition 1 and the related job-specific data are loaded into the cache, the related jobs (i.e., the PageRank job and the SSSP job) are triggered to concurrently handle it and update their own vertex states. When the two jobs have handled the partition 1, the partition 2 can be loaded for processing. When both the two partitions are handled by the jobs, the new iteration of each job begins.

3.2 Correlations-aware Execution of Jobs

This section discusses how to efficiently implement our LTP model for the execution of multiple CGP jobs.

3.2.1 Graph Storage for Multiple CGP Jobs

We first show how to efficiently store the graph for the CGP jobs in our approach.

Data Structure of Graph Partition. For parallel processing, large-scale graph needs to be divided into partitions. However, the real-world graph usually has highly skewed power-law degree distributions [12], incurring imbalanced load among the partitions. Thus, our system also uses existing vertex-cut partitioning method [31], and evenly divides the edges of the graph into same-sized partitions in terms of the number of edges. Note that a vertex may have multiple replicas (e.g., v_3 in Figure 4(b)), where one of the replicas is nominated as the master vertex and the others are regarded as the mirror vertices. In this way, it not only gets balanced load for the partitions, but also does not incur communication cost when handling each partition. The communication only occurs when the replicas of the same vertex in different

Figure 4: An example to show how to store data for multiple jobs, where the graph is divided into two partitions.

partitions synchronize their states. In order to effectively store the graph partitions for the CGP jobs, multiple key-value tables are established. In detail, a single global table is created to store the graph structure data for all CGP jobs. Multiple private tables are used to store the vertex states of the jobs, i.e., one table for each job.

Each global table entry represents a graph structure partition indexed by its key and with three other fields to describe corresponding information. The first two fields indicate the location of this graph structure partition and the number of its vertices, respectively. The third field stores the IDs of the jobs to process it at the next iteration (along with the locations of the related private tables associated with these jobs). The information of each graph structure partition is also stored in a key-value table and each of its data item indicates a vertex and contains four fields: vertex ID, edges assigned in this partition, flag, master location and the information associated with its edges, e.g., priority. Each private table entry represents a vertex state and has two fields, i.e., vertex ID and its state. Figure 4 gives an example to illustrate how to store the data for multiple jobs.

Suitable Size of Graph Partition. In order to efficiently use the parallelism of CPU and ensure good cache locality, the cache is expected to be just fully loaded when each core has data to handle. Therefore, the suitable size of each graph structure partition, i.e., P_g, is determined by the number of CPU cores, i.e., N, and the size of the cache, i.e., C. The value of P_g is expected to be the maximum integer such that $P_g + \frac{P_g}{s_g} \times s_p \times N + b \leq C$, where

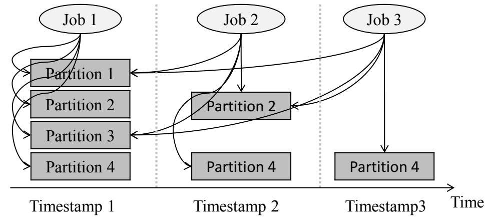

Figure 5: An example to illustrate how to store evolving graph structure for the CGP jobs submitted at different timestamps, where partitions 2 and 4 are changed at timestamp 2, and partition 4 is changed at timestamp 3.

s_g is the average size of each graph structure partition's item, s_p is the size of each private table's item, and b is the size of reserved buffer.

Details to Store Evolving Graph Structure. In practice, the graph structure may evolve with time. Thus, we also maintain a series of snapshots for it, where the graph updates, e.g., the adding/deleting of vertices and edges, are only visible to the jobs submitted later than the updates. In this way, different jobs are able to correctly handle the related snapshots of the graph, respectively. Because the changes of graph structure are usually very small at each time, the most part of these snapshots is the same. Thus, the series of snapshots can be stored in an incremental way for low overhead. For each snapshot, it creates a new global table and labels it with a timestamp, where this table only stores the new version of the partition with changes. The newly submitted job handles the graph partitions with the highest timestamp yet less than its arrival time. Figure 5 gives an example to illustrate it. Note that most graph structure partitions, e.g., the partitions 1 and 3, are usually shared by the jobs when they handle different snapshots, respectively.

3.2.2 Loading of Graph Partition

In practice, a partition is to be handled by a job in the next iteration only when its vertices are activated by the other ones of this job at the current iteration. Therefore, it is easy for each partition to identify the set of CGP jobs to process it within the next iteration through tracing the partitions activated within the current iteration. This profiled information, i.e., the temporal correlations of the jobs, is stored in the global table for each partition. The spatial correlations between the data accesses issued by the CGP jobs can be gotten by calculating the intersection of the set of graph partitions to be processed by different jobs. After that, it is able to load the shared graph partitions for exactly once along a common order to serve multiple CGP jobs within each iteration, amortizing the data access cost. Note that the correctness will not be affected by any loading order and the runtime loads the partitions in a round-robin way by default.

For each job, the states of most vertices may have converged at the early iterations, although some vertices

Algorithm 1 Details of each trigger

```
1: procedure TRIGGER($G^i$, $S^i_j$)
2:     for each $v_h \in S^i_j \wedge$ IsNotConvergent($v_h$) do
3:         Compute($G^i$, $v_h$)
4:         if $v_h$ is a mirror vertex then
5:             $D \leftarrow v_h.MasterLocation$
6:             $S^{new}_j$.Insert($v_h$, $i$, $D$, $v_h.\Delta value$)
7:         end if
8:     end for
9: end procedure
```

need hundreds of iterations for convergence. The loading and processing of the inactive vertices can be skipped for the related job for low overhead. In detail, when a graph structure partition G^i is loaded into the cache, it only loads the related job-specific private partitions, e.g., S^i_j, of the CGP jobs which need to process G^i. It does not load G^i when there is no job to handle G^i, i.e., the states of the vertices in G^i are inactive for all jobs. Specifically, when a graph structure partition is not used by any job at the next iteration, this graph structure partition is labeled as an inactive one so as to skip its loading. Similarly, it is relabeled as an active one when it needs to be processed by some jobs at the next iteration.

3.2.3 Parallel Processing of Graph Partition

After loading a graph partition G^i into the cache, it triggers the related CGP jobs (e.g., j) to concurrently handle their private vertex states (e.g., S^i_j) associated with this partition, respectively. Note that any newly submitted job only needs to register the partitions to be processed by it at its first iteration and waits to be triggered to handle them. It is possible that the number of CGP jobs is more than the number of CPU cores, i.e., N. Assume a partition is shared by $|J|$ number of jobs. When the value of $|J|$ is larger than N, these CGP jobs are assigned to be processed as different batches, where the shared graph structure partition is fixed in the cache and only the job-specific partitions are replaced. A graph structure partition is swapped out of the cache only when it has been processed by the related jobs within the current iteration. Otherwise, the unprocessed jobs need to load it again.

For the processing of each partition, the computation load of different CGP jobs is usually skewed, leading to low utilization ratio of hardware. In order to tackle this problem, it identifies the straggler, i.e., the job with the most number of unprocessed vertices in its private table for this partition. Note that the number of unprocessed vertices can be easily gotten, because the number of active vertices for each job in each partition is known as this partition is handled by the jobs at the previous iteration. Then, as described in Figure 6, it logically divides the unprocessed vertices in the private partition of the straggler into pieces and assigns them to the free cores to assist its processing.

Cache

Figure 6: An example to illustrate how to get balanced load, where the core 1 and the core 2 are handling the partition 1 of the private table of the job 1 together.

The processing details for a job are given in Algorithm 1, where each job only computes the new state for its vertices in S^i_j according to their local neighbors recorded in the graph structure partition G^i (See Lines 2-8). Therefore, there is no cache miss when handling a partition, because no communication occurs between the vertices on different partitions. Obviously, the vertex with replicas on different partitions needs to synchronize their states. The mirror vertex needs to push its new state to its master vertex to get this vertex's final state at the current iteration. The new calculated state on the master vertex needs to be pushed to its mirrors. As a result, for such a vertex state synchronization, many partitions of private table are frequently loaded into the cache and incur high cache miss rate. In order to tackle this problem, for each mirror vertex, its new state is directly buffered in S^{new}_j (See Line 6), which will be implicitly sent to the master replica for batched vertex state synchronization at the data synchronization stage.

3.2.4 Data Synchronization

When there are multiple CGP jobs to synchronize vertex state, it is done for the jobs one by one to reduce resource contention, because there is no data sharing between the jobs. For efficient vertex state synchronization among replicas, as depicted in Algorithm 2, they are done together in batches at this stage for each job, aiming to avoid the frequent load of private table's partitions at runtime. The items buffered in the queue S^{new}_j (with the new states of the mirror vertices, e.g., v_h) are firstly sorted according to the IDs (e.g., $v_h.MasterLocation$, which is described in Figure 4(b)) of the partitions with the related master vertices (See Line 2), before pushing them.

By such means, it only needs to load fewer partitions of private table for the state updates of master vertices, since many updates become successive accesses to the same partition. Besides, when the successive updates for a master vertex are done (See Line 7), the final state of this vertex for the current iteration is gotten. Then, such a new value can be directly buffered for batched state updating of mirror vertices as well (See Lines 10-12). Note that, with the traditional solutions, it is impossible to

Algorithm 2 Details of data synchronization

```
1:  procedure PUSH($j$, $S_j^{new}$)
2:      SortD($S_j^{new}$) /*Sort the items recorded in $S_j^{new}$*/
3:      for <$v_h$, $i$, $MasterLocation$, $\Delta value$> $\in S_j^{new}$ do
4:          $D \leftarrow S_j^{new}[v_h].MasterLocation$
5:          $value \leftarrow S_j^{new}[v_h].\Delta value$
6:          $S_j^D[v_h].\Delta value \leftarrow Acc(S_j^D[v_h].\Delta value, value)$
7:          if Last update of $S_j^D[v_h].\Delta value$ is end then
8:              $val \leftarrow S_j^D[v_h].value$
9:              $S_j^D[v_h].value \leftarrow Acc(val, S_j^D[v_h].\Delta value)$
10:             for each $S_j^{new}[v_h].MasterLocation = D$ do
11:                 $S_j^{new}[v_h].\Delta value \leftarrow S_j^D[v_h].\Delta value$
12:             end for
13:         end if
14:     end for
15:     SortS($S_j^{new}$) /*Sort the items recorded in $S_j^{new}$*/
16:     for <$v_h$, $i$, $MasterLocation$, $\Delta value$> $\in S_j^{new}$ do
17:         $i \leftarrow S_j^{new}[v_h].i$
18:         $S_j^i[v_h].\Delta value \leftarrow S_j^{new}[v_h].\Delta value$
19:     end for
20: end procedure
```

know whether the final state is gotten for a master vertex until all updates are done. Then, the master vertex needs overhead to be reloaded for accessing, because it may have been swapped out of the cache. After that, it is done in a similar way to update mirror vertices' states according to the related master vertices' states (See Lines 15-19), where the items are sorted according to the IDs of the partitions with the mirror vertices (See Line 15).

3.3 Scheduling Based on Core-subgraph

With existing solutions, the partitions loaded into the cache may be underutilized. First, some vertices need more iterations to converge than the others for much higher degree. They make the partitions containing them repeatedly loaded into the cache and incur high overhead to load and store the early convergent vertices in the same partition. Second, the usage frequency of different partitions is also skewed and also evolving with time. In detail, the same partition of different jobs and different partitions in the same job all may need various iterations to converge. Besides, a graph partition is only visible to the jobs with the arrival time later than its timestamp. As a result, a loaded partition may need to be processed by very few (even one) jobs when the partition is arbitrarily loaded into the cache, inducing poor performance.

In order to maximize the utilization ratio of each partition loaded into the cache, we propose a scheduling algorithm based on core-subgraph partitioning. The key idea is to firstly put the core vertices (with degree higher than a given threshold) together and then make the loaded partition shared by as many jobs as possible on average via arranging the loading order of graph partitions. In detail, it firstly identifies a core subgraph, consisting of the core vertices and the edges on the paths between them, from the graph. Then it evenly divides the graph based on such a subgraph, where the edges of this subgraph are put together into several same-sized partitions and the remaining edges are divided into the other same-sized partitions. By such means, the frequently loading and processing of core vertices incur less cost to load the early convergent vertices in the same partition, sparing the consumption of bandwidth and the cache space.

After that, it gives each partition P a priority $Pri(P)$ and schedules the loading order of them based on the dynamically profiled priorities of them. The partition with the highest priority is firstly loaded into cache for the CGP jobs to handle, so as to improve the cache utilization ratio. The basic scheduling rules are as follows:

- First, a partition should be given the highest priority and be firstly loaded into the cache when it is needed by the most number of jobs for processing.
- Second, a partition should be set with a higher priority when it has a higher average vertex degree or a larger average vertex state changes, because more vertex states will be propagated to others through them. Then, most vertices need less iterations (also less consumption of the cache) to absorb other vertices' states for convergence.

The above rules are captured by such an equation:

$$Pri(P) = N(P) + \theta \cdot \overline{D}(P) \cdot C(P) \qquad (1)$$

where $N(P)$ is the number of jobs to process P and is used to capture the temporal correlations for the CGP jobs. $\overline{D}(P)$ is the average degree of the vertices in P, and $C(P)$ is the average state changes of the vertices in P for all its jobs at the previous iteration. The initial values of $N(P)$ and $C(P)$ and the value of $\overline{D}(P)$ are gotten at preprocessing time, while $N(P)$ and $C(P)$ are incrementally updated at the execution time. There, $0 \leq \theta < \frac{1}{\overline{D}_{max} \cdot C_{max}}$ is the scaling factor set by the runtime system at preprocessing time to ensure that a partition with the highest value of $N(P)$ is firstly processed, where $\overline{D}_{max}$ and C_{max} are the maximum values of any partition's $D(P)$ and $C(P)$, respectively. By such means, the partition loaded into the cache can serve as many jobs as possible, while the other partitions have more opportunity to be needed by more jobs after a time interval, further improving the throughput via reducing the average data access cost.

3.4 Implementation and Interfaces

The implementation details of CGraph are described in Algorithm 3. It repeatedly loads the unprocessed partitions, e.g., G^i, of the global table into the cache according to the scheduling algorithm (See Line 4). For each G^i,

Algorithm 3 Executor for CGraph

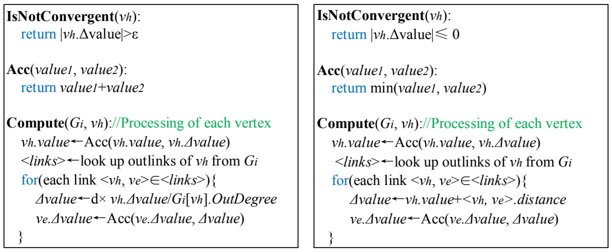
```
1:  procedure EXECUTOR($G$, $S_{Jobs}$)
2:      while the job set $S_{Jobs}$ is not empty do
3:          while $G$ has unprocessed $G^i$ for some jobs do
4:              $G^i \leftarrow$ LoadPartition($G$) /*Load $G^i$*/
5:              /*Get the set of jobs to handle $G^i$*/
                $J \leftarrow$ GetJobs($G^i$, $S_{Jobs}$)
6:              for each $j \in J$ do
7:                  /*Trigger the job $j$ to handle $G^i$*/
                    ParallelTrigger($j$, $G^i$, $S^i_j$)
8:              end for
9:              for each $j \in J$ and $S^{new}_j$ are gotten do
10:                 /*Vertex state synchronization for $j$*/
                    Push($j$, $S^{new}_j$)
11:                 if vertex states of $j$ are inactive then
12:                     /*Remove $j$ from the set $S_{Jobs}$*/
                        Remove($S_{Jobs}$, $j$)
13:                 end if
14:             end for
15:         end while
16:     end while
17: end procedure
```

the job-specific partitions, e.g., S^i_j, of the related CGP jobs are also loaded and these jobs are triggered to concurrently handle the loaded data (See Lines 5-8), where each job calculates the new states of its vertices according to the states of their local neighbors. When all active partitions of G have been handled for a job, e.g., j, at the current iteration (See Line 9), this job synchronizes the states of the vertices with several replicas distributed over different partitions (See Line 10). Then, its new iteration begins. Each job is repeatedly triggered until all its vertex states are inactive (See Lines 11-13). Note that it allows to add new jobs into S_{Jobs} at runtime.

For programming, a user only needs to instantiate three functions, i.e., IsNotConvergent(), Compute(), and Acc(), which are used in existing systems [23, 30, 31]. The first one indicates whether a vertex is convergent. Compute() is employed to update a vertex state and calculate the contributions of a vertex for the new states of its neighbors, and Acc() is utilized for a vertex to accumulate the contributions of its neighbors. Figure 7 gives two examples to show how to implement iterative graph algorithm on CGraph. Within each iteration, each vertex updates its state according to the accumulated contributions of its neighbors. After that, it calculates and sends its contributions to its neighbors for their state updates.

4 Experimental Evaluation

The hardware platform used in our experiments is a server containing 4-way 8-core 2.60 GHz Intel Xeon CPU E5-2670 and each CPU has 20 MB last-level cache, running a Linux operation system with kernel version 2.6.32. Its memory is 64 GB and the secondary storage for it is a disk with 1TB. It spawns a worker for each core to run benchmarks. The program is compiled with cmake version 2.6.4 and gcc version 4.7.2.



```
IsNotConvergent(vh):
   return |vh.Δvalue|>ε

Acc(value1, value2):
   return value1+value2

Compute(Gi, vh)://Processing of each vertex
   vh.value←Acc(vh.value, vh.Δvalue)
   <links>←look up outlinks of vh from Gi
   for(each link <vh, ve>∈<links>){
      Δvalue←d× vh.Δvalue/Gi[vh].OutDegree
      ve.Δvalue←Acc(ve.Δvalue, Δvalue)
  }
```

(a) PageRank

```
IsNotConvergent(vh):
   return |vh.Δvalue|⩽ 0

Acc(value1, value2):
   return min(value1, value2)

Compute(Gi, vh)://Processing of each vertex
   vh.value←Acc(vh.value, vh.Δvalue)
    <links>←look up outlinks of vh from Gi
   for(each link <vh, ve>∈<links>){
      Δvalue←vh.value+<vh, ve>.distance
      ve.Δvalue←Acc(ve.Δvalue, Δvalue)
  }
```

(b) SSSP

Figure 7: Instantiation of graph algorithms on CGraph

Table 1: Properties of data sets

Data sets	Vertices	Edges	Sizes
Twitter [3]	41.7 M	1.4 B	17.5 GB
Friendster [4]	65 M	1.8 B	22.7 GB
uk2007 [3]	105.9 M	3.7 B	46.2 GB
uk-union [3]	133.6 M	5.5 B	68.3 GB
hyperlink14 [5]	1.7 B	64.4 B	480.0 GB

In experiments, four popular iterative graph algorithms from web applications and data mining are employed as benchmarks: (1) PageRank [21]; (2) *single-source shortest path* (SSSP) [20]; (3) *strongly connected component* (SCC) [14]; (4) *breadth-first search* (BFS) [10]. The datasets used for these graph algorithms are real-world graphs existing on the websites [3, 4, 5] as described in Table 1. The performance of CGraph is compared with three cutting-edge graph processing solutions, i.e., CLIP [6], Nxgraph [11], and Seraph [29, 30], implemented by us on GridGraph [32]. Seraph is the state-of-the-art system optimized to support the efficient execution of multiple CGP jobs. Note that the jobs (e.g., PageRank, SSSP, SCC, and BFS) in the experiments are submitted to each system simultaneously.

4.1 Performance of Scheduling Strategy

First, we discuss the contributions of our scheduling algorithm on the performance of CGraph. In order to get this goal, PageRank, SSSP, SCC and BFS are executed as four CGP jobs to evaluate the total execution time of them over CGraph (with our scheduler described in Section 3.3) and CGraph-without (without our scheduler), respectively. Note that the graph partitions in CGraph-without are loaded in a round-robin way. As shown in Figure 8, the execution time of CGraph-without is more than that of CGraph under any circumstances. The execution time of CGraph is even only 60.5% of CGraph-without over hyperlink14. It is because that the scheduling scheme is able to maximize the utilization ratio of each partition in the cache via firstly loading the most important partition for the jobs.

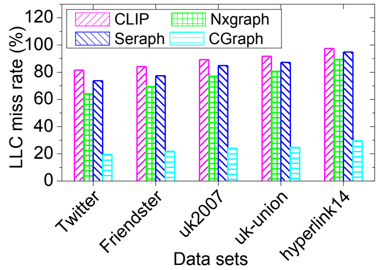

Figure 11: Last-level cache miss rate for the four jobs

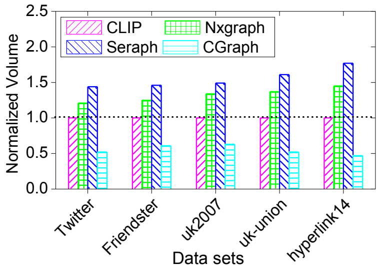

Figure 12: Volume of data swapped into the cache for the four jobs

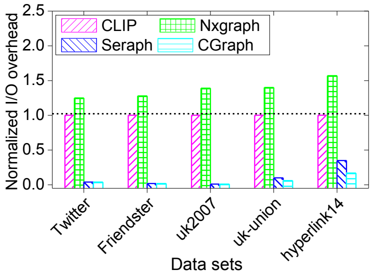

Figure 13: I/O overhead for the four jobs with different solutions

4.2 Overall Performance Comparison

To compare CLIP, Nxgraph, Seraph, and CGraph, we simultaneously submit PageRank, SSSP, SCC, and BFS as four jobs to each of these systems. Figure 9 shows the total execution time of the four jobs over different systems. We find that the four jobs over CGraph are able to converge with less time, which indicates higher throughput than the other systems. For example, over hyperlink14, CGraph can improve the throughput by 2.31 times, 3.29 times, and 4.32 times in comparison with Seraph, CLIP, and Nxgraph, respectively. We identify that the highest throughput of CGraph mainly comes from much lower average data access cost to computation ratio than them.

Figure 10 depicts the execution time breakdown of different jobs evaluated on hyperlink14 with different solutions. We can observe that the pure vertex processing time of the job over CGraph occupies the most ratio of its total execution time, while the ratio is very low in CLIP, Nxgraph, and Seraph. There are two reasons leading to lower average data access cost to computation ratio for CGraph than the other solutions. First, through efficiently exploiting the data access correlations between the CGP jobs, CGraph needs to store less data into the cache, getting a lower cache miss rate. Second, CGraph needs to access less volume of data due to efficient share of data accesses for the jobs, which means less consumption of bandwidth for main memory and the disk.

In order to demonstrate it, we firstly evaluate the last-level cache miss rates of CLIP, Nxgraph, Seraph, and CGraph using Cachegrind [1]. The miss rates of the above four jobs over them are given in Figure 11. As described, the cache miss rate of CLIP is larger than that of Nxgraph, because CLIP tries to trade off locality for the reduction of the total amount of data accesses while Nxgraph uses destination-sorted sub-shard structure to store a graph for better locality. However, the cache miss rate of Nxgraph is still more than that of CGraph. For example, the cache miss rate of Nxgraph is 89.5% for hyperlink14, while the rate is only 29.6% for CGraph. It is mainly because that a single copy of graph structure data in the cache is able to serve multiple jobs of CGraph.

Next, we evaluate the total volume of data swapped into the cache for the above four jobs over different systems. The normalized results of them against CLIP are depicted in Figure 12. We can find that CLIP needs to swap much smaller volume of data into the cache than Nxgraph and Seraph, because it is able to reduce the number of iterations for convergence via reentry of loaded data and beyond-neighborhood accesses. Note that the method employed by CLIP can also be used in Seraph as well as CGraph, rather than Nxgraph.

Besides, from Figure 12, we can observe that the volume of CGraph is much less than those of the other solutions. For example, the value of CGraph is only 47.1% of CLIP over hyperlink14, because CGraph does not need to load and to store the shared graph structure data for each job, separately. However, CLIP suffers from many redundant data accesses due to ignoring the data access correlations between the CGP jobs. Although Seraph can spare some data accesses from the disk to the main memory via sharing in-memory data, each job loads data into the cache in an individual way, incurring high data access overhead as well. It also means that Seraph is only suitable to out-of-core computation.

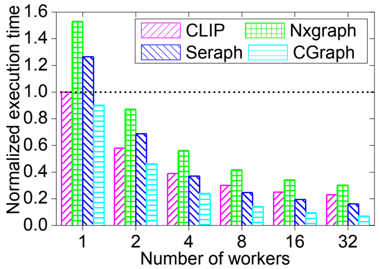

Figure 14: Scalability of the four jobs on hyperlink14

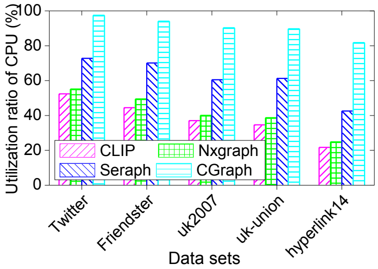

Figure 15: Utilization ratio of CPU for the four jobs

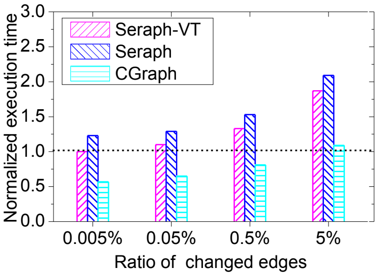

Figure 16: Execution time of the eight jobs on hyperlink14 with changes

Finally, the I/O overhead of the above four jobs is also evaluated over different systems. As shown in Figure 13, the jobs on the first three graphs almost not incur I/O overhead for both CGraph and Seraph, because they only needs to store one copy of the graph structure data in the main memory and these graphs can be totally loaded. When the graph size is larger than the memory size, CGraph needs less I/O overhead than Seraph through consolidating data accesses for the jobs. It also indicates a better performance of CGraph for out-of-core computation, because the data access time dominates the total execution time under such circumstances.

4.3 Scalability of CGraph

The scalability of CGraph is evaluated via executing the above four jobs on hyperlink14 and increasing the number of workers. Figure 14 gives the results relative to that of CLIP with only one worker. We can observe that CGraph has much better scalability than the other ones. The best scalability of CGraph mainly comes from efficient share of data accesses, while the other systems suffer from limited bandwidth for main memory and magnetic disk. Meanwhile, such a limited bandwidth also induces low utilization ratio of CPU for them.

In Figure 15, we evaluate the average utilization ratio of CPU for the vertex processing of the four jobs over different systems. As observed, existing systems suffer from low CPU utilization ratio, because the long data access time leads to the waste of CPU for them. Besides, from Figure 14 and Figure 15, we can find that the CPU cores of CGraph are almost fully utilized due to balanced load and low data access cost to computation ratio. It indicates that the limited computation ability of the CPU cores becomes the bottleneck of CGraph. GPGPU may be a suitable accelerator to help CGraph to process the CGP jobs for its powerful computing ability.

4.4 Performance on Graph with Changes

In real-world applications, several snapshots may be created for the graph with changes, and multiple CGP jobs are generated to handle them, respectively. In this part, we evaluate CGraph for the graph with structure changes. In the following experiments, we repeatedly generate the CGP jobs in the order of PageRank, SSSP, SCC, and BFS until a given number of jobs are created, where the CGP jobs are executed over a series of snapshots, respectively. Note that Seraph-VT is the version of Seraph incorporating multi-version switching approach [15].

First, we evaluate the total execution time of eight CGP jobs over different systems for hyperlink14 with the graph change ratio ranging from 0.005% to 5%. In detail, the change on the successive two snapshots ranges from 0.005% to 5%. Figure 16 gives the results relative to the execution time of Seraph-VT when the ratio of changed edges is 0.005%. We can observe that CGraph always gets the best performance under different graph change ratios. It is because CGraph still gets a low average data access cost to computation ratio, although the snapshots have differences in graph structure. Besides, we can also find that CGraph needs longer execution time to handle the graph when the graph change ratio is larger, because of less data access correlations between the jobs.

In the following experiments, we take a series of snapshots of hyperlink14 as datasets, where the change ratio between any successive two snapshots is 5% and each job handles a snapshot. Figure 17 depicts the execution time breakdown of the jobs over different systems on hyperlink14 when the the number of jobs increases. We can find that the jobs over CGraph have a lower average data access cost to computation ratio with the increase of the number of jobs, because there are more jobs to amortize the data access cost. However, for Seraph-VT and Seraph, the condition with more jobs leads to much more volume of data loaded into the cache and makes them suffer from serious cache interference and limited bandwidth. Thus, CGraph performs much better than Seraph-VT and Seraph when the number of jobs is larger.

The last-level cache miss rate is also evaluated for them on hyperlink14. As depicted in Figure 18, the cache miss rate of CGraph is significantly reduced when the number of jobs is increased, because the data in the cache can be repeatedly used by different CGP jobs. For example, in CGraph, the cache miss rate of the condition with eight jobs is even only 32.8% of the condition with one job. However, in the other solutions, the cache miss rate is significantly increased when the number of jobs is more, because of serious cache interference.

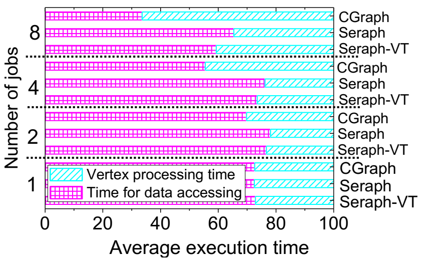

Figure 17: Execution time breakdown of different solutions on hyperlink14

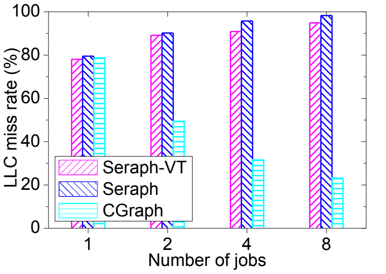

Figure 18: Last-level cache miss rate of different solutions on hyperlink14

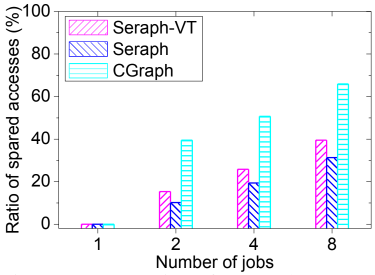

Figure 19: Ratio of spared accessed data on hyperlink14

Figure 19 gives the ratio of the total accessed data (including the data from the disk to the main memory and the main memory to the cache) spared by different solutions on hyperlink14 in comparison with the way sequentially executing the jobs over Seraph. As expected, the number of data accesses spared by CGraph is much more than the other solutions. For example, when the number of jobs is eight, the ratio is even up to 65.9% for CGraph, while the ratios of Seraph-VT and Seraph are only 39.5% and 31.3%, respectively. Besides, as observed, CGraph spares much more data accesses when the number of jobs increases, due to more opportunity to share data accesses between different jobs.

5 Related Work

With the explosion of graph scale, many systems [18, 19, 27] have focused on achieving high efficiency for iterative graph analysis. However, most of them focus on supporting single graph processing job. They improve the efficiency either by fully utilizing the sequential usage of memory bandwidth, or by achieving a better data locality and less redundant data accesses, which consequently reduces the volume of the accessed data.

GraphChi [17] achieves sequential storage access by employing parallel sliding windows. X-Stream [23] and Chaos [22] improve GraphChi by using streaming partitions for better sequential access of out-of-core data. Xie etc. [28] propose a novel block-oriented computation model, in which computation is iterated locally over blocks of highly connected nodes, which improves the amount of computation per cache miss. PathGraph [31] models a large graph using a collection of tree-based partitions for better locality. GridGraph [32] proposes 2-Level hierarchical partitioning scheme to improve the locality and reduce the amount of I/Os. NXgraph [11] uses destination-sorted sub-shard structure to store graph for better locality and adaptively chooses the fastest strategy to fully utilize memory and reduce data transfer. Instead of targeting a better locality, CLIP [6] proposes to reduce the total data access cost through the reentry of the loaded data and beyond-neighborhood accesses.

Although these systems can support efficient execution of a single iterative graph processing job, multiple separate copies of the same graph need to be created in the main memory by them for the CGP jobs. Following on this direction, Seraph [29, 30] is designed to allow multiple jobs to correctly share one copy of the in-memory graph structure data. However, in Seraph, the accesses to the same graph partitions are performed separately by the jobs along different graph paths, incurring redundant accesses and wasting the cache as well. Note that graph databases [8] are recently proposed to support concurrent queries over a graph. For example, TAO [9] provides a simple data model and APIs to store and query graph data. Wukong [24] uses a RDMA-based approach to provide low-latency concurrent queries over large graph-based RDF datasets. However, these graph database solutions can not efficiently support the execution of the CGP jobs because they are dedicated to graph queries which usually only touch different small subsets of a graph for exactly once, instead of iteratively processing the entire graph for many rounds.

6 Conclusion

This paper discovers that many redundant data accesses exist in the CGP jobs for their strong temporal and spatial correlations. A novel data-centric LTP model and an efficient scheduling algorithm is then proposed to exploit our observed data access correlations in these jobs and allows multiple CGP jobs to efficiently amortize the data access cost for higher throughput. Experimental results show that our approach significantly improves the throughput for the CGP jobs against the state-of-the-art solutions. This work mainly focuses on static graph processing. In the future, we will research how to further optimize our approach for evolving graph analysis and also extend it to distributed platform and also heterogeneous platform consisting of GPUs so as to get higher throughput for the CGP jobs.

Don't share, Don't lock: Large-scale Software Connection Tracking with Krononat

Abstract

To simplify software updates and provide new services, ISPs are interested in migrating network functions implemented in residential gateways (such as DSL or Cable modems) to the cloud. Two key functions of residential gateways are Network Address Translation (NAT) and stateful firewalling, which both rely on connection tracking. To date, these functions cannot be efficiently implemented in the cloud: current OSes connection tracking is unable to meet the scale and reliability needs of ISPs, while hardware appliances are often too expensive. In this paper, we present Krononat, a distributed software NAT that runs on a cluster of commodity servers, providing a cost-efficient solution with an excellent reliability. To achieve this, Krononat relies on 3 key ideas: (i) sharding the connection tracking state across multiple servers, down to the core level; (ii) steering traffic exploiting the features of entry-level switches; and (iii) avoiding all locks and data sharing on the data path. Krononat supports a rate of 77 million packets per second on only 12 cores, tracking up to 60M connections. It is immune to single node failures, and supports elastic workloads by a fast reconfiguration mechanism ($<$ 500ms).

1 Introduction

Over the last years, network and datacenter operators have started *virtualizing network functions* such as routers, firewalls or load balancers. Network Function Virtualization (NFV) consists in replacing network functions implemented in hardware appliances by software implementations deployed on commodity servers. Thus, major companies such as Google or cloud providers such as Microsoft Azure rely on software implementations for their load balancing needs [9, 29]. In these cases, software implementations bring a number of benefits: (i) a better scalability than hardware devices, thanks to the use of a scale-out model, (ii) better redundancy properties and (iii) a higher flexibility, as new software can be easily deployed while hardware is hard to change.

Because of its benefits, Internet Service Providers (ISPs) are also embracing NFV. ISPs have expressed a growing interest in moving network functions implemented in residential gateways (also known as DSL, cable or fibre modems) to commodity servers in the core network. In addition to the physical layer, residential gateways usually implement tunneling, stateful firewalling, and Network Address Translation (NAT). While the physical layer and tunneling have to be implemented in the gateway, there is an opportunity for moving the firewall and NAT functions to commodity servers in the core network. For an ISP, this brings two main benefits: (i) simplifying updates by running software on a few servers rather than millions of gateways spread across a country, (ii) exposing the user's local network, creating opportunities for new services or troubleshooting.

If NFV brings many benefits to ISPs, it also comes with two critical challenges: cost efficiency and reliability. In current OSes, the performance of connection tracking and firewalls (such as netfilter in Linux) is such that deploying them at the scale of an ISP would require a prohibitive amount of servers. Moreover, they only provide limited options for fault tolerance, making them unable to meet the reliability requirements of large ISPs. In this paper, we tackle the problem of connection tracking at the scale of an ISP. We introduce Krononat, a distributed high-performance software stateful firewall and NAT that is able to meet the requirements of an ISP. This paper makes the following contributions:

- We highlight the features of modern CPUs and commodity server hardware architectures that enable the design of a resource-efficient connection-tracking system. We propose a hardware platform able to serve millions of users.
- We propose three software design principles that enable the construction of efficient network functions: (i) sharding the connection-tracking

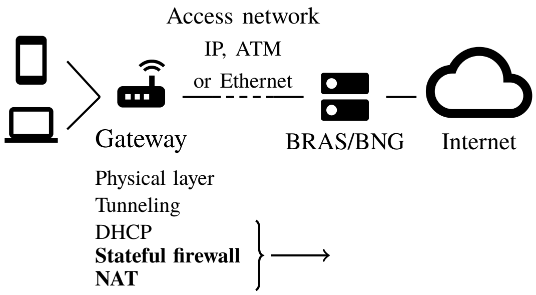

Figure 1: Simplified view of an ISP access network

	Without NFV	With NFV
Tunnel source IP	172.17.128.1	172.17.128.1
Tunnel destination IP	172.17.128.2	172.17.128.2
Source IP	**198.51.100.1**	**192.168.0.3**
Destination IP	203.0.113.1	203.0.113.1
	Payload	Payload

Figure 2: Tunneled packets on the access network

state down to the core level, (ii) using entry level switches to steer traffic to specific cores in multi-servers systems and (iii) avoiding all locks on the data path. We show how these principles are implemented in Kronanat's software architecture.

- We show that Krononat can manage 60M flows, corresponding to an aggregated total throughput of 70 Mpps (equivalent to 155 Gbps Simple IMIX traffic), on just 12 cores (spread on 4 servers).

2 Background

In this section, we quickly review what NAT and stateful firewalls are, and explain their relationship with connection tracking. We then give a simplified overview of an ISP network to show where our software, Krononat, fits.

Connection Tracking is an essential building block for numerous network functions. In this paper, we focus on two of them (i) NAT and (ii) stateful firewall.

We are interested in port-restricted cone NAT [35], which is commonly implemented in residential gateways. NAT is used to address the scarcity of IPv4 addresses by making several devices (e.g., laptops, smartphones etc.) with local IP addresses (typically in the 192.168.0.0/24 range) appear as a single IP address on the internet, the public address of the gateway. Once a connection between (local address; local port) and (external address; external port) has been established, the NAT: (i) sends every packet from (local address; local port) through (public address; public port), and (ii) sends packets sent to (public address; public port) to (local address; local port) if and only if they go to/originate from (external address; external port). NAT thus requires tracking connections by storing entries in a table.

A stateful firewall allows incoming traffic that belongs to connections established by a local host and rejects all other incoming traffic. More formally, a stateful firewall allows an incoming packet for an external socket (external address; external port) if and only if a connection between a local socket (local address; local port) and this external socket (external address; external port) was previously established. Just like NAT, stateful firewalls require to track established connections in a connection-tracking table. Stateful firewalls are an essential security measure useful for both IPv4 and IPv6 Internet access.

Residential Access Networks We depict a simplified architecture of a residential access network on Figure 1.

The first component of an ISP network is the user's residential gateway. It is located at the user side and is known as the Customer Premises Equipment (CPE). Local devices (smartphones, laptops etc.) are connected to the gateway either through wired Ethernet or Wi-Fi. The gateway also connects to the ISP access network (xDSL, Cable or Fiber). In addition to implementing the physical layer, the residential gateway performs a number of network functions. First, the gateway attributes IP addresses to local devices through DHCP. The gateway also restrict incoming traffic to connections established by local devices (stateful firewall). Lastly, the gateway performs Network Address Translation (NAT), so that local devices appear as a single IP address on Internet (Fig. 1).

The access network carries customer traffic from the DSLAM (DSL Access Multiplexer) or OLT (Optical Line Termination) to the Broadband Remote Access Server (BRAS). Customer traffic is tunneled using PPP, L2TP or GRE and transported over IP, ATM or Ethernet. Krononat uses GRE but can be easily adapted to other tunneling protocols. For GRE, the original IP packet (inner, grayed on Figure 2) is encapsulated into another IP packet (outer, white) for routing on the access network.

The Broadband Remote Access Server (BRAS) also named Broadband Network Gateway (BNG) collects customer traffic in a central location. The BRAS decapsulates tunneled packets and forwards them to Internet routers. With NFV, ISPs are moving network functions from the gateway (DHCP, Firewall, NAT) to the BRAS. Low-traffic functions (e.g., DHCP which handles a few packets per hour) are easy to move to the BRAS. By contrast, for firewall and NAT, *every* packet must be checked against the connection-tracking table, requiring the infrastructure to handle millions of packets per second.

ISP Contraints are unique and challenge existing NAT solutions. We review the most decisive ones.
Scale: ISPs operate at a very large scale: they have millions of simultaneously connected customers, which

CPU	2x Intel Xeon E5-2698v4 2x 20 cores, 2.2 Ghz 2x 40 PCIe v3 lanes
Memory	128 GiB (>100 GB/s bandwidth)
NICs	10x Intel XL710 40Gbps **400Gbps Total Throughput**
Price	$30000

Table 1: Commodity server for high-performance NAT

translates into dozens of millions of connections. In addition, at peak hours, they forward traffic in excess of 100Gbps. Thus, any solution should be computationally and cost efficient, i.e., the cost per user should be low.
Reliability: NAT service is crucial for Internet connectivity, as a disruption of NAT service translates into a loss of Internet connectivity for users. An ISP NAT solution must therefore be highly reliable, and should continue working in the event of a node failure.
Elasticity: ISPs operate in a limited geographical area and have a load with strong diurnal patterns [21, 12, 32, 36]. Thus, there is an opportunity to reduce the operating cost by dynamically adapting the number of servers.

Software NAT solutions OSes offer NAT functionality, usually implemented in kernel-mode (e.g., netfilter on Linux). However, a single node is not able to handle the load generated by all users of an ISP, and these implementations do not offer easy ways to aggregate multiple servers (i.e., distribute load accross servers). Projects such as Residential Cord [2] have been started to allow the use of multiple servers but remain impaired by the low computational efficiency of OSes NAT implementations, which translates into a high consumption of computing resources and high costs. In Residential Cord [2], their Linux-based vSG (virtual Service Gateway) hits a memory limit at 2000-4000 users per server. In [25], Linux NAT achieves 200 kpps (kilo packets per second) using a single core and 1 Mpps with 8 cores while BSDs achieve 220 kpps using 1 core and 500 kpps using 8 cores of an Intel Atom C2758 processor.

Appliances	Vendor A	Vendor B	COTS server
Max. Throughput	130 Gbps	140 Gbps	400 Gbps
Max. Connections	76M	180M	1000M
List Price	$65000	$200000	$30000
Price / Gbps	**$500**	**$1400**	**$75**

Table 2: NAT Hardware Solutions

Hardware NAT solutions Major vendors offer NAT solutions that can accommodate the traffic generated by a high number of users. However, these solutions tend to have a high cost (see Table 2). Also, they lack elasticity: the addition of a device requires manual configuration. They offer limited reliability options (often limited to 1+1 redundancy). Lastly, these solutions rely on tightly coupled specialized processors and specialized software. They therefore do not offer the flexibility of a full software solution, slowing down the addition of new features and preventing independent sourcing of hardware.

3 Designing a Software NAT

In this paper, we present Krononat, a multi-user stateful firewall and NAT service. Krononat is distributed on multiple servers so that it can handle the load generated by millions of users. Krononat groups users into *shards* that are dynamically mapped on servers. Krononat ensures that a server failure does not cause service disruption by replicating the state for a shard on two servers (a slave and a master). Krononat sits at the BRAS level and thus receives IP/GRE tunneled traffic and forwards NAT-ed packets to the Internet, and handles reverse traffic.

Our implementation builds on DPDK [1] and supports IPv4; yet our design generalizes to IPv6. We show that a careful software design and adequate hardware choice, allows achieving a high performance, and thus low-cost operations, without jeopardizing fault-tolerance.

3.1 Hardware Architecture

Current commodity servers and switches offer an opportunity for building NAT solutions that are competitive in performance with specialized solutions. Generally, specialized network appliances offer better performance than general-purpose servers through the use of content addressable memories (e.g., TCAM), that are notably used in routers and switches. However, maintaining connection-tracking tables requires much more memory than maintaining routing or switching tables: several gigabytes for connection tracking tables compared to tens of megabytes for routing tables. As TCAM are strongly limited in size (< 100 Mb), network appliances such as those of Table 2 must store connection-tracking tables in DRAM. Thus, for connection tracking, network appliances do not have a decisive advantage over commodity servers, which also use DRAM. Moreover, modern CPUs compensate memory latency by caches and out-of-order execution.

Thus, to minimize the cost, we rely on commodity servers equipped with a large number of Network Interface Cards (NICs). Current dual Intel Xeon servers offer 40 PCIe lanes, enough to handle 10 40-Gbps NICs, for a total throughput of 400 Gbps. For a typical Internet workload (Simple IMIX), this corresponds to 180 Mpps. An optimal NAT solution must therefore process at least 4.5 Mpps *per core*, so that one server (Table 1) can forward 400 Gbps, thus saturating its NICs.

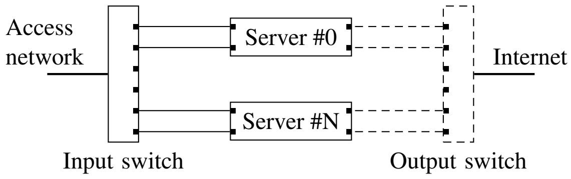

Figure 3: Hardware architecture

3.2 Software Design Principles

Achieving 4.5 Mpps per core or 400 Gbps per server requires an highly efficient implementation: each packet must be processed in less than 500 CPU cycles. We achieve this goal by relying on three design principles that allow an optimal exploitation of the hardware (servers, switches and NICs).

Sharding to the core To enable a high-performance implementation of a software NAT, we completely avoid cross-core data sharing. To this end, in Krononat, we use the CPU core as the unit of sharding in the overall system, thus departing from the traditional per-server or per-NIC sharding scheme. Hence, each CPU core can use its own dedicated connection-tracking table to process the traffic. Each customer is independent and we do not require a global shared connection-tracking table.

To implement this sharding scheme, each CPU core is associated with a NIC and exposed to the network as a distinct entity (i.e., each core has its own dedicated MAC addresses for load balancers to send traffic to it). The load balancers can thus forward the packets to a specific core. Our approach of having a dedicated network entity per core allows a greater control of the traffic-to-core mapping compared to commonly-used hashing-based methods, available on NICs (RSS) or routers (ECMP). This enables (i) a precise control of traffic steering whenever a failed master is replaced by its slave, (ii) sending upstream traffic and downstream traffic, which access the same connection-tracking table, to the same core. This cannot be achieved by Symmetrical RSS [40], because of rewritten IP headers.

To use the hardware as efficiently as possible, we do not dedicate one physical NIC for the input and one to the output for each core. Instead, we use the multi-queue capabilities of NICs (e.g., Intel VMDQ, MACVLAN filter, PCI SR-IOV) to have a dedicated queue for traffic from/to the input switch and a dedicated queue for traffic from/to the output switch[1]. Indeed, residential traffic is highly assymetrical, and dedicated NICs would not evenly use their RX and TX capabilities. Similarly, while a single core can handle the traffic of a 10 Gbps NIC, multiple cores are needed to handle the traffic of 40+ Gbps NICs. Thus, we also use the multi-queue capabilities of the NIC to expose one set of queues/identities per core to implement sharding to the core.

Sharding to the core is therefore highly beneficial for two main reasons: (i) it obviates the need for cross-core synchronization and (ii) it naturally provides NUMA-awareness, as a core never accesses data belonging to another core, and thus only accesses data on his socket.

Switch-based hardware load balancing To handle more than 400 Gbps of traffic, we use several servers. This requires balancing the traffic accross cores and across servers. To balance the load, we rely on the IP routing capabilities[2] of the input/output switches (Figure 3) which (i) remain more efficient than software for routing packets, especially when routing tables are small, (ii) are already present in the system for interconnection. Each shard has its own tunnel endpoint IP, and a dedicated subnet of public IPs. For each shard mapped to a core, a route to this core for the corresponding tunnel endpoint IP is declared to the input switch (to receive upstream traffic); and a route to this core for the corresponding subnet of public IPs is declared to the output switch (to receive downstream traffic). These routes are declared to the switches via BGP. Furthermore, all cores of Krononat thus act as IP routers by having their own IP/MAC addresses and implementing ARP protocol. Our sharding management is detailed in Section 3.4.

This approach avoids dedicating any CPU resources to traffic steering by leveraging existing switches. Also, it allows a more precise traffic steering than hash-based methods (e.g., ECMP). This precise control is needed by stateful network functions (e.g., NAT) that (i) require all packets of a connection to be handled by single core, (ii) have asymmetric headers for upstream and downstream, (iii) require controlling the route after a failover (transitioning from the master to the slave).

No locks on data path Our sharding approach ensures that threads running on different cores can forward or reject traffic without accessing data structures on other cores. This approach removes the need to lock the table to process traffic. Yet, maintenance or fault tolerance traditionally require locking data structures. For fault tolerance, connection-tracking tables need to be copied to other nodes. Traditionally, this is done by locking the table to ensure it is not modified while it is being copied. Because lock acquisition is costly and may block pro-

[1] For the sake of clarity, Figure 4 shows the NIC queues (dedicated MAC and VLAN) to which NAT thread of high-performance nodes are bound rather than the physical network interfaces. Despite the use of a shared hardware infrastructure, we still provide security isolation between the access network and the Internet. To this end, we rely on VLANs (layer 2) and VRF (layer 3) to provide isolated networks such that no packet can be switched/routed directly from the access network to the Internet without going through Krononat. Hence, input/output switch designate the input/output VRF on the physical switch.

[2] All modern entry-level 10/40 Gbps switches offer IP routing capabilities for routing tables of moderate size.

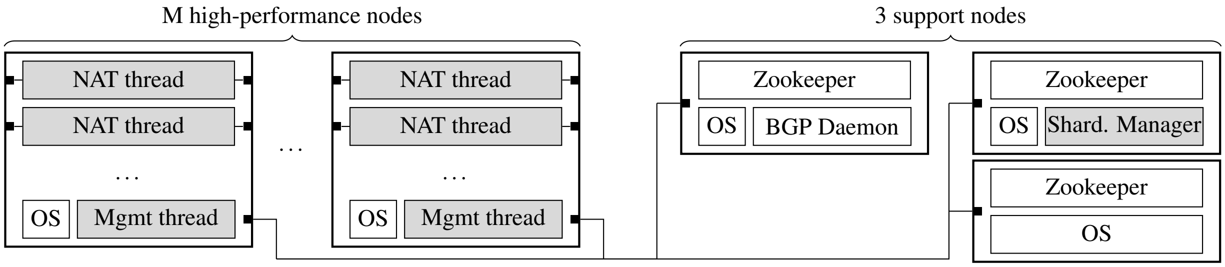

Figure 4: Software architecture

cessing on a given core, locking the table would strongly impair forwarding and is therefore not tractable in our use case. Therefore, we do not use a any lock on the data path. This requires a careful design of data structures and fault tolerance mechanisms, detailed in Section 3.5.

3.3 Software Architecture

We now present how these principles are applied to our system. Krononat comprises software components of its own (Figure 4, gray background) and uses external components (Figure 4, white background). The main functions of each component are detailed below.

NAT Thread The NAT Thread is the central component of Krononat and implements the core functionality of a NAT, as described in Section 2. Each NAT thread is pinned to a CPU core, and has the exclusive use of a set of NIC queues for output and input that it reads in poll-mode. The input switch forwards outbound traffic (GRE-encapsulated) to one input queue of a given NIC and server, depending on the Tunnel destination IP (Figure 2), which is used as the shard identifier (Section 3.2). The NAT thread associated with this input queue receives the traffic, and decapsulates GRE packets. It then forwards traffic to its output queue, and creates entries in its connection-tracking table for new connections. Conversely, each NAT thread receives inbound traffic forwarded by the output switch on its output queue. Inbound traffic is forwarded if and only if it belongs to a connection that has an entry in the table.

Management Thread The management thread communicates with Zookeeper, a strongly-consistent datastore and synchronization service that we use to coordinate all instances of Krononat. It fetches instructions (e.g., master/slave roles for NAT threads) and subscribes to asynchronous events sent by Zookeeper. This cannot be done directly by the NAT threads, because they cannot be interrupted for performance reasons. The management thread is also reponsible for most bookkeeping operations: initialization, statistics collection, etc. It synchronizes with the NAT thread using only non-blocking primitives (i.e., reads and writes to shared memory without locking nor spining).

Sharding Manager To scale to a large number of customers, we divide the load between multiple servers. The sharding manager allocates several shards on each core of each server based on the load of machines and on the traffic. The sharding manager does not directly communicate with the management thread. Instead, it writes the requested shard allocation in Zookeeper. The management thread reacts to updates in Zookeeper and propagates the allocation changes.

Zookeeper In Krononat, Zookeeper is used as central point for storing configuration (shard allocation, network configuration, addressing configuration, routes, etc.) and communicating configuration changes between servers. The use of Zookeeper for storing configuration data greatly simplifies the design of Krononat. For instance, the sharding manager does not need to persist shard allocation by itself. It can be easily restarted, or moved to another server and recover its state from Zookeeper. Similarly, when we start a new Krononat instance to handle more load it can load the global system configuration thanks to Zookeeper. We also use Zookeeper as a distributed lock service, and for detecting server failures.

3.4 Sharding and Fault tolerance

Shard In Krononat, a shard is a fixed-size group of users. In our experiments, we use shards of 256 users, but this number can be adapted. Users in the same shard share the same Tunnel destination IP, but have different Tunnel source IPs (Figure 2). In our experiments, we simulate 16384 users in 64 shards. Each user has a tunnel source IP in the range 172.17.0.0/18, and users belonging to the same shard share an address in the 172.16.0.0/26 range. Users of shard 0 have a source IP in 172.17.0.0-255 and share the tunnel destination IP 172.16.0.0; users of shard 1 have a source IP in 172.17.1.0-255 and share the tunnel destination IP 172.16.0.1; etc. One could also use the 10.0.0.0/8 range to support 4096 shards of 4096 users (i.e., a total of 2^{24} or 16M users).

Shard allocation Based on the traffic in each shard and on the load of each machine, the sharding manager allocates several shards to each NAT thread running on each CPU core of each host. The sharding manager then writes the shard allocation in Zookeeper. In order to steer the traffic to the right core, we leverage IP routing. Each core has its own IP and MAC addresses. Whenever a given core is a master for a given shard, the routing tables are updated so that the given core becomes the default gateway for reaching all subnets associated to the given shard. Each Krononat core thus appear as an independent router in the network. This update is performed by another process that reads the routes in Zookeeper and announces them via BGP to the switches. For instance, if shard 1 has been allocated to a NAT thread (i.e., core) whose input NIC has the IP 172.27.0.1 and output NIC has the IP 127.28.0.1, the BGP will instruct the input switch to route traffic with destination IP 172.16.0.1/32 to 172.27.0.1, and the output switch to route traffic with destination 172.16.1.0/24 to 172.28.0.1. In this way, traffic for shard 1 will be received by the appropriate thread.

Fault tolerance NAT threads store their connection-tracking tables in RAM, which means they will be lost in case of hardware or software failures. One solution would be to persist the connection tracking table to a database. However, this solution would induce a high recovery time. In addition, the database would need to support a very high insertion rate, as each connection establishment results in an insertion. Database systems typically do not support such a high insertion rate because of the consistency and durability guarantees they offer. Instead, we choose to replicate the connection tracking tables in RAM, on another node. More precisely, each NAT thread is declared as *master* for a set of shards, and as *slave* for a distinct set of shards. The master NAT thread for a shard receives the traffic, updates its connection tracking table if necessary and forwards or rejects traffic. The master NAT thread for a given shard also forwards connection tracking table updates to the slave NAT thread of this shard. The slave NAT thread record these tables updates into its own connection tracking table so that entries are replicated. If the server on which the master NAT thread of the shard runs fails, the slave NAT thread becomes the master NAT thread for the shard, and a new slave NAT thread will be assigned for the shard. Server failures are detected using Zookeeper, and shard re-allocations are performed by the sharding manager. We design an ad-hoc replication protocol that allows incremental replication of the connection tracking table without locking it.

3.5 NAT Thread Implementation

The NAT thread continuously polls the NIC queues. To increase efficiency, it processes batches of packets using a run-to-completion model (i.e., packets are not queued except for sending on the network) [1, 33]. It also batches lookups in the connection-tracking table [43, 19].

Hash table Each NAT thread has a single connection-tracking table for all shards it manages either as a master or as a slave. The connection-tracking table is composed of *two* hash tables: one hash table for outgoing traffic and one hash table for incoming traffic. The outgoing traffic hash table maps 6-tuples identifying a connection (customer, protocol; private source ip; private source port; destination ip; destination port) to a 2-tuple (public source ip; public source port) used to rewrite outgoing packets. Symmetrically, the incoming traffic hash table maps 5-tuples (protocol; public source ip; public source port; destination ip; destination port) to a 3-tuple (customer, private source ip; private source port) used to rewrite incoming packets. We use Cuckoo++ hash tables [19] to store the incoming traffic table and the outgoing traffic table. Cuckoo hash tables store an entry at either one of two locations $\mathrm{h}_1(k)$ or $\mathrm{h}_2(k)$, where h_1 and h_2 are two distinct hash functions, and k the key of the entry. Therefore, a key lookup takes at most two memory accesses, allowing Cuckoo hash tables to support a very high lookup rate. This is key requirement in Krononat, as every packet triggers a table lookup. Cuckoo++ hash tables augment Cuckoo hash tables with a small cache-resident bloom filter that avoids checking the second location $\mathrm{h}_2(k)$ in most cases including for negative lookups. This allows Cuckoo++ hash tables to maintain their high performance in presence of large volumes of invalid traffic or Denial-of-Service (DoS) attacks. Furthermore, to support replication without blocking traffic processing in the NAT thread, Cuckoo++ provide specific iterators, that support interleaving of updates and iteration steps by guaranteeing that all entries are iterated over at least once during a full hash-table scan.

Replication As ISPs need to provide uninterrupted Internet access, fault tolerance is a fundamental prerequisite for any network function deployed in their core network. Consequently, Krononat must support single server failures. We achieve this through *replication* of the connection-tracking entries. The master NAT thread for a shard receives all traffic belonging to the shard, and updates its hash tables accordingly. The slave NAT thread of a shard maintains a replica of all connection-tracking entries corresponding to that shard, so that it can take ownership of the shard if the master NAT thread fails. A naive approach for replication would be to lock the hash table on the master NAT thread, and dump the whole data structure on the network. This naive approach has two major defects that make it intractable: (i) locking the hash tables means stopping accepting new connections, which is obviously impossible for availability reasons, (ii) constantly dumping the whole data structure on the network would generate a high replication traffic, and also consume CPU cycles. To address both issues, we design a more elaborate replication protocol that has two modes: (i) *initial replication*, where we transfer the entire contents of the hash tables without locking them thanks to the aforementionned iterators in Cuckoo++, and (ii) *streaming replication*, where the master NAT thread sends incremental updates to the slave NAT thread, so as to reduce network traffic.

Initial replication When a NAT Thread becomes a slave for a shard, it has no knowledge of the connection-tracking entries the master for that shard has: the slave NAT thread needs to receive a full copy of the entries for that shard. This is achieved by the initial replication mode. In this mode, the master NAT thread iterates over hash tables entries, serializes them, and sends them over the network to the slave NAT thread. Note that this initial replication is not performed by an additional thread, it is performed by the NAT thread itself to avoid locking the table. After processing a batch of packets, the master NAT thread iterates over a few entries, and sends them over the network. It then processes the next batch of packets and iterates over the next group of entries. This procedure is repeated until the whole table has been replicated. This interleaving ensures that the initial replication does not preclude packet processing. When a packet is processed, the master NAT thread may update hash table entries (when creating new connections). Therefore, the hash table may be modified in the middle of the initial replication. To support this, Cuckoo++ iterators support modifications. More specifically, we associate a *modification bit* with each table entry. When the iterator sees a table entry, the modification bit is cleared. When a hash table entry is modified, the modification bit is set. The initial replication repeatedly iterates over entries as long as it sees a modified entry to guarantee that no unseen modified entries is left. To accelerate this process, multiple levels of modification bits are used to skip entire groups of unmodified entries.

Streaming replication When the initial replication is completed, the master NAT thread switches to streaming replication mode. In streaming replication mode, whenever it makes a change to the hash tables, the NAT thread inserts a description of this change into a *changelog*. After processing a batch of packets, the master NAT thread extracts remaining entries from the changelog, serializes them and sends them to the slave NAT thread. Because it does not constantly iterate over the hash tables, the streaming replication mode uses less CPU cycles and less network bandwidth than the initial replication mode. The replication protocol uses acknowledgments and retransmissions and in case of failure the slave is declared out of sync and must go through initial replication again.

Server CPU	Krononat (10G port)	Traffic gen.
1x E5-2695v3	1	2
1x E5-2695v3	3	2
1x E5-2643v3	4	0
2x E5-2690v4	4	4

Table 3: Allocation of servers in our testbed

4 Evaluation

Implementation Krononat (see Fig 4) is implemented in C (30K lines – gcc 5.4) on top of DPDK 17.08. The sharding manager is implemented in Scala (2K lines). The BGP part consists of a 500 lines wrapper between ZooKeeper 3.4.8 and GoBGP 1.18.

Hardware Our hardware testbed consists of four Dell R730 servers with varying CPU configurations (Table 3). They are configured in performance mode, with Turboboost disabled and equipped with Intel X540 10Gbps dual-port NICs. They are interconnected by an entry-level 10Gbps Alcatel OS6900-T20 switch, which is configured to operate as an IP router with multiple VLANs and VRFs (Virtual Routing Functions), so as to provide isolation between access, Internet, and management networks. Our testbed uses addresses in the range 172.16.0.0/12 so as not to conflict with the enterprise networks. This slightly limits the range of some parameters but our experiments show that those parameters have very little impact on performance anyway (Subsection 4.1). The hardware of the testbed is shared between Krononat and a traffic generator that we designed. Table 3 shows the mapping of 10G NIC ports.

Traffic Generator Testing the limits of Krononat requires generating a very large amount of traffic (tens of Mpps). We did not find a traffic generator that is able to generate such a load by utilizing several nodes, so we designed our own traffic generator to test Krononat. Our traffic generator builds upon DPDK, similarly to MoonGen [10] or pkt-gen [39], and borrows principles from Krononat such as (i) share-nothing, (ii) sharding to the core, (iii) switch-based hardware load balancing. It generates stateful traffic and keeps track of established connections. Each 10 Gbps NIC allocated is managed by a group of 4 threads (RX/TX Access/Internet). All instances (1 per server) emulate independant users and synchronize using Zookeeper (results, parameters, phase). This scale-out design allows a close to linear scalability and generating traffic beyond the scale of one server.

Metrics In our evaluation, we measure:

Rate for Connection initialization correspond to the rate at which packets (UDP) of new flows/connections are processed (100% upstream traffic). On actual Internet traffic, connection initialization packets represent 1-5% of the traffic [37, 18, 24, 5, 38, 31].

Rate for Established connections is the rate at which packets (UDP) belonging to existing flows are processed by the system. Our objective is to exceed 4.5 Mpps. We

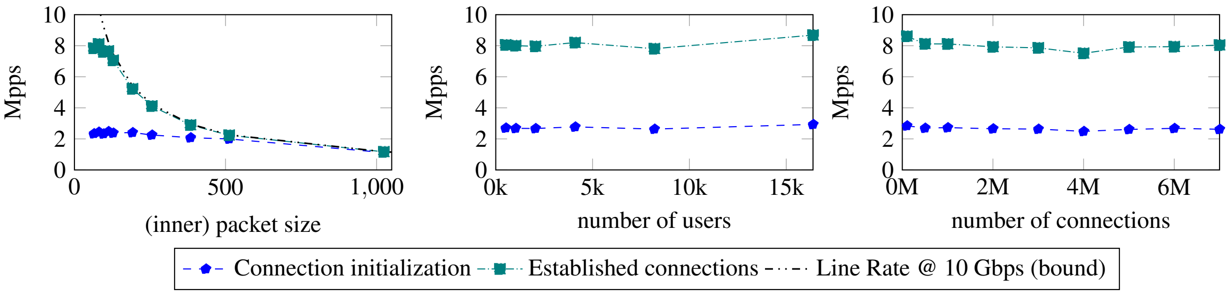

Figure 5: Performance impact of parameters in single-core case for Krononat (raw performance) (1 server)

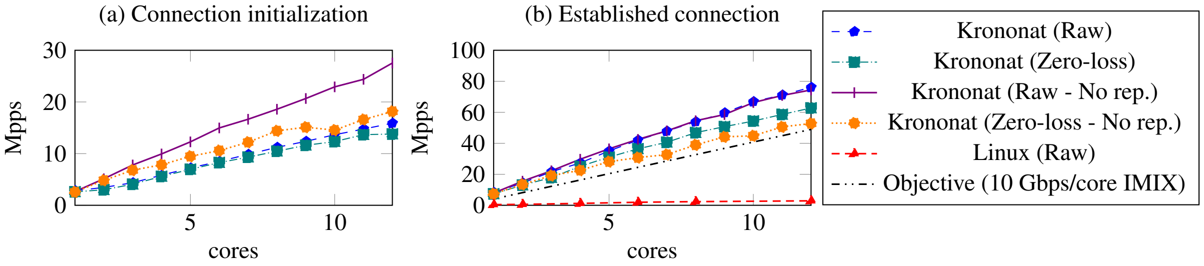

Figure 6: Performance (Mpps) in the multi-core case (4 servers).

measure for 50% upstream and 50% downstream traffic.

They are reported [7] as: (i) *raw* is the rate of traffic going through the system while flooding it; (ii) *zero-loss* is the rate which can be sustained without losing packets during 15 seconds. The *zero-loss* rate is only relevant for systems with real-time guarantees/non-blocking implementations (i.e., not for Linux-based NAT).

We also evaluate ***the duration of service interruption*** whenever a server leaves the system or crashes.

4.1 Influence of parameters

First, we evaluate the impact of a few parameters on Krononat performance. We report the raw rate for both connection initialization and established connections on Figure 5. Performance is stable at approximately 8 Mpps for established connections regardless of the number of users or connections. The performance is reduced as the packet size is increased: this is because the system achieves line rate (10 Gbps) and is therefore NIC-bound rather than CPU-bound. This shows the high efficiency of Krononat.

As we have shown that the packet size, number of users and number of connections have little to no impact on performance, we use fixed values in the remainder of this section: (i) 64-bytes packets, (ii) 16k users, (iii) 5M connections per core. We use the lowest packet-size (64 bytes without GRE encapsulation) to remain CPU-bound since we aim at evaluating the CPU-efficiency. This also allows our traffic generator, which is allocated only 8 NIC ports, to generate as many packets as necessary to evaluate Krononat on 12 cores without being limited by the speed of network interfaces.

4.2 Scalability

We benchmark Krononat with multiple cores, on all 4 testbed servers. Krononat is evaluated both with and without replication to show the overhead of replication. To give an idea of the achieved performance, we also plot performance of a trivial NAT system that uses the Linux kernel implementation and Linux namespaces[3]. We also display our performance objective: 400 Gbps/server or 4.5 Mpps per core, which enables the use of dense servers (i.e., fitted with as many NICs as CPUs support).

The results are reported on Figure 6 using 1 to 12 cores, averaged over 10 runs with random placement of NAT threads on our 4 servers. Krononat on 12 cores achieves 15 million connection initialization per second, with replication enabled (halved from Krononat without replication). For established connections, Krononat with replication is able to process packets at 77 Mpps on 12 cores[4]. The penalty when measuring performance with the zero-loss constraint is limited.

Kronont offers much higher performance than the Linux-based NAT. For established connections, Linux only achieves 0.6 Mpps on 1 core and scales to 2.9 Mpps on 12 cores. This is because Linux is a general-purpose system not dedicated to multi-tenant NAT; thus its design

[3] To maximize Linux performance, we take care to avoid extreme settings, and limit the experiment to 32 users (i.e., 32 namespaces) and 50000 flows. We distribute traffic accross cores of our Intel Xeon E5-2690v4 using RSS in a NUMA-aware way (i.e., on cores on the same socket as the NIC). Despite these advantageous settings, Linux performance remains low compared to Krononat.

[4] The performance for established connections without replication is lower as in this case, the sharding manager is not able to rebalance the load by swapping roles between master and slave cores.

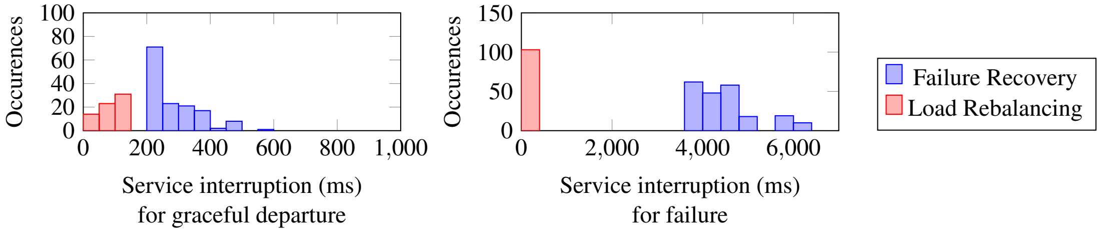

Figure 7: Service interruption due to failure or departure injection (4 servers)

favors configurability and generality over performance. This shows that Linux is unusable as an ISP-grade NAT solution. This is even more salient considering that Krononat also provides by default distribution accross servers and fault-tolerance. Krononat performance is well above our objective, reaching 6.3 Mpps/core when run on 12 cores, with replication enabled. These experiments show the excellent scalability obtained thanks to our scale-out architecture, consistently with the scalability of the underlying hash-table [19].

Running such experiments proved challenging: (i) network requirements inhibits the use of the cloud; (ii) commodity networking remains relatively expensive for large-scale experiments, (iii) simulation or virtualization overhead would make performance evaluation of such DPDK-based implementation irrelevant. We were thus limited by the networking equipment that we shared between traffic generation and Krononat. Nonetheless, our experiments involve four real servers and up to 12 cores, reaching up to 76 Mpps (6.3 Mpps/core), which is well above our target of 4.5 Mpps/core. The scale of these experiments also show the interest of using sharding to the core and hardware-based traffic steering to implement stateful multi-core multi-server traffic generators.

4.3 Service interruption duration

Beyond its high-performance and scalability, a major feature of Krononat is fault tolerance. As the state for each shard is continuously replicated on a master and a slave core, Krononat can recover from a server failure without disrupting service. Replication is also useful for dynamically adapting the number of servers (e.g., graceful departure) and rebalancing the load (i.e., swapping master and slave). We inject both graceful departures and hard failures and measure the durations of service interruptions in both cases. We report the durations of service interruptions due to recovery (i.e., the slave replaces the departed master – red) and to load-rebalancing (i.e., master and slave swap their roles – blue) on Figure 7.

Service interruptions due to graceful departure (i.e., the server disconnects gracefully from Zookeeper) remain below 500ms. This corresponds to the delay for the sharding manager to compute a new allocation, which is applied to NAT thread; and to announce routes via BGP. In the case of hard failures (i.e., the server does not disconnect gracefully from Zookeeper), the detection is left to ZooKeeper heartbeat. This increases the recovery delay to 4-7 seconds. This recovery is automatic, without any human intervention, ensuring that the system is highly available. Finally, interruptions due to load rebalancing last less than 100ms. Indeed, to rebalance the load, the sharding manager swaps roles between some masters and slaves. In this case, the interruption is mainly the delay for BGP to apply the new routes.

In all cases, these durations are low enough so that clients retransmit lost packets without declaring connections dead. This ensures that end users are not impacted. We performed real-life experiments by redirecting our own Internet traffic through Krononat for a few hours. The interruptions due to injected failures remained unnoticeable in web browsing and video streaming usages. Indeed, short interruptions are hidden by software buffering or retransmission, thus avoiding user-visible errors.

4.4 Recovery from failure

To further illustrate the system reaction to a crash, we report how Krononat (4 NAT threads on 4 servers) reacts step-by-step when one of the servers is electrically powered down. An electrical failure is triggered at the 7th second. For a short duration, approximately 16 shards have lost their master, and 13 have lost their slave. The service is thus interrupted for 16 shards. The system becomes fully available again within 200ms (i.e., no more shards in slave only mode). Shards that lost their slave or master are allocated a new slave that is being initialized (20th to 35th second). This initialization generates limited replication traffic ($<$ 65 Mbps) and has a very limited impact on the performance: traffic is still processed at approximately 24 Mpps. The performance drops slightly during recovery because the master must read and transmit its state to the new slave, and the new slave must record this state. The performance drop is limited thanks to the absence of locking of the connection-tracking table allowed by our replication protocol that allows initial replication to occur without freezing state. Without any human operator intervention, at the 35th second, the system becomes fully tolerant to failures again: all shards have a master and a synchronized slave.

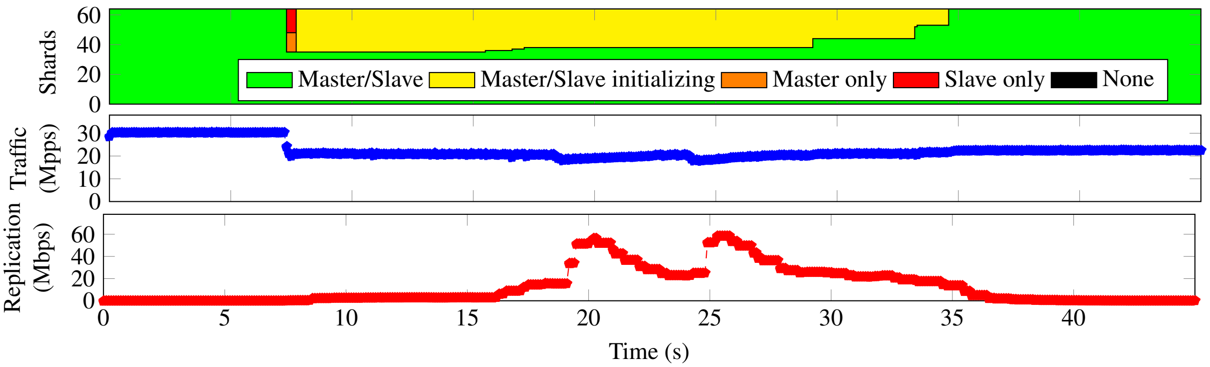

Figure 8: Execution on a system with 4 workers, on 4 servers. A server crash is introduced at time t=7s.

5 Discussion

SDN For load-balacing, Krononat relies on IP routing configured through BGP, and ARP/MAC learning for the discovery of Krononat instances. This greatly simplified the implementation of hardware-based load balancing. This choice also allows using VRF-based isolation, as well as easy inspection of routing table (e.g., using standard switch user interface). Furthermore, many production-ready BGP libraries are available.

Openflow [23] or P4 [6] could have been an alternative, but it requires specific models of switches. Also, the configuration or capabilities of switches for OpenFlow are not always well documented. Note that BGP requires routing based on IP addresses : OpenFlow could thus be advantageous if we want to do traffic steering based on other criteria (e.g., MAC addresses) or if non-IP protocols were used for tunneling on the access side.

Unavailability delay Krononat relies on Zookeeper for failure detection. This leads to uncompressible delays for recovery (4-7s) mainly due to Zookeeper failure detection. To improve this, one could rely on BFD [17] to monitor links at the switches and declare in BGP a primary route to the master and a secondary route to the slave. This way, in case of server or link failure, the switch could immediately react and route packets to the slave without waiting for Zookeeper to detect the failure. Yet, the unavailabilities we observe remain un-noticed in practice with typical web traffic including live streaming, mostly hidden by buffering and TCP retransmission.

6 Related Work

Krononat applies techniques such as kernel-bypass, run-to-completion, and core pinning [33, 1, 4, 8, 20] which are necessary to achieve high-performance on modern processors. Krononat shows how to put these in practice when dealing with a mutable state by relying on sharding-to-the-core to achieve share-nothing.

Switching or routing NFVs, targetting COTS servers, have already been studied and implemented [8, 30, 22]. ClickOS [22] also considers advanced middleboxes such as BRAS and CG-NAT but achieves only 2.3 Mpps with a 4-core processor. Switching and routing NFVs rely on a *small and static* state. They can thus share state between cores with limited performance penalty, which is not tractable in connection-tracking systems. Our papers extends the share-nothing principle beyond NIC queues and details how to distribute traffic to cores with finer control than classical hash-based traffic distribution.

NFV frameworks [28, 27, 42, 15, 41] consider the communication between NFV functions. They show that context switches have huge overhead and either (i) avoid containers/VMs by using other types of isolation [28, 42], (ii) optimize communication between containers/VMs [14, 15, 30]. They provide capabilities to share resources between multiple VMs running services consuming only a fraction of the resources. In Krononat, we do not need to isolate several chained components of our datapath, nor to share server resources between multiple small applications. Thus, these frameworks do not fit our use case and add complexity for little benefits.

Virtual switches [15, 30], can help in providing features missing from hardware switches or NICs. In our case, rather than providing software-based traffic distribution to address limitations of hardware NIC and switches, we choose to design our sharding scheme (e.g., using IP routing features) so that it can be supported by entry-level 10 Gbps switches and commodity 10 Gbps NICs. To avoid context switches, we use a single process and the run-to-completion model similarly to NetBricks [28] or BESS [15]. Yet, the modularity they bring comes at a cost: during prototyping we noticed that dynamic dispatch used in BESS or NetBricks can have a non-negligible overhead compared to static dispatch as it prevents some compiler optimizations.

The aforementionned frameworks focus on directing packets within a server, while Krononat provides a solution for directing packets accross servers through switch-based load balancing. Also, these frameworks [15, 28] have limited features for directing packets for both flow directions to a single core (e.g., tunneled traffic, rewritten headers) as they rely on hash-based distribution (e.g., RSS), or attach a thread per NIC. By using MAC addresses to direct packet to per-core queues, we borrow from SoftBricks [8], an interesting paper that considers distribution accross server but for routing and VPN applications. It features an inspiring description of hardware capabilities and their impact on software router design.

Interestingly, designing for multi-tenancy can impact efficiency. CORD vSG [2] relies on namespace per user. This leads to one queue or datastructure per user. It prevents batching, which is yet key to high performance in large hash tables [19]. Indeed, a received batch is unlikely to contain only packets for a single user. On the contrary, Krononat relies heavily on batching to achieve its performance objective as commonly practiced in high-performance networking [1, 33].

Systems tracking connections such as load-balancers [9, 13, 29] or NAT/FW [16] also deal with the difficulty of preserving mutable state. A first approach is to rely on an external reliable database such as Memcached [11], RamCloud [26] or Adhoc [13]; while simplifying design, this comes with the cost of running the database (additional servers) and accessing it (dedicated NICs consuming PCIe lanes). A second approach is to rely on consistent-hashing, like the Maglev load balancer [9]. One enabler for this approach is that Maglev handles only unidirectionnal traffic as reverse traffic relies on DSR (Direct Server Return). MagLev achieves 2-3 Mpps/core. Krononat tackles a more challenging use case than Maglev (NAT versus load balancing), which requires handling bidirectional traffic. The NAT in [16] achieves 5 Mpps on 12 cores using RAMCloud. Krononat largely exceeds the performance of [16]. This is because Krononat underlying hash table is much faster (e.g., 10M insertions/second/core, 35M lookups/second/core and 350M lookups/second for 12 cores) than a remote RAMCloud (0.7M insertion/second and 4.7M lookups/second on 12 cores [16]). In addition, remote database accesses prevent run-to-completion.

Despite not relying on an external database, Krononat still offers reliability as it passively replicates of all connection entries. This design allows Krononat to offer a much higher performance than [16], strongly reducing costs for ISPs. An alternative design [34] to using a reliable databases is to snapshot the NFV periodically and log all packets to allow restarting the NFV from a snapshot and replaying traffic if needed. Interestingly, this approach allows adding reliability to any middlebox with little to no modification. Yet, this also comes at the cost of performance as FTMB is limited to 6 Mpps using 16 cores. Overall, Krononat favors liveness and performance over strong consistency. Indeed, for networking applications, strong consistency has a high performance impact, and may even be undesirable. A common choice in databases is to block or delay updates if they cannot be durably recorded, but for networking this means dropping any new connection thus interrupting the service. An alternative choice is thus to favor liveness: in the rather unlikely event of simultaneous failure of two servers, software clients will re-establish connections, causing little trouble.

Load-balancers [9, 29] often rely on IP routing as a first layer for traffic distribution from the Internet. Each load-balancer owns one or several of the VIP (virtual IPs) to capture traffic from the Internet. This is similar in design to our Tunnel end point IP addresses. Krononat further exploit this to also capture reverse traffic and use a different granularity by sharding down to the core-level so as to allow an highly efficient implementation.

Interesting concurrent work by, Araujo et al [3], describes a load-balancer design that shares a few key observation with Krononat : (i) commodity switches are incredibly efficient at distributing packets, both papers thus offload as much of their work as possible onto the switch, (ii) doing so requires to adapt the sharding and the network addressing scheme so that it is supported by commodity switches. Yet, as we target different applications (i.e., NAT and stateful firewall for us and load-balancing for them), other points of the design differ (e.g., permanent replication vs on-demand draining, handling bi-directional traffic, updating the routing table rather than updating the ARP table).

7 Conclusion

We presented Krononat, a high performance stateful networking service providing NAT and firewall for large-scale residential access network of ISPs. Krononat has a close to linear scalability thanks to its design relying on sharding to the core, and was shown to handle 77 Mpps on 12 cores, fully exploiting our testbed. It is designed for scale-out both accross cores and accross servers; it should scale linearly well beyond 12 cores and 4 servers.

Our design relies on sharding to the core, by exposing each core as an independent entity on the network. This allows traffic steering accross cores and servers to be performed by the switches freeing precious CPU resources. Traffic steering is based on IP routing as it allows a fine control, useful for stateful NFV functions for which RSS/ECMP offer insufficient control. Beyond Krononat, these principles proved useful for building the scale-out traffic generators that we use for the performance evaluation. We believe these principles can also apply widely to high-performance implementations of stateful NFV functions.

Accurate Timeout Detection Despite Arbitrary Processing Delays

Abstract

Timeout is widely used for failure detection. This paper proposes SafeTimer, a mechanism to enhance existing timeout detection protocols to tolerate long delays in the OS and the application: at the heartbeat receiver, SafeTimer checks whether there are any pending heartbeats before reporting a failure; at the heartbeat sender, SafeTimer blocks the sender if it cannot send out heartbeats in time. We have proved that SafeTimer can prevent false failure report despite arbitrary delays in the OS and the application. This property allows existing protocols to relax their timing assumptions and use a shorter timeout interval for faster failure detection. Our evaluation shows that the overhead of SafeTimer is small and applying SafeTimer to existing systems is easy.

1 Introduction

This paper presents SafeTimer, a mechanism to enhance existing timeout detection protocols to prevent false failure reports caused by long delays in the OS and the application. With the help of SafeTimer, existing protocols can relax their timing assumptions and thus use a shorter timeout interval for faster failure detection.

Timeout is widely used in distributed systems to detect failures [1, 6, 13, 24, 29, 45]: a node periodically sends a heartbeat packet to others and if the receiver does not receive the heartbeat in time, it may report a failure and may take actions to recover the failure.

Although this idea is simple, delays of packet transfer create a problem: if a receiver misses a heartbeat, is it because the sender has not sent the heartbeat, which indicates a failure, or is it because the heartbeat is delayed somewhere, which should not indicate a failure?

To address this problem, existing systems use one of the following approaches: the first is to prevent false failure reports by setting an appropriate timeout interval. However, such setting requires certain timing assumptions about the communication channel [4, 5, 18] and creates a dilemma: on one hand, these assumptions should be conservative enough to tolerate abnormal events that can cause long delays (e.g., congestion), which means the timeout interval should be long. On the other hand, long timeout interval can hurt system availability, because the system has to wait for a long time before recovering the failure. A recent study shows that inappropriate timeout interval is a major cause of timeout related bugs, leading to various problems like data loss or system hanging [19]. The second approach is to ensure correctness despite false failure reports, using protocols like Paxos [34, 35, 42]. This approach allows short timeout for better availability, but its cost is usually higher.

SafeTimer enhances the first approach to tolerate a subset of those abnormal events, without requiring any timing assumptions. It thus allows existing protocols to relax their timing assumptions to use a shorter timeout interval, without sacrificing the accuracy of timeout detection. It is motivated by two insights.

First, conservative assumptions are only necessary if the communication channel is a blackbox, which cannot provide any additional information other than receiving a packet. If the channel can tell whether a packet is pending or dropped, the receiver can simply check whether there is a pending or dropped heartbeat when missing a heartbeat. This approach can prevent false failure reports without requiring any timing assumptions.

Second, we observe that modeling the whole communication channel as a blackbox is too pessimistic: the routing layer usually does not provide the users with information like packet drops, so it is reasonable to model routing as a blackbox; the OS and the application, however, can provide precise information about its packet processing and thus could be modeled as a whitebox. Furthermore, in today's datacenters, the whitebox part often incurs delays that are comparable to or even larger than those of the blackbox part: on one hand, intra-datacenter networking delays usually range from tens of microseconds to a few milliseconds and can be further reduced to hundreds of nanoseconds with techniques like Infiniband [31]. Improvement in bandwidth and protocols [14, 46] have significantly reduced the chances of packet drops. On the other hand, a traditional OS can delay processing by several milliseconds because of time sharing or page fault, etc. Such delay can occasionally grow to several seconds for reasons like SSD garbage collection [32] and can grow even higher in abnormal cases (see Section 2).

Because of these two insights—1) the delay of the whitebox part is significant among communication and 2) there exist more effective solutions for the whitebox part—SafeTimer naturally uses a more effective solution for the whitebox part; for the blackbox part, SafeTimer relies on existing protocols and their assumptions.

At the receiver side, SafeTimer guarantees that *as long as the network interface card (NIC) has either delivered or dropped the heartbeat before the deadline, the receiver will not report a failure.* To achieve this property, SafeTimer's receiver module checks whether there are any pending or dropped heartbeats in the system before reporting a failure. Implementing this idea, however, is challenging, because modern OS incorporates a highly concurrent pipeline for fast packet processing. Naive solutions like pausing all its threads requires an intrusive modification to kernel, which is undesirable.

To solve this problem, we propose a non-blocking solution: when the timer expires at t, SafeTimer's receiver module will send a barrier packet to itself. By crafting the barrier packet and configuring the OS properly, SafeTimer ensures that if the receiver module receives the barrier, all heartbeats processed by the NIC before t must have been either delivered to the application or dropped. Therefore, if the receiver module has neither received the heartbeat nor observed any packet drops, it can safely report a failure.

At the sender side, SafeTimer guarantees that *if the sender has not sent out a heartbeat in time, the sender will not be able to send out any new packets.* Such suicide idea is not novel [8, 22], but previous solutions that actively kill or reboot the sender do not work when considering long processing delays, because the kill or reboot operations may be delayed as well, leaving the sender alive. To solve this problem, SafeTimer incorporates a passive design: SafeTimer's sender module maintains a timestamp to identify till when it is valid for the sender to send new packets. The sender module updates this timestamp when successfully sending a heartbeat and checks this timestamp before sending any packets. By doing so, SafeTimer prevents a sender which fails to send heartbeat in time to affect other nodes in the system.

One can enhance an existing timeout detection protocol by applying SafeTimer at both the sender and the receiver. We can prove that, as long as the existing protocol's assumptions about the blackbox part hold, SafeTimer is accurate (i.e., never report failure for a correct sender) despite arbitrary delays in the whitebox part and is complete (i.e., eventually report failure for a failed sender) when the receiver does not experience slow processing or packet drops for sufficiently long [12]. Such properties indicate that one does not need to make conservative assumptions about the whitebox part, and thus can use a shorter timeout interval to improve availability.

Our evaluation shows that the overhead of SafeTimer is negligible when processing big packets and at most 2.7% when processing small packets; SafeTimer can prevent false failure reports when long processing delays are injected; and applying SafeTimer to HDFS [27, 45] and Ceph [9] is easy.

2 Motivation

2.1 Long delays in OS and application

SafeTimer allows existing timeout detection protocols to relax their timing assumptions by excluding delays in the OS and the application. To demonstrate the potential benefits of such relaxation, we present a number of abnormal events that can cause long delays.

- **Disk access.** Disk accesses caused by logging heartbeats [29, 45] or page faults can block heartbeat processing. A typical hard drive has an average latency of tens of milliseconds and an SSD usually has a lower average latency. Worst-case latency, however, is much longer: SSD's internal garbage collection can delay an access by more than one second [32]. Our experiment with hard drives shows that when processing frequent random writes, the buffering mechanism in the file system can occasionally introduce a latency of tens of seconds, when it flushes many random writes.
- **Packet processing.** OS kernel can drop packets at different layers when it runs out of buffer space, which can cause extra delay. Furthermore, handling of abnormal packets may cause a significant delay as well. For example, when Linux receives a packet to an unopened port, it will report "port unreachable" to the router using ICMP [30]. In our experiment, a large number of such abnormal packets can delay the processing of heartbeat by more than two seconds.
- **JVM garbage collection.** Garbage collection in a Java Virtual Machine (JVM) can block the execution of the application. Our experiment on a JVM with 32GB of memory shows that when the memory is close to be fully utilized, a single garbage collection can take up to 26 seconds, even when using parallel GC. A recent survey [19] has observed similar problems in ZooKeeper and HBase (HBase-3273 [26]).

- **Applicaton specific delays.** Applications may have specific logics that can cause long delays occasionally. For example, previous works have reported that HDFS DataNode's heartbeat sending thread may be blocked by the task of scanning local data, which could take long [48]. Although newer versions of HDFS have fixed this problem, our investigation shows that similar problems still exist: the heartbeat sending thread can also be blocked by the task of deleting directories, which can take long as well. A similar problem has been reported in Ceph, in which a heavy rejoin operation can block heartbeat processing [11].

As shown in these examples, some events in the OS and the application can cause delays of tens of seconds, which are comparable to or larger than many systems' default timeout intervals (e.g., 30 seconds in HDFS [28], 5 seconds in ZooKeeper [25], 20 seconds in Ceph [10]). Furthermore, some of these delays may grow longer if a machine has more resource (e.g., more memory for JVM garbage collection).

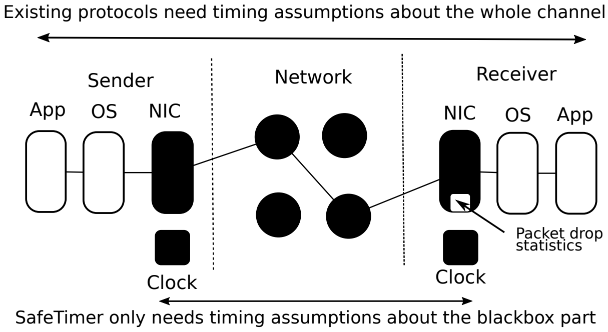
Existing timeout detection protocols must make their timing assumptions conservative enough to cover all the events mentioned above. For example, to tolerate long garbage collection in ZooKeeper [26], the developers increased their timeout intervals, which will hurt system availability as discussed previously. With the help of SafeTimer, however, they can tolerate these events without requiring any timing assumptions, and thus can use a shorter timeout for faster failure detection.

2.2 Can we provide timing guarantees?

The above problems would be trivial if the OS and the application can provide hard real-time guarantees for heartbeat processing, but during our failed attempts, we find this is a challenging task on commodity OS.

Isolated resource for heartbeats. To prevent other tasks from interfering with heartbeat processing, the application can reserve resources (e.g., a socket) for heartbeat processing. However, this approach cannot prevent such interference in OS kernel. For example, packets from different sockets can be handled by the same thread or CPU core in the kernel; even if heartbeat handling does not need to make disk I/Os, page fault in the kernel may incur a disk I/O, blocking heartbeat processing.

Processing heartbeats at lower layers. To avoid delays in the OS kernel, one can implement heartbeat sending and checking at lower layers, as close as possible to the NIC. This approach can avoid many types of delays, but cannot eliminate them, because heartbeat checking can only happen after the OS reads a packet, which means delays in handling interrupts and reading packets can still cause false failure reports.



Existing protocols need timing assumptions about the whole channel
Sender
Network
Receiver

OS
NIC
NIC
OS
App
Packet drop statistics
Clock
Clock
SafeTimer only needs timing assumptions about the blackbox part

Figure 1: System model: SafeTimer can tolerate long delays in the whitebox part without timing assumptions.

Real-time OS. Real-time Linux [43] and other real-time frameworks for Linux such as RTAI [44] and Xenomai [49] can give higher priority to certain interrupts, so that they wouldn't be delayed by other interrupts. However, this approach can only guarantee an interrupt handler is triggered in time, but cannot guarantee when the OS can finish reading a packet. The latter requires us to analyze the worst-case execution time of handling interrupts and reading packets, which is a challenging task on complicated kernel code with frequent synchronizations.

We find these approaches, even combined, cannot achieve hard timing guarantees for heartbeat processing. The fundamental problem is that commodity OSes are designed with the principles of resource sharing and high concurrency, which is against the goal of strict timing guarantees. Therefore, finally we give up the attempts to provide timing guarantees. Instead, we investigate whether we can prevent false failure reports **assuming delays in the OS and the application can be arbitrary**.

3 Model

The goal of SafeTimer is to enhance existing timeout detection protocols to tolerate long processing delays in the OS and the application. To achieve this goal, SafeTimer makes a few assumptions about the existing protocol: at the receiver side, SafeTimer assumes the receiver defines multiple time intervals and reports a failure if it does not receive any heartbeats during an interval. At the sender side, SafeTimer assumes the application has its own rules to decide when to send heartbeats and whether heartbeats are sent successfully, based on its timing assumptions. Furthermore, SafeTimer assumes these intervals and assumptions are configurable, so that the user can use a shorter timeout interval with the help of SafeTimer.

SafeTimer enhances existing protocols to tolerate a subset of abnormal events without requiring timing assumptions. Figure 1 shows which events SafeTimer can tolerate: the blackbox part includes the network interface cards (NICs) at both sides, the clocks at both sides, and packet routing between two NICs; the whitebox part includes the OS and the application's logic to process packets at both sides. SafeTimer can tolerate long delays in the whitebox part without requiring any timing assumptions. Instead, SafeTimer only assumes that, a node will eventually finish processing a heartbeat and SafeTimer can observe the result (either delivered or dropped). For the blackbox part, SafeTimer relies on existing protocols and their assumptions.

Abnormal events in the whitebox part may affect the processing speed of the blackbox part. SafeTimer assumes such effect can be observed at the boundary: a slow receiver may cause its NIC to drop packets because the receiver's buffer is full and SafeTimer assumes the NICs can provide packet drop statistics. We find this function is commonly provided by modern NICs.

With the help of SafeTimer, existing timeout detection protocols only need to make conservative assumptions about the blackbox part, which means the protocol can use a shorter timeout interval to accelerate failure detection. Note that SafeTimer cannot make concrete suggestions about timeout interval: the user still has to estimate possible delays in the blackbox part. However, considering the various kinds of abnormal events in the whitebox part (Section 2), SafeTimer should be able to reduce timeout interval by at least tens of seconds.

Case studies. We present a few existing timeout detection protocols to show how SafeTimer models them and how they can benefit from SafeTimer.

Budhiraja et al. [5] discuss how to detect failures in primary-backup protocols, given different models. In the simplest model, which assumes clocks are sufficiently synchronized, links are reliable, and packet delay is bounded (δ), the sender can send heartbeats every τ seconds and the receiver reports a failure if it does not receive a heartbeat for $\delta + \tau$ seconds. SafeTimer can model this protocol in the following way: when the receiver receives a heartbeat at t, it creates a new interval from t to $t + \delta + \tau$ and checks whether it receives a heartbeat by the end of the new interval; the sender can define a successful heartbeat sending for interval i as sending a heartbeat at t_i and $t_i \leq t_{i-1} + \tau$. With the help of SafeTimer, this protocol may reduce δ because it does not need to include the delays of the whitebox part. This work also discusses more complicated models, which consider link failures and proposes a gossip protocol to route heartbeats through multiple links, which is adopted in Ceph. SafeTimer can model it accordingly. For example, to tolerate one link failure, the sender can define a successful heartbeat sending as sending two heartbeats to two nodes by $t_{i-1} + \tau$. Similarly, SafeTimer may help to reduce δ.

```
/* The application calls safetimer_check when
      missing heartbeats from $start_i$ to $end_i$ */
function safetimer_check($start_i$)
    send a barrier to itself
    wait for barrier (with a timeout)
    if barrier received and $t_{lastHeartbeat}$ < $start_i$
        read drop count in OS and NIC and reset to 0
        if (drop count = 0 and $t_{drop} < start_i$)
            return TRUE_FAILURE
        else if (drop count != 0)
            $t_{drop}$ = current_time()
        end
    end
    return FALSE_FAILURE

function safetimer_recv_thread()
    when receiving heartbeat
        $t_{lastHeartbeat}$ = current_time()
    when receiving barrier
        notify safetimer_check
```

Figure 2: Pseudo code of SafeTimer's receiver module. For simplicity, it assumes there is only one sender, but it can easily be extended to support multiple senders. $t_{lastHeartbeat}$ records the timestamp of the last heartbeat. t_{drop} records the timestamp of the last drop event.

In HDFS, a DataNode sends a heartbeat to the NameNode every three seconds, and the NameNode marks the DataNode as stale if it misses heartbeats for 30 seconds. In the common case, the NameNode will acknowledge a heartbeat to the DataNode; if the DataNode detects errors, it will send heartbeats more aggressively every second. SafeTimer can model it in the following way: when the receiver receives a heartbeat at t, it creates a new interval from t to $t + 30$ and checks whether it receives a heartbeat by the end of the new interval (note intervals can overlap in this case); the sender can define a successful heartbeat sending for interval i as 1) getting acknowledgement for one heartbeat or 2) sending heartbeats with an interval of less than one second. SafeTimer may help to reduce the 30-second interval because it does not need to consider delays in the whitebox part.

4 Design

SafeTimer enhances existing timeout detection protocols to tolerate long processing delays in the whitebox part. In this section, we first present SafeTimer's mechanisms and then prove its accuracy and completeness.

4.1 Accurate timeout at the receiver

As discussed in Section 3, SafeTimer assumes the application's heartbeat receiver defines multiple time intervals (interval i from $start_i$ to end_i), and reports a failure if no heartbeat is received during an interval.

SafeTimer guarantees that as long as the receiver's NIC has processed (either delivered or dropped) a heartbeat during interval i, SafeTimer's receiver module will not report a failure for interval i.

Its key idea is simple: if the receiver module does not receive any heartbeats by the end of an interval, it will check whether there are any pending or dropped heartbeats in its whitebox part, and if not, the receiver module can safely report a failure.

The key challenge, however, is how to implement this idea in modern OS. For fast packet processing, modern OS incorporates a highly concurrent design, which involves a pipeline with multiple threads in each stage. To identify whether some heartbeats are pending, a naive solution is to pause all threads and check all buffers, but this solution will have negative impact on performance and require intrusive modification to the kernel.

To solve this problem, SafeTimer incorporates a non-blocking design as shown in Figure 2: if the application does not receive any heartbeat by end_i, it will check whether any heartbeats are pending or dropped by calling *safetimer_check*, which sends a barrier packet to itself (line 3). By crafting the barrier packet and configuring the system properly, SafeTimer ensures that a barrier will follow the same execution path of heartbeats. Therefore, if the receiver module receives the barrier, it can know that any heartbeats processed by the NIC before end_i must have been processed by the OS and SafeTimer as well, either delivered to the receiver module or dropped. We will present details about how to implement the barrier mechanism in Section 5. For now, the readers can simply assume SafeTimer somehow drives the heartbeats and the barriers into a FIFO channel.

If the receiver module receives the barrier, it will check again whether it has received a heartbeat ($t_{lastHeartbeat} < start_i$ in line 5). If not, the receiver module will read drop statistics from both the OS and the NIC: if $dropcount = 0$ and $t_{drop} < start_i$ (line 7), which means there are no drops in interval i, the receiver module can safely report a failure. If the barrier is dropped as well, the receiver module will not report a failure for interval i. In this case, the application will perform the same check in the following intervals and will eventually report a failure.

4.2 Stop sender when missing heartbeat

As discussed in Section 3, SafeTimer assumes that the application has rules to decide when to send heartbeats and whether they are sent successfully. In particular, without losing generality, SafeTimer assumes for each interval i, the application defines a deadline end'_i to send heartbeats, which should be earlier than end_i at the receiver side because of clock drift and network latency.

SafeTimer guarantees that if a sender cannot successfully send heartbeats by end'_i, the sender will not be able to send out any other packets after end'_i, because the receiver may report a failure at that time. This is necessary because the accuracy property requires that if the receiver reports a failure, the sender must have failed: violating this property can cause correctness issues. Taking the primary backup protocol as an example, a backup should only become active if the primary fails. If a backup receives a failure report and becomes active while the primary is still active, there will be two active nodes, creating a classic "split brain" problem [20].

```
1  function safetimer_send_heartbeat($end'_i$, $end'_{i+1}$)
2      send heartbeats
3      if sending succeeded before $end'_i$
4          $t_{valid} = end'_{i+1}$
5      end

7  function safetimer_intercept_sending()
8      if (current_time() > $t_{valid}$)
9          drop the packet
10     else
11         perform the send
12     end
```

Figure 3: Pseudo code of SafeTimer sender module. The application defines end'_i as the deadline to send heartbeats for interval i; the application defines whether sending succeeds; SafeTimer maintains a timestamp t_{valid} to identify till when it is safe to send out packets.

Killing a sender when it is slow is not a new idea [8, 22], but how to implement it correctly despite arbitrary processing delays requires careful thought. Existing solutions ask a specific component (e.g., a watchdog [22]) to actively kill the sender. When considering arbitrary processing delays, however, such active solution is incomplete, because the delay of processing the "kill" command may allow the sender to be alive for an arbitrary amount of time, violating the accuracy property.

SafeTimer uses a passive solution by utilizing the idea of output commit [41]: a slow sender may continue processing, but as long as other nodes do not observe the effects of such processing, the slow sender is indistinguishable from a failed sender. As shown in Figure 3 (lines 3-12), SafeTimer's sender module maintains a timestamp t_{valid}, which indicates it is safe for the sender to send packets before t_{valid}. During startup, the sender sets t_{valid} to end'_0. If the sender successfully sends heartbeats for interval i, the sender extends t_{valid} to end'_{i+1} (line 4). Whenever the sender is about to send a packet, SafeTimer will compare the current time with t_{valid}: if current time is larger than t_{valid}, the sender will discard the packet (lines 7-12). Since heartbeat is blocked as well in this case, an invalid sender cannot extend t_{valid} and send packets in the future, unless with recovery operations.

Note that since the sending operation itself may take arbitrarily long, SafeTimer allows a packet generated before t_{valid} to be actually sent out after t_{valid}. This is fine because the packet is generated when the sender is still valid (i.e., when the receiver has not reported the failure).

4.3 Proof of accuracy and completeness

As discussed in Section 3, SafeTimer relies on the existing protocol to send and receive heartbeats in the blackbox part. When the existing protocol's assumptions about the blackbox part hold, we can prove that SafeTimer is accurate (i.e., never report failure for a correct node) despite arbitrary delays in the whitebox part and is complete (i.e., eventually report failure for a failed node) when the receiver does not experience slow processing or packet drops for sufficiently long. We provide the detailed proof in the appendix.

4.4 Benefit of SafeTimer

Because of the accuracy and completeness properties, the users of SafeTimer do not need to make conservative timing assumptions about the whitebox part. They do need to provide a reasonable estimation of such delay in the common case, because the sender needs some time to send out heartbeats. However, this requirement is only for performance: if the actual delay is longer than estimation, which means the sender cannot send the heartbeat in time, SafeTimer will block the sender, which may cause unnecessary recovery and hurt performance, but this will not violate accuracy. Therefore, SafeTimer only requires the user to provide a reasonable estimation to make sure such events are *rare*. As a comparison, in existing protocols, if the actual delay is longer than estimation, system correctness can be violated, and that is why existing systems require conservative assumptions so that such events *never* happen. The gap between "rare" and "never" is where SafeTimer gains its benefit.

5 Implementation

This section presents the barrier mechanism at the receiver and the packet checking at the sender in detail.

5.1 Barrier mechanism at the receiver

The goal of the barrier mechanism is to ensure that if SafeTimer's receiver module sent a barrier to itself at t and received it later, then all heartbeats delivered by NIC before t must have been either delivered to the application or dropped. Achieving this property would be trivial if the OS processes all packets in FIFO order, but unfortunately, this is not true in modern OS. To illustrate the problem and motivate our design, we first present how Linux processes incoming packets.

Background. As shown in Figure 4, Linux incorporates a multi-stage pipeline to process incoming packets.

At the lowest level, an NIC buffers incoming packets in its RX queues and tries to transfer them to kernel's ring buffers: if the ring buffer has empty slots, the NIC will transfer the packet using DMA and fire an interrupt; if the buffer is full, the NIC will retry and may drop packets. For efficiency, modern NIC and Linux incorporate the Receive Side Scaling (RSS) technique [40] to allow parallel packet processing: the NIC creates multiple RX queues and the kernel creates an equal number of ring buffers so that each RX queue is mapped to a unique ring. Furthermore, Linux assigns a unique interrupt request (IRQ) number to each RX queue so that Linux can handle interrupts from different RX queues in parallel.

For efficiency, Linux separates interrupt handling into two parts—hard IRQ and soft IRQ—and invokes hard IRQ first. For an NIC interrupt, its hard IRQ simply sets some registers and triggers a soft IRQ. The soft IRQ reads packets from the ring buffer and executes the logic of the networking protocol, such as TCP/IP. The RSS technique allows Linux to handle IRQs in parallel.

By default, the soft IRQ reads from the ring buffer and executes the protocol logic within a single critical section protected by the lock of the ring. For more parallelism, Linux incorporates the Receive Packet Steering (RPS) technique [40]: when RPS is enabled, a soft IRQ reads a packet from the ring, puts it into a buffer called *backlog*, and then releases the lock of the ring. A separate thread, which may run on another CPU, will retrieve packets from the backlog and execute the protocol logic.

Finally the soft IRQ puts packets into socket buffers and the user-space threads may read from these buffers in parallel.

Such a multi-stage pipeline may re-order packets. Modern NIC and Linux preserve FIFO order for TCP packets with the same (sender IP, sender port, destination IP, destination port) and UDP packets with the same (sender IP, destination IP), by directing packets with same such information to the same RX queue, backlog and socket buffer. For SafeTimer, such guarantee is not enough since heartbeats and barriers are from different senders.

Overview of SafeTimer's solution. Our implementation is driven by three principles: 1) for portability, we hope to minimize modification to OS kernel code; 2) for performance, it should not incur significant overhead; 3) for portability, we hope to minimize dependence on specific NIC features or modification to NIC drivers.

As shown in Figure 4, SafeTimer re-directs heartbeats and barriers to a separate FIFO queue (called STQueue) early in the pipeline, so that they are not affected by re-ordering in later stages. However, since the earliest place we can perform such re-direction is after the soft IRQ reads the packets, RSS technique in the earlier stage may still re-order packets from different ring buffers. To solve this problem, SafeTimer sends a barrier packet to each RX queue/ring. If all of them later go through the

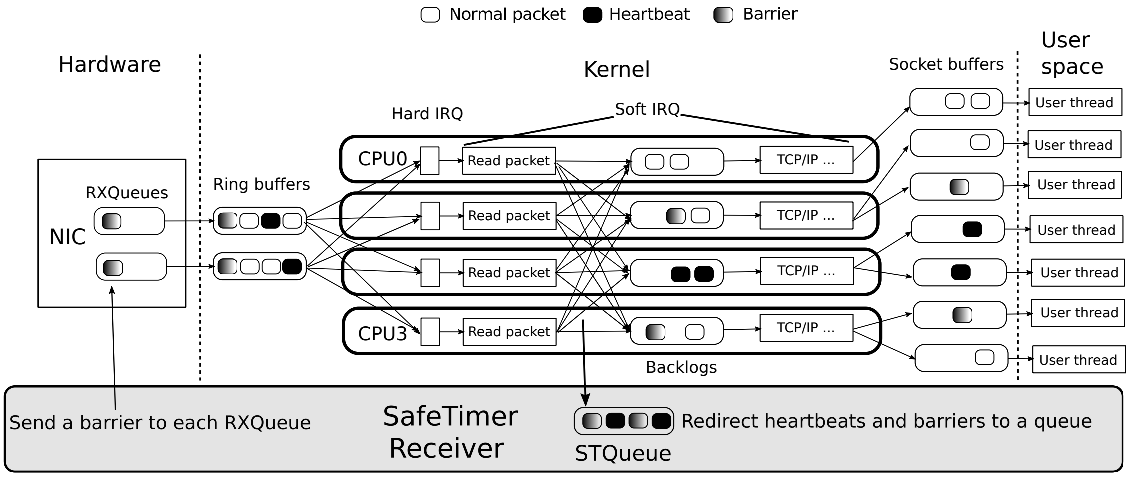

Figure 4: Barrier mechanism at the receiver. The algorithm in Figure 2 reads from STQueue.

STQueue, SafeTimer can know that all previous heartbeats are processed. The key to the correctness of this approach is that a soft IRQ needs to grab the lock of the ring buffer when reading a packet from the ring, and thus packets from each ring are read in a FIFO manner. As long as SafeTimer re-directs a packet before the soft IRQ releases the lock, such per-ring FIFO order will be retained in the STQueue. Therefore, when SafeTimer retrieves a barrier from the STQueue, it knows all previous heartbeats from the same ring must have been processed.

Next we present each step in detail.

Forcing a barrier to go through NIC. SafeTimer requires a barrier packet to follow the same execution path of a heartbeat packet. Putting a barrier in the ring buffer does not work because the OS won't read from the buffer until an NIC interrupt is triggered. Therefore, SafeTimer receiver forces the barrier packet to go through its NIC. This task, however, is challenging for multiple reasons.

First, Linux has the loopback optimization to route a local packet by memory copy instead of sending it to the NIC. SafeTimer bypasses this optimization by sending the barrier directly to the device driver. This approach, however, creates a new problem: the NIC will actually send the packet to the router. To prevent loops, routing protocols usually have a constraint that a router should never forward a packet to the port where the packet is received. Therefore, the router will drop a barrier packet, whose destination and source are the same.

Our prototype uses an NIC with two ports and sends a barrier from one port to the other, which eliminates the above problem. This solution requires the receiver to have at least two links to the router, but considering the fact that redundant links are already widely used for fault tolerance, such requirement often does not incur additional cost. If redundant link is not available, another alternative is to use the virtual LAN (vLAN) technique to virtualize a physical port into two virtual ports [47].

Sending a barrier to a specific RX queue. A few NICs provide the "N-tuple filter" feature to direct packets to specified RX queues, which makes this problem trivial. However, we find this feature is not common so far [21]. Most NICs calculate a hash value based on the IPs and ports information in a packet and then direct the packet to an RX queue based on the hash value. Therefore, we propose a general solution based on the assumption that one cannot control which RX queue a packet is directed to, but packets with same IPs and ports will always be directed to the same RX queue.

SafeTimer uses a brute-force search approach: during initialization, its receiver module sends barriers with different sender ports to its NIC to see which RX queue they are directed to, until SafeTimer can find a port for each RX queue. Since usually there are not many RX queues, such procedure could finish quickly. The challenge, however, is how to know which RX queue (represented by its IRQ number) a packet is directed to. SafeTimer uses netfilter [39], which is a tool provided by Linux, to intercept soft IRQ functions to check whether a packet is a barrier, but soft IRQ functions do not carry the IRQ number of the RX queue. We can modify the driver to pass the IRQ number to the soft IRQ, but this violates our principle to minimize driver-specific modifications.

To solve this problem, we leverage the *irq-cpu affinity* configuration provided by Linux, which can configure the mapping between RX queues and CPUs during RSS. By default, it is configured to be an all-to-all mapping, which means any CPU can execute any IRQ to read from its corresponding RX queue/ring, but Linux also allows one-to-one mapping. We leverage this option to "test" whether a barrier is sent to a specific IRQ *i*: we map IRQ *i* to CPU 0 and the other IRQs to the remaining CPUs arbitrarily. When intercepting the soft IRQ function, Safe-

Timer reads the CPU ID: if the packet is a barrier and the IRQ function is run on CPU 0, we can know the barrier must be sent to IRQ *i*; otherwise, SafeTimer tests a different *i* until it can find the right one.

Note that since the NIC always directs packets with same IPs and ports to the same RX queue, we only need to run the inferring procedure once for one machine. Afterwards we can use all-to-all mapping for efficiency.

Re-directing packets to STQueue. As shown in Figure 4, SafeTimer re-directs heartbeats and barriers to a FIFO STQueue after packets are read.

To implement this functionality, SafeTimer uses *netfilter* to hook the *ip_local_deliver* function, and configures iptable to re-direct heartbeats and barriers to a FIFO netfilter queue, which is called STQueue in SafeTimer. SafeTimer hooks *ip_local_deliver* because this is the earliest point packets can be re-directed in *netfilter*. SafeTimer sends heartbeats and barriers to specific ports so that they can be efficiently distinguished from normal packets.

This approach, however, is not fully correct when RPS is enabled: recall that when RPS is enabled, a soft IRQ will put a packet into the backlog and then releases the lock of the ring. In this case, *ip_local_deliver* is called after the lock is released and thus re-direction may not preserve the order of packets from the corresponding ring. To solve this problem, we use kretprobe [33] to intercept *get_rps_cpu* to return -1 for heartbeats and barriers: doing so essentially disables RPS for heartbeats and barriers. As a result, the re-direction will be executed under the protection of the lock of each ring and thus STQueue will preserve the order of packets from each ring. Normal packets, however, are not affected.

The timeout detection protocol (Figure 2) always reads heartbeats and barriers from the STQueue. However, SafeTimer does not remove heartbeats and barriers from later stages of the pipeline, because the OS needs to execute the logic of the network protocol, like congestion control or sending acknowledgements in TCP.

Reading drop count. SafeTimer's receiver module needs to read packet drop counts from both the OS and the NIC. Linux and most NICs have provided such statistics, but their implementation cannot achieve our goal.

In Linux, the NIC device driver periodically reads the drop count from the NIC, which can be fetched by reading /proc files system or using tools such as ethtool. Periodic reading means such statistics may be stale, which can cause SafeTimer's receiver module to miss recent drops and generate a false failure report. To make things worse, the NIC will reset drop count to 0 after it is read, so even if SafeTimer reads the drop count directly from the NIC, it may still get inaccurate results. To solve this problem, SafeTimer reads drop count from the NIC and then merges it with the number reported by the NIC driver. This is the only place SafeTimer requires modification to device drivers and OS kernel.

5.2 Blocking slow sender

As shown in Figure 3, SafeTimer's sender module blocks the sender if it cannot deliver heartbeats to the NIC in time. However, when sending a packet, Linux does not notify users whether or not the packet is delivered to the NIC successfully. Instead, it may write the packet to a buffer, return to the user, and send the packet to the NIC later, which may fail. To solve this problem, we use *kprobe* to intercept the function that the NIC driver invokes to reclaim resources after transmission is complete (e.g., *napi_consume_skb* or *__dev_kfree_skb_any*). As shown in Figure 3, SafeTimer applies the rules of the existing timeout detection protocol to check whether heartbeats are sent successfully. If so, SafeTimer's sender module will update t_{valid}. To block invalid packets, we use *netfilter* to intercept the *ip_output* function: if current time is larger than t_{valid}, the packet will be dropped.

Because of the processing delay, SafeTimer cannot get the exact time when a packet is sent. Instead, SafeTimer conservatively uses the timestamp after sending a packet, t_{after}: when checking whether a heartbeat is sent before end_i^{l} (line 3 in Figure 3), SafeTimer compares t_{after} with end_i^{l}. Such conservative approach ensures a sender failing to send heartbeats in time must be blocked, but it may also block a sender that has sent heartbeats in time, which is unnecessary but does not violate accuracy. Previous works have discussed how to minimize the impact of such unnecessary killing [38].

Since a slow sender process may communicate with other processes on the same machine, SafeTimer needs to block those processes as well, and thus it provides two blocking modes: the first blocks all processes on a machine; the second blocks only the sender process if the user is sure it does not communicate with other processes. Automatically tracking the information flow among different processes is out of the scope of this paper.

5.3 Supporting virtual machine

To maximize the benefit of SafeTimer in a virtual machine architecture, we could implement SafeTimer in the host OS or hypervisor and provide related functions to applications using hypercalls or remote procedure calls. By doing so, we can model the host OS or hypervisor as a whitebox. We plan to implement such support in the future. However, if the user has no control of the host OS or hypervisor, he/she can still deploy SafeTimer to the guest OS and model the host OS/hypervisor as a blackbox, but this approach of course loses the ability to tolerate long delays in the host OS/hypervisor.

6 Evaluation

Our evaluation tries to answer three questions:

- What is the overhead of SafeTimer?
- Can SafeTimer achieve the expected accuracy property, despite long delays in the OS and the application?
- How much effort does it take to apply SafeTimer to existing systems?

To answer the first question, we have evaluated SafeTimer with a performance benchmark, which can send packets with different sizes, and compared its throughput and latency to those without SafeTimer. For the blackbox part, we use a simple protocol that sends heartbeats periodically with a configurable interval.

To answer the second question, we have injected long delays and packet drops at different layers at both the sender and the receiver to observe whether SafeTimer can prevent false failure report. Of course, this is by no means a complete test: we have proved the accuracy of SafeTimer in the appendix. This set of experiments serves as a sanity check about whether our implementation has actually achieved the expected properties.

To answer the third question, we have applied SafeTimer to HDFS and Ceph to enhance their timeout detection protocols and report our experience.

Testbed setting. We ran all experiments on CloudLab [15]. Each machine is equipped with two Intel Xeon E5-2630 8-core CPUs, 128GB of memory, 1.2 TB of SAS HDD, and a dual-port Intel X520-DA2 10Gb NIC. All machines are connected to a Cisco Nexus C3172PQs switch. Linux 4.4.0 is installed on all machines.

6.1 Overhead

SafeTimer incurs overhead for each packet at both the sender and the receiver: SafeTimer's sender module compares current time with t_{valid} before sending each packet; SafeTimer's receiver module re-directs heartbeats and barriers to the STQueue. To know whether a packet is a heartbeat or a barrier, the receiver module checks the destination port of each packet. When a sender fails, SafeTimer performs additional operations to block the sender, send barriers, and read drop counts, but since failure is rare, we focus on overhead in the failure-free case.

Since SafeTimer incurs overhead for each packet, such overhead should be relatively higher for workloads with smaller packets and thus we measure the overhead of SafeTimer with different packet sizes. However, TCP may merge small packets in the same connection and thus affect our experiment results. To prevent such effect, we use a ping-pong benchmark as suggested in a previous work [2]: we create multiple sender threads at the sender, each creating a connection to the receiver. The sender thread sends a packet to the receiver and waits for the receiver to forward the packet back. In this case, since each connection has only one outstanding packet, TCP has no chance to merge packets. To increase load, we can increase the number of sender threads.

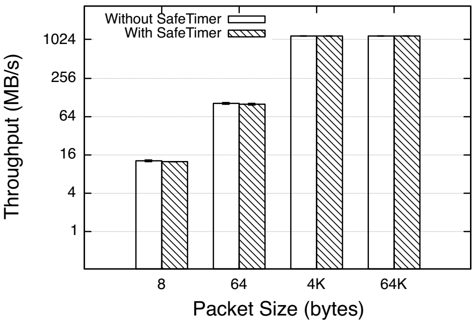

Figure 5: Throughput of the ping-pong benchmark with and without SafeTimer.

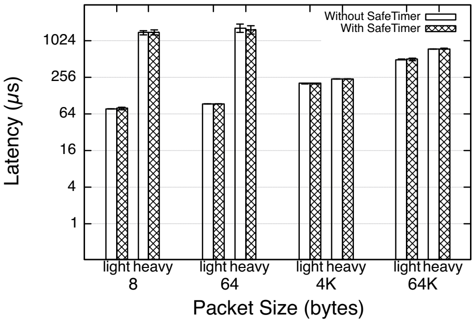

Figure 6: 99 percentile latency of the ping-pong benchmark with and without SafeTimer.

To measure the overhead of SafeTimer, we apply SafeTimer to the ping-pong benchmark and measure how it affects throughput and latency. To measure the maximal throughput, we increase the number of sender threads till we cannot gain higher throughput. To measure the latency, we run experiments under two loads: a light load of about 40% of the maximal throughput and a heavy load of about 90% of the maximal throughput. We do not measure the latency under the maximal throughput because in this case, the latency will be dominated by queuing delay. We run each setting 20 times to compute the average and standard deviation. We set the timeout interval of the blackbox part to be one second.

As shown in Figures 5 and 6, SafeTimer's overhead is small: for 4KB and 64KB packets, the overhead is less than 1%; for 8B and 64B packets, SafeTimer can

Node	Instrument Position	Injected Event	SafeTimer	Vanilla
Receiver	System call (recv)	Delay	No timeout	Timeout
Receiver	Socket (sock_queue_rcv_skb)	Delay/Drop	No timeout	Timeout
Receiver	NFQueue (nfqnl_enqueue_packet)	Delay/Drop	No timeout	N/A
Receiver	IP (ip_rcv)	Delay	No timeout	Timeout
Receiver	RPS (enqueue_to_backlog)	Delay/Drop	No timeout	Timeout
Receiver	Ethernet (napi_gro_receive)	Delay	No timeout	Timeout
Sender	System call (send)	Delay	Blocked	Alive
Sender	Socket (sock_sendmsg)	Delay	Blocked	Alive
Sender	IP (ip_output)	Delay/Drop	Blocked	Alive. Can observe drop.
Sender	Ethernet (dev_queue_xmit)	Delay	Blocked	Alive

Table 1: Verifying accuracy of SafeTimer by injecting long delay or packet drops. Gray cells indicate injection in kernel. N/A means this test case does not apply.

increase 99p latency by 0.7% to 2.7% and decrease throughput by 1.6% to 2.4%. Such low overhead is reasonable because SafeTimer's additional work (i.e., comparing t_{valid} at the sender and reading destination port at the receiver) is small compared to other work the OS has to perform for each packet (e.g., interrupt handling, memory copy). To confirm the result, we run the same benchmark on another set of machines on CloudLab (m510 [16]) with different NICs (Mellanox ConnectX-3 10G) and we find the overhead of SafeTimer is similar.

6.2 Accuracy

Although we have proved the accuracy of SafeTimer, we hope to sanity check whether our implementation has achieved the expected property. For this purpose, we inject long delays and packet drops at different layers at the sender and the receiver. We compare SafeTimer to a vanilla timeout implementation, which has a user thread to periodically send heartbeats at the sender and a user thread to periodically check timeout at the receiver.

Table 1 summarizes the events we injected and how SafeTimer responds to these events. We inject long delays at all positions but only inject drops if the corresponding function can actually drop packets. In these experiments, we set timeout interval to be one second and inject a delay of two seconds. As shown in the table, SafeTimer correctly prevents false failure report at the receiver and blocks the sender in all cases. The vanilla implementation, however, violates accuracy in almost all cases except when a heartbeat is dropped in *ip_output*: in this case, the sender receives an error and can retry.

6.3 Case studies

To evaluate how much effort it takes to apply SafeTimer to real-world applications and its performance overhead, we have applied SafeTimer to HDFS [45] and Ceph [9].

APIs of SafeTimer. At the sender side, SafeTimer provides two APIs: *safetimer_send_HB* to send a heartbeat and check whether it is delivered to the NIC in time; *safetimer_extend* to extend the *t_valid* value. At the receiver side, SafeTimer provides one API: *safetimer_check* to check whether it is safe to report a failure.

HDFS. In HDFS, a DataNode needs to periodically send a heartbeat to the NameNode and if the NameNode misses a number of consecutive heartbeats, the NameNode will mark the DataNode as "stale".

We modified one line of code in NameNode's *isStale* function, which checks whether heartbeats are missing for a DataNode, to perform the additional *safetimer_check*. We modified six lines of code in DataNode to use SafeTimer's APIs to send heartbeats and check whether heartbeats are sent in time. To simplify modification, we do not remove HDFS' original heartbeat mechanism: this leads to duplicate heartbeats but during our experiments, the overhead is negligible.

We killed a DataNode and found the NameNode can correctly mark a failed DataNode as stale. We have measured the performance of an HDFS deployment with three DataNodes by using Hadoop's built-in benchmark tool DFSIO. We ran each experiment five times. Without SafeTimer, DFSIO can achieve a write throughput of 203 MB/s (stdev 12.6) and a read throughput of 627 MB/s (stdev 18.4); with SafeTimer, it can achieve a write throughput of 206 MB/s (stdev 5.5) and a read throughput of 632 MB/s (stdev 8.4). The difference is not statistically significant.

Ceph. In Ceph, an Object Storage Daemon (OSD) sends heartbeats to its two peers every 6 seconds and if they can't receive the heartbeat for 20 seconds, they will send a failure report to the Monitor, which will consider the OSD as failed if receiving two reports.

In this mechanism, an OSD is both the sender and receiver of heartbeats. We modified two lines of code in OSD's *heartbeat_check* function to perform the *safetimer_check* before sending the failure report; we modified five lines of code to use SafeTimer's APIs to send heartbeats and check whether heartbeats are sent in time.

We killed an OSD and found the Monitor can mark it as down. We have measured the performance of a Ceph deployment with three OSDs by using Ceph's inbuit benchmark tool RADOS. We ran each experiment five times. Without SafeTimer, RADOS can achieve a bandwidth of 43.3 MB/s (stdev 1.6); with SafeTimer, it can achieve a bandwidth of 42.2 MB/s (stdev 1.1). The difference is not statistically significant.

7 Related work

Chandra et al. show that many classic problems in distributed system, such as consensus, can be solved with an accurate and complete failure detector [12]. In practice, timeout is widely used for failure detection, whose accuracy depends on their timing assumptions.

Synchronous systems. Under synchronous assumptions (i.e., delay of message transfer and clock deviation are bounded [12]), timeout can achieve both accuracy and completeness for failure detection. Many systems like primary-backup replication and HDFS [4, 5, 18, 24, 45] work under this assumption. To guarantee accuracy, these systems must make conservative assumptions about message delay and clock deviation. Previous works have tried to improve its accuracy by estimating the upper bound adaptively at runtime [3] and by killing a node if the failure detector reports the node has failed [8, 22]. SafeTimer can enhance synchronous systems to tolerate abnormal events in the OS and the application, without requiring any timing assumptions.

Asynchronous systems. Under asynchronous assumptions (i.e., delay of message transfer and clock deviation are unbounded), building a failure detector that is both accurate and complete is proved to be impossible [23]. Paxos [34, 35, 42] is a replication protocol designed for asynchronous environments: it is always correct (i.e., all correct replicas process the same sequence of requests) and is live (i.e., the system can make progress) when the environment is synchronous for sufficiently long. Paxos is used as building blocks in larger systems like Spanner [17] and Microsoft Azure Storage [7]. Compared to synchronous replication systems, Paxos is more expensive in terms of number of replicas and messages. Asynchronous systems don't need accurate failure detection for correctness, but since there is a cost to recover a failure, SafeTimer may help to reduce such unnecessary recovery by reducing the number of false failure reports.

Lease systems. A number of systems [1, 13] install a replicated lease manager (e.g., Chubby [6] and ZooKeeper [29]): a server needs to acquire a lease from the lease manager before it can service clients; the server has to renew the lease before it expires, and if not successful, the server will stop servicing clients. For accuracy, this approach requires the clock speed of servers and the lease manager to be sufficiently close, but it does not require the delay of message transfer to be bounded. Lease systems strike a balance between cost and timing assumptions, but it has its own limitations: first, the centralized nature of the lease manager means if a long delay happens at the lease manager, all leases will expire and all servers will stop servicing, which does not violate the accuracy property, but is certainly undesirable. As a result, lease systems prefer coarse-grained leases [6], which hurts system availability as well, similar as using a long timeout. Second, the requirement of a replicated lease manager makes it less desirable in small-scale systems. Systems using leases can benefit from SafeTimer by installing its sender module to ensure a server will not continue servicing after its lease expires.

Failure detection without timeout. A few systems implement a failure detector without using timeout. For example, Falcon [38] and its following works [36, 37] install probes in routers to monitor servers and install probes at different layers in a server to monitor upper layers. This approach essentially converts the whole communication channel into a white box. As a result, it requires intrusive modification to the routing layer, which makes its deployment challenging and sometimes impossible if the routers are out of the control of the user. To solve these problems, Falcon uses timeout as a backup.

Real-time OS. Real-time Linux [43] and other real-time frameworks for Linux such as RTAI [44] and Xenomai [49] can guarantee important tasks or interrupts are scheduled before given deadlines. However, this is not sufficient to achieve our goal, because long delay is not only caused by untimely scheduling, but also caused by the fact that an important task is occasionally blocked by a heavy task (Section 2). Real-time scheduling can address the former problem, but not the latter one.

8 Conclusion

This paper shows that we do not need to include the maximal local processing delay in timeout interval. Because of the whitebox nature of local processing, we can build efficient and accurate failure detection for this part, despite arbitrary processing delays. Our prototype SafeTimer allows one to use a shorter timeout to improve system availability, without sacrificing accuracy.

A Appendix: Proof of accuracy and completeness

Assumption of the blackbox part. *The existing protocol can guarantee that if a sender has successfully sent heartbeats for interval i, at least one of the heartbeats will be processed (either delivered to the OS or dropped) by the receiver's NIC by end_i.*

Theorem A.1. *(Accuracy) If SafeTimer's receiver module reports a failure at time t, the sender will not be able to send any packets generated after t.*

Proof. As shown in the protocol, SafeTimer's receiver module reports a failure for interval i if two conditions are both satisfied: first, the receiver module has received the barrier but not any heartbeats for interval i. Because the barrier is sent after end_i and because of the barrier's semantic, any heartbeats processed by the NIC before end_i must either have been delivered to the receiver module or have been dropped. Since the receiver module has not received any heartbeats, we can conclude that it is either because the NIC has not processed any heartbeat by end_i or because some heartbeats are dropped at the receiver side.

The second condition is $dropcount = 0$ and $t_{drop} < start_i$, which means there are no packet drops at the receiver side in interval i. By combining this condition with the first one, we can conclude that the receiver's NIC must have not processed any heartbeat packets for interval i before end_i. This means the sender must have not successfully sent the heartbeats for interval i (Assumption of the blackbox). In this case, the sender will not extend its $t_{valid} = end_i'$, and thus will stop sending any messages after t_{valid}.

Since t is larger than end_i and $t_{valid} = end_i'$ at the sender should be earlier than end_i at the receiver, we can conclude that $t_{valid} < end_i < t$ and thus the sender will not send any packets generated after t. □

Theorem A.2. *(Completeness) If the sender has failed, SafeTimer's receiver module will eventually report a failure if the following two conditions both hold for sufficiently long (five consecutive intervals in the worst case): 1) the receiver's processing speed is normal, which means events (e.g., heartbeat, barrier, and reading drop count) generated before or during an interval can be handled by the end of the interval; 2) the receiver does not experince any packet drops.*

Proof. Suppose the sender fails to send heartbeats in interval i, and afterwards, there are five consecutive intervals j to $j+4$ ($j > i$) during which the receiver's processing speed is normal and the receiver does not experience any packet drops.

Since the receiver's processing speed is normal in interval j, the receiver should be able to handle all delayed heartbeats from the sender, if any, by the end of interval j, which means the receiver won't receive any heartbeats in interval $j+1$. Therefore, the receiver will send a barrier at the end of interval $j+1$. Since the receiver's processing speed is normal and there are no packet drops in interval $j+2$, the receiver will receive the barrier and read drop count by the end of interval $j+2$. If drop count is 0 (t_{drop} must be smaller than $start_{j+2}$ because the receiver does not read drop count in interval $j+1$), the receiver will report the failure; otherwise, the receiver will update t_{drop} (the new t_{drop} must be smaller than $start_{j+3}$) and repeat the above procedure. At the end of interval $j+3$, the receiver must report a failure because both conditions to report a failure can be met: 1) since the processing speed is normal and there are no packet drops in interval $j+4$, the receiver can receive the barrier for $j+3$ but it cannot receive any heartbeats; 2) drop count is 0 because there are no packet drops in interval $j+3$ and $j+4$; $t_{drop} < start_{j+3}$. □

Note that five intervals are the worst case: if previously there are no delayed heartbeats or packet drops, the receiver will report the failure after one interval.

Improving Service Availability of Cloud Systems by Predicting Disk Error

Abstract

High service availability is crucial for cloud systems. A typical cloud system uses a large number of physical hard disk drives. Disk errors are one of the most important reasons that lead to service unavailability. Disk error (such as sector error and latency error) can be seen as a form of gray failure, which are fairly subtle failures that are hard to be detected, even when applications are afflicted by them. In this paper, we propose to predict disk errors proactively before they cause more severe damage to the cloud system. The ability to predict faulty disks enables the live migration of existing virtual machines and allocation of new virtual machines to the healthy disks, therefore improving service availability. To build an accurate online prediction model, we utilize both disk-level sensor (SMART) data as well as system-level signals. We develop a cost-sensitive ranking-based machine learning model that can learn the characteristics of faulty disks in the past and rank the disks based on their error-proneness in the near future. We evaluate our approach using real-world data collected from a production cloud system. The results confirm that the proposed approach is effective and outperforms related methods. Furthermore, we have successfully applied the proposed approach to improve service availability of Microsoft Azure.

1 Introduction

In recent years, software applications are increasingly deployed as online services on cloud computing platforms, such as Microsoft Azure, Google Cloud, and Amazon AWS. As cloud service could be used by millions of users around the world on a 24/7 basis, high availability has become essential to the cloud-based services. Although many cloud service providers target at a high service availability (such as 99.999%), in reality, service could still fail and cause great user dissatisfaction and revenue loss. For example, according to a study conducted on 63 data center organizations in the U.S, the average cost of downtime has steadily increased from $505,502 in 2010 to $740,357 in 2016 (or a 38 percent net change) [33].

Various software, hardware, or network related problems may occur in a cloud system. Our experience with Microsoft Azure shows that disk problem is the most severe one among hardware issues. A typical cloud system like Azure uses hundreds of millions of hard disk drives. Disk-related problem has become one of the most significant factors that contribute to the service downtime. The importance of disk problem is also observed by researchers in Facebook and Google, who reported that 20-57% of disks experience at least one sector error in datasets collected over 4-6 years [27, 35].

To improve service availability, many proactive disk failure prediction approaches have been proposed [18, 31, 32, 42, 41]. These approaches train a prediction model from historical disk failure data, and use the trained model to predict if a disk will fail (i.e., whether a disk will be operational or not) in near future. Proactive actions, such as replacement of failure-prone disks, can then be taken. The prediction model is mainly built using the SMART [1] data, which is disk-level sensor data provided by firmware embedded in disk drives.

The existing approaches focus on predicting *complete disk failure* (i.e., disk operational/not operational). However, in a cloud environment, before complete disk failure, upper-layer services could already be affected by *disk errors* (such as latency errors, timeout errors, and sector errors). The symptoms include file operation errors, VM not responding to communication requests, etc. Disk errors can be seen as a form of *gray failure* [22], which are fairly subtle failures that can defy quick and definitive detection by a conventional system failure detector, even when applications are afflicted by them. Gunawi et al. also pointed out the impact of fail-slow hardware that is still functional but in a degraded mode [20].

If no actions are taken, more severe problems or even service interruptions may occur. Therefore, we advocate that it is important to predict disk errors so that proactive measures can be taken before more severe damage to the service systems incur. The proactive measures include error-aware VM allocation (allocating VMs to healthier disks), live VM migration (moving a VM from a faulty disk to a health one), etc. In this way, service availability can be improved by predicting disk errors.

In this paper, we develop an online prediction algorithm for predicting disk errors, aiming at improving service availability of a cloud service system. We find that disk errors can be often reflected by system-level signals such as OS events. Our approach, called CDEF (stands for Cloud Disk Error Forecasting), incorporates both SMART data and system-level signals. It utilizes machine learning algorithms to train a prediction model using historical data, and then use the built model to predict the faulty disks. We design the prediction model to have the following abilities:

- Be able to rank all disks according to the degree of error-proneness so that the service systems can allocate a VM to a much healthier one.

- Be able to identify a set of faulty disks from which the hosted VMs should be live migrated out, under the constrains of cost and capacity.

However, it is challenging to develop an accurate disk error prediction model for a production cloud system. We have identified the following challenges:

1. In real-world cloud service systems, the extremely imbalanced data make prediction much more difficult. In average, only about 300 out 1,000,000 disks could become faulty every day. We need to identify the faulty disks and be careful not to predict a healthy disk as faulty. In our work, we propose a cost-sensitive ranking model to address this challenge. We rank the disks according to their error-proneness, and identify the faulty ones by minimizing the total cost. Using the cost-sensitive ranking model, we only focus on identifying the top *r* most error-prone disks, instead of classifying all faulty disks. In this way, we mitigate the extreme imbalance problem.

2. Some features, especially system-level signals, are time-sensitive (their values keep changing drastically over time) or environment-sensitive (their data distribution would significantly change due to the ever-changing cloud environment). We have found that models built using these unstable features may lead to good results in cross-validation (randomly dividing data into training and testing sets) but perform poorly in real-world online prediction (dividing data into training and testing sets by time). We will elaborate this challenge in Section 2.2. To address this challenge, we perform systematic feature engineering and propose a novel feature selection method for selecting stable and predictive features.

We evaluate our approach using real-world data collected from a production cloud system in Microsoft. The results show that CDEF is effective in predicting disk errors and outperforms the baseline methods. We have also successfully applied CDEF in industrial practice. In average, we successfully reduce around 63k minutes of VM downtime of Microsoft Azure per month.

In summary, we make the following contributions in this paper:

- We propose CDEF, a disk error prediction method. In CDEF, we consider both system-level signals and disk-level SMART attributes. We also design a novel feature selection model for selecting predictive features and a cost-sensitive ranking model for ranking disks according to their error-proneness.

- We have successfully applied CDEF to Azure, a production cloud system in Microsoft. The results prove the effectiveness of CDEF in improving service availability in industrial practice. We also share the lessons learned from our industrial practice.

The rest of this paper is organized as follows: In Section 2, we introduce the background and motivation of our work. Section 3 describes the proposed approach and detailed algorithms. The evaluation of our approach is described in Section 4. We also discuss the results and present the threats to validity. In Section 5, we share our experience obtained from industrial practice. The related work and conclusion are presented in Section 6 and Section 7, respectively.

2 Background and Motivation

2.1 Disk Error Prediction

A cloud system such as Microsoft Azure contains hundreds of millions of disks serving various kinds of services and applications. Disks are mainly used in two kinds of clusters, clusters for data storage and clusters for cloud applications. For the former of clusters, redundancy mechanisms such as RAID [30] could tolerate disk failures well. The latter form of clusters hosts a tremendous amount of virtual machines, disk errors could bring undesirable disruptions to the services and applications. In this paper, we focus on the disks used in the cloud application cluster.

For cloud systems such as Microsoft Azure, Amazon AWS, and Google Cloud, service problems can lead to great revenue loss and user dissatisfaction. Hence, in today's practice, the service providers have made every effort to improve service availability. For example, from "four nines" (99.99%) to "five nines" (99.999%), and then to "six niness"(99.9999%). Disks are among the most frequently failing components in a cloud environment and have attracted much attentions from both academia and industry. For example, BackBlaze publishes quarterly reports and the underlying data for users to keep track of reliability of popular hard drives in the market. In their data, disk failure is labelled *0 if the drive is OK, and 1 if this is the last day the drive was operational before failing* [2].

To mitigate cost incurred by disk failures, researchers have proposed to automatically predict the occurrence of disk failure before it actually happens. In this way, proactive measures, such as disk replacement, can be taken. Disk failure prediction has been a hot subject of study. Existing work [9, 18, 31, 32, 41, 42] mostly use the SMART data (Self-Monitoring, Analysis and Reporting Technology, which monitors internal attributes of individual disks) to build a disk failure prediction model.

However, before a disk completely fails, it already started reporting errors. There are various disk errors such as disk partition errors (disk volumes and volume size become abnormal), latency errors (unexpected long delay between a request for data and the return of the data), timeout errors (exceeding the predefined disk timeout value), and sector errors (individual sectors on a drive become unavailable), etc. Disk failures can be detected by a conventional system failure detection mechanisms. These mechanisms often assume an overly simple failure model in which a component is either correct or failed. However, such mechanisms are inadequate to deal with disk errors as they are subtle *gray failures* [22]. In our practice, the disk error data is obtained through root cause analysis of service issues performed by field engineers.

Disk errors are common. For example, a study by Bairavasundaram et al. [8] reports that 5-20% of hard disk drives in Netapps storage systems report sector errors over a period of 24 months. The disk errors can affect the normal operations of upper-layer applications and can be captured by unexpected VM downtime. The symptoms include I/O requests timeout, VM or container not responding to communication requests, etc. If no actions are taken, more severe problems or even service interruptions may occur. Therefore, it is important that disk errors to be captured and predicted before the virtual machines get affected.

2.2 Challenges

In this work, we propose to predict the error-proneness of a disk based on the analysis of historical data. The ability to predict disk error can help improve service availability from the following two aspects:

- VM allocation, which is the process of allocating a VM (virtual machine) to a host. To enable more effective VM allocation, we can proactively allocate VMs to a host with a healthier disk rather than to a host with a faulty disk.
- Live migration, which is the process of moving a running VM among hosts without disconnecting the client or application. To enable more effective live migration, we can proactively migrate VMs from a host with a faulty disk to a host with healthy disks.

To achieve so, we can build a prediction model based on historical disk error data using machine learning techniques, and then use the model to predict the likelihood of a disk having errors in the near future. There are several main technical challenges in designing the disk error prediction model for a large-scale cloud:

Extremely imbalanced data: For a large-scale cloud service system such as Microsoft Azure, each day, at most only 3 disk in ten thousand disks could become faulty. The extreme 3-in-10,000 imbalanced ratio poses difficulties in training a classification model. Fed with such imbalanced data, a naive classification model could attempt to judge all disks to be healthy, because in this way, it has the lowest probability of making a wrong guess. Some approaches apply data re-balancing techniques, such as over sampling and under sampling techniques, to address this challenge. These approaches help raise the recall, but at the same time could introduce a large number of false positives, which dramatically decrease the precision. In our scenario, the cost of false positives is high as the cost of VM migration is inneglectable and the cloud capacity may be affected by the false positives.

Online prediction: Existing work [9, 26] usually deals with prediction problem in a cross-validation manner. However, we found that it is inappropriate for evaluating our disk error prediction model. In cross validation, the dataset is randomly divided into training and testing set. Therefore, it is possible that the training set contains parts of future data, and testing set contains parts of past data. However, when it comes to online prediction (using historical data to train a model and predict future), training and testing data will have no time overlap. Besides, some data, especially system-level signals, are time-sensitive (their values keep changing drastically over time) or environment-sensitive (their data distribution could change due to the ever-changing cloud envi-

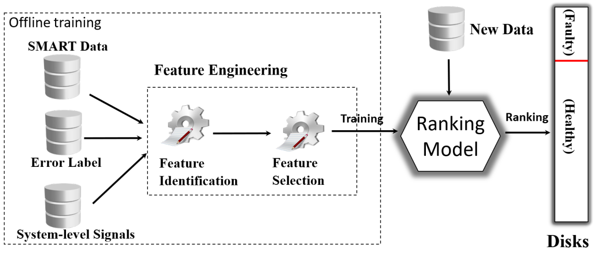

Figure 1: The overview of the proposed approach

ronment). For example, a rack encounters an outage at time t, all disks on it will experience such a change at the same time. Using cross validation, the environment-specific knowledge can spread to both training set and testing set due to random splitting. The knowledge learned from the training set could be applied to the testing set, which causes high accuracy in cross validation but poor result when evaluating new data.

Therefore, to construct an effective prediction model in practice, we should use online prediction instead of cross-validation: the future knowledge should not be known at the time of prediction.

3 Proposed Approach

In this section, we present CDEF (Cloud Disk Error Forecasting), our proposed approach that can improve service availability by predicting disk errors. Figure 2 shows the overview of CDEF. First, we collect historical data about faulty and health disks. The disk label is obtained through root cause analysis of service issues by field engineers. The feature data includes SMART data and system-level signals. We then select for training those features that are stable and predictive. Based on the selected features, we construct a cost-sensitive ranking model, which ranks the disks and identifies the top r ones that minimize the misclassification cost as the predicted faulty disks.

CDEF addresses the challenges described in the previous section by incorporating: 1) a feature engineering method for selecting stable and predictive features 2) a ranking model to increase the accuracy of cost-sensitive online prediction. We describe these two components in this section.

3.1 Feature engineering

3.1.1 Feature Identification

We collect two categories of data, SMART data and system-level signals. SMART (Self-Monitoring, Analysis and Reporting Technology) is a monitoring firmware which allows a disk drive to report data about its internal activity. Table 1 gives some of the SMART features. More information about SMART can be found in [31].

Table 1: Examples of SMART features

SMART ID	Description
S2	Start/Stop Count
S12	Power Cycle Count
S193	Load Cycle Count
S187	The number of read errors that could not be recovered using hardware ECC
S5	Count of reallocated sectors. When a read or a write operation on a sector fails, the drive will mark the sector as bad and remap (reallocate) it to a spare sector on disk.
S196	The total count of attempts to transfer data from reallocated sectors to a spare area. Unsuccessful attempts are counted as well as successful.

Table 2: The system-level signals

Signal	Description
PagingError	Windows encounters an error in creating a paging file.
FileSystem-Error	An error occurs when trying to read, write, or open a file.
DeviceReset	Device is forced to reset or shutdown.
TelemetryLoss	Telemetry data cannot be captured over a period.
DataExchange-Disabled	The data exchange integration service cannot be enabled or initialized.
VMFrozen	VM is unresponsible to communication request
Windows Event 129	A Windows event log caused by dropped requests.

In cloud systems, there are also various system-level events, which are collected periodically (typically every hour). Many of these system-level events, such as Windows events, file system operation error, unexpected telemetry loss, etc., are early signals of disk errors. Table 2 gives the descriptions of some system-level signals. For example, the *FileSystemError* is an event that is caused by disk related errors, which can be traced back to bad sectors or disk integrity corruption.

Apart from the features that are directly identified from the raw data, we also calculate some statistical features as follows:

Diff Through data analysis, we have found that the changes in a feature value over time could be useful for distinguishing disk errors. We call such a feature $Diff$.

Given a time window w, we define $Diff$ of feature x at time stamp t as follows:

$$Diff(x,t,w) = x(t) - x(t-w) \tag{1}$$

Sigma Sigma calculates the variance of attribute values within a period. Given a time window w, Sigma of attribute x at time stamp t is defined as:

$$Sigma(x,t,w) = E[(X-\mu)^2], \tag{2}$$

where $X = (x_{t-w}, x_{t-w-1}, ..., x_t)$ and $\mu = \frac{\Sigma(X)}{w}$.

Bin Bin calculates the sum of attribute values within a window w as follows:

$$Bin(x,t,w) = \sum_{j=t-w+1}^{t} x(j) \tag{3}$$

In our work, we use three different window sizes 3, 5, 7 in calculating $Diff$, Bin, and $Sigma$.

3.1.2 Feature Selection

Through the feature identification process described in the previous section, we have identified 457 features in total from SMART and system-level data. However, we have found that not all of the features can well distinguish between healthy and faulty disks, especially in the context of online prediction.

Feature selection proves very useful in selecting relevant features for constructing machine learning models. Existing feature selection methods fall into two main categories, statistical indicators (Chi-Square, Mutual Information, etc.) and machine-learning based methods like Random Forest [17]. However, in our scenario, the traditional feature selection methods cannot achieve good prediction performance because of the existence of time-sensitive and environment-sensitive features. These features carry information that are highly relevant to the training period, but may not be applicable for predicting samples in the next time period. We call this kind of features non-predictive features, meaning they have no predictive power in online prediction. Our experimental results (to be described in Section 4.3.2) show that the traditional feature selection methods lead to poor performance in our scenario.

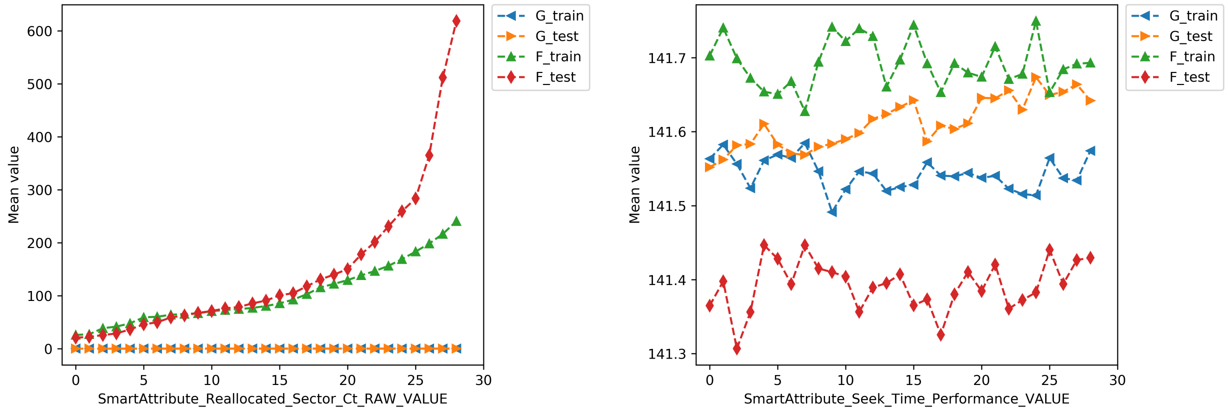
Figure 2(b) illustrates an example of a non-predictive feature *SeekTimePerformance*. Line G_train indicates the feature values of healthy disks over time in training set, and Line F_train indicates the feature values of faulty disks in the training set. Clearly, in the training set, the mean feature value of healthy disks is lower than that of faulty disks. We expect the same pattern for the same feature in the testing set (which is collected from the next time period). However, our data shows that it is not the case. In Figure 2(b), Lines G_test and F_test indicate the feature values of healthy and faulty disks over time in the testing set, respectively. Clearly, in the testing set, the mean feature value of healthy disks is higher than that of faulty disks. Therefore, the behavior of this feature is not stable. We consider this feature a non-predictive feature and not suitable for online prediction. As a comparison, Figure 2(a) shows a predictive feature *ReallocatedSectors*, from which we can see that the behavior of this feature is stable - the values of healthy disks are always close to zero and the values of faulty disks keep increasing over time, in both training and testing sets.

Algorithm 1: Prune non-predictive features

```
Input  : Training data TR with feature set $F$
         $(f_1, f_2, , , , f_m)$
Output: Reduced feature set $F'$
Split TR by time equivalently into TR1 and TR2
foreach $f_i$ in $F$ do
    // use TR1 to predict TR2, get accuracy result
    $r \leftarrow$ train(TR1) and test(TR2)
    // remove data about $f_i$ from TR, then predict
    $r_{f_i} \leftarrow$ train(TR1-$f_i$) and test(TR2-$f_i$)
    if $r_{f_i} > r$ then
        delete $f_i$ from $F$
    end
    if number of remaining features $<= \theta * m$
     then
        Break
    end
end
Return $F'$
```

To select the stable and predictive features, we perform feature selection to prune away the features that will perform poorly in prediction. The idea is to simulate online prediction on the training set. The training set is divided by time into two parts, one for training and the other for validation. If the performance on validation set gets better after deleting one feature, then the feature is deleted until the number of remaining features is less than $\theta\%$ of the total number of the features. The details are described in Algorithm 1. In our experiment, we set $\theta = 10\%$ by default, which means that the pruning process will stop if the number of remaining features is less than 10%.

At last, we re-scale the range of all selected features using zero-mean normalization as follows: $x_{zero-mean} = x - mean(X)$.



(a) Predictive features

(b) Non-predictive feature

Figure 2: An example of predictive and non-predictive feature

3.2 Cost-sensitive ranking model

Having collected features from historical data, we then construct a prediction model to predict the error-proneness of disks in the coming days. In this step, we formulate the prediction problem as a ranking problem instead of a classification problem. That is, instead of simply telling whether a disk is faulty or not, we rank the disks according to their error-proneness. The ranking approach mitigates the problem of extreme imbalanced fault data because it is insensitive to the class imbalance.

To train a ranking model, we obtain the historical fault data about the disks, and rank the disks according to their relative time to fail (i.e., the number of days between the data is collected and the first error is detected). We adopt the concept of Learning to Rank [24], which automatically learns an optimized ranking model from a large amount of data to minimize a loss function. We adopt the FastTree algorithm [28, 14], which is a form of “Multiple Additive Regression Trees” (MART) gradient boosting algorithm. It builds each regression tree (which is a decision tree with scalar values in its leave) in a step wise fashion. This algorithm is widely used in machine learning and information retrieval research.

To improve service availability, we would like to intelligently allocate VMs to the healthier disks so that these VMs are less likely to suffer from disk errors in near future. To achieve so, we identify the faulty and healthy disks based on their probability of being faulty. As most of the disks are healthy and only a small percentage of them are faulty, we select the top r results returned by the ranking model as the faulty ones. The optimal top r disks are selected in such a way that they minimize the total misclassification cost:

$$cost = Cost1 * FP_r + Cost2 * FN_r,$$

where FP_r and FN_r are the number of false positives and false negatives in the top r predicted results, respectively. Cost1 is the cost of wrongly identifying a healthy disk as faulty, which involves the cost of unnecessary live migration from the “faulty” disk to a healthy disk. Although we have very good technology for live migration, the migration process still incurs an unneglectable cost and decreases the capacity of the cloud system. Cost2 is the cost of failing to identify a faulty disk. The values of Cost1 and Cost2 are empirically determined by experts in product teams. In our current practice, due to the concerns about VM migration cost and cloud capacity, Cost1 is much higher than Cost2 (i.e., we value precision more than recall). The ratio between Cost1 and Cost2 is set to 3:1 by the domain experts based on their experience on disk error recovery. The number of false positives and false negatives are estimated through the false positive and false negative ratios obtained from historical data. The optimum r value is determined by minimizing the total misclassification cost. The top r disks are predicted faulty disks, which are high-risk disks and the VMs hosted on them should be migrated out.

4 Experiments

In this section, we evaluate the effectiveness of our approach. The aim is to answer the following research questions:

RQ1: How effective is the proposed approach in predicting disk errors?

RQ2: How effective is the proposed feature engineering method?

RQ3: How effective is the proposed ranking model?

4.1 Dataset and Setup

Dataset To evaluate the proposed approach, we collect real-world data from a large-scale Microsoft cloud service system. We use one-month data (October 2017) for training, and divide the data of November 2017 into three parts for testing. In each dataset, the ratio between healthy disks and faulty disks is around 10,000 : 3.

Setup We utilize Microsoft COSMOS [3] to store and process data collected from product teams. For ranking algorithm, we use the FastTree algorithm implemented in Microsoft AzureML [4]. We use 200 iterations in FastTree setting. The experimental evaluation is performed on a Windows Server 2012 with (Intel CPU E5-4657L v2 @2.40GHz 2.40 with 1.0 TB Memory).

4.2 Evaluation Metric

Following the existing work [23, 32, 42], we evaluate the accuracy of the proposed approach using the FPR and TPR metrics. We consider faulty disks as positive and healthy ones as negative. True Positive (TP) denotes the faulty disks that are predicted as faulty. False Positive (FP) denotes the healthy disks that are falsely predicted as faulty. True Negative (TN) denotes the healthy disks that are predicted as healthy. False Negative (FN) denotes the faulty disks that are falsely predicted as healthy. False Positive Rate (FPR) denotes the proportion of FP among all healthy disks. $FPR = FP/(FP+TN)$. True Positive Rate (TPR) denotes the proportion of TP among all faulty disks. $TPR = TP/(TP+FN)$.

We also use the ROC curve [5] that plots TPR (True Positive Rate) versus FPR (False Positive Rate), and compute the Area Under Curve (AUC). Following the related work [23, 29], we compute the TPR value when FPR is 0.1%, which indicates how good an algorithm can predict faulty disks under a high precision requirement.

4.3 Results

4.3.1 RQ1: How effective is the proposed approach in predicting disk errors?

We evaluate the effectiveness of the proposed CDEF approach on all three datasets. We also compare CDEF with the Random Forest and SVM based methods proposed in the related work on disk failure prediction [26, 32]. These methods use the Random Forest or SVM classifiers to classify disks based on the SMART data. We treat them as baseline methods in this experiment.

The experimental results are shown in Figure 3. The diagonal lines indicate the accuracy obtained by Random Guess (meaning random prediction with 50% probability). The results show that CDEF outperforms the baseline methods consistently under different FPR/TPR ratios on all datasets. For example, on Dataset 1, the AUC values for our approach is 0.93, while the AUC value for Random Guess, Random Forest, and SVM is 0.5, 0.85, and 0.53, respectively.

We evaluate the effectiveness of the proposed ranking approach in terms of misclassification cost and the TPR value (when FPR is 0.1%). The misclassification cost is obtained as: cost= Cost1*FP+Cost2*FN, where Cost1 and Cost2 are set to 3 and 1 respectively by the product team. Table 3 shows the results. Clearly, CDEF obtains better results than the other two methods. The TPR value is 36.50%, 41.09%, and 29.67% on Dataset 1, 2, and 3, respectively. CDEF is also cost-effective. In average, CDEF achieves around 187.92% cost reduction than Random Forest, and 10.13% cost reduction than SVM. SVM has low cost because SVM is accurate in predicting healthy disks and induces less false positives. But SVM performs worse in predicting faulty disks and induces low TPR.

In summary, the experimental results show that CDEF is effective in predicting disk errors. This is because of two reasons: the proposed feature engineering method and the proposed ranking model. We will show the effectiveness of these two methods in the following RQs.

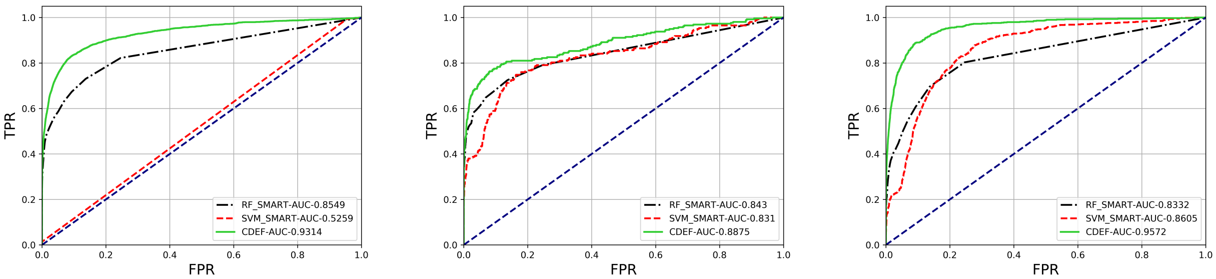
Table 3: Experimental results of CDEF on three datasets

	CDEF		RandomForest		SVM	
	Cost	TPR	Cost	TPR	Cost	TPR
Dataset 1	2508	36.50%	3157	30.51%	2907	15.51%
Dataset 2	234	41.09%	1211	34.11%	258	21.71%
Dataset 3	760	29.67%	1675	18.81%	792	7.20%

4.3.2 RQ2: How effective is the proposed feature engineering method?

In our work, we propose to use system-level signals in disk error prediction. We also propose a feature selection method to select the predictive features for model training. In this RQ, we evaluate the effectiveness of our proposed feature engineering method. We experiment with three feature engineering methods: S (traditional SMART-based features), S+A (SMART and system-level signals), and S+A+F (SMART and system-level signals with feature selection, which is used in CDEF). All other experimental settings remain the same.

The results are shown in Figure 4. We can see that the results achieved by incorporating system-level signals outperform those achieved by SMART alone on all the three datasets. Furthermore, by incorporating SMART and system-level signals with feature selection, we can obtain the best results on all the three datasets. In average, the TPR value (when FPR is 0.1%) is 27.6%, 30.3%, and 35.8%, for S, S+A, and S+A+F, respectively. These results confirm the effectiveness of the proposed feature engineering methods.



(a) Dataset 1 (b) Dataset 2 (c) Dataset 3

Figure 3: ROC of comparative methods

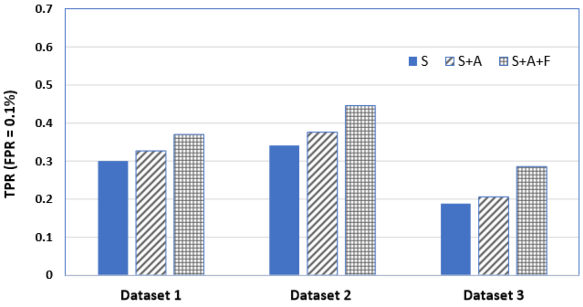


Figure 4: Evaluation results with different features
S: traditional SMART-based features; S+A: SMART and system-level signals; S+A+F: SMART and system-level signals with feature selection.

We also evaluate the effectiveness of CDEF using the features selected by the proposed feature selection method and the features selected by conventional feature selection methods Chi-Square, Mutual Information, and Random Forest [17, 21]. The results are given in Figure 5, which shows that the proposed feature selection method outperforms the conventional feature selection methods on all datasets.

4.3.3 RQ3: How effective is the proposed ranking model?

In our work, we propose to use a cost-sensitive ranking method to rank the disks and then select the top *r* disks as faulty ones by minimizing the total misclassification cost. In this RQ, we evaluate the effectiveness of the proposed ranking approach.

To perform classification for imbalanced data, one common approach is to apply the over-sampling technique SMOTE [10] to balance the training data for model construction. The other approach is weighted classification, which is essentially cost-sensitive learning [12] that learns from extremely imbalanced data and assigns a larger weight to minority class. The weight is usually set inversely to the sample portion. In our experiment, we compare the proposed cost-sensitive ranking method with these two approaches. To better evaluate the accuracy of the proposed method, we also compare with the random guess method.

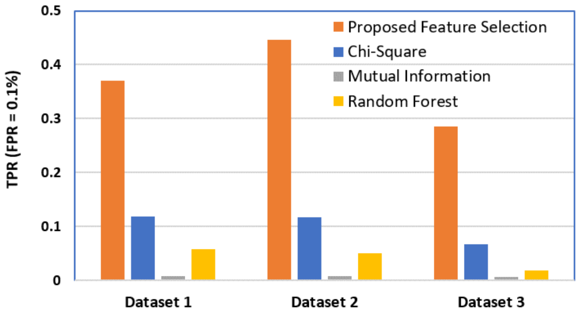

Figure 5: The comparison between the proposed feature selection method and existing methods

We evaluate the effectiveness of the proposed ranking approach in terms of misclassification cost. The proposed cost-sensitive ranking model achieves the minimum cost among all comparative methods on all datasets. For example, on Dataset 2, the misclassification cost obtained by our model is 234, while cost obtained by Random Guess, weighted classification, and classification with SMOTE are much higher (1146662, 717, and 7812, respectively).

We also evaluate the effectiveness of the proposed ranking approach in terms of TPR and FPR values. Figure 6 shows the ROC curves achieved by the comparative methods. Table 4 shows the TPR values when FPR is 0.1%, achieved by different methods on all the datasets. Clearly, our cost-sensitive ranking method achieves the best accuracy values. For example, on Dataset 2, the TPR value (when FPR is 0.1%) achieved by our model is 41.09%, while the values achieved by Random Guess, weighted classification, and classification with SMOTE are much lower (0.1%, 27.91%, and 27.94%, respectively). The AUC value achieved by our model is 88.75%, while the values achieved by Random Guess, weighted classification, and classification with SMOTE are 0.5%, 84.22%, and 83.56%, respectively.

In summary, the experimental results confirm the effectiveness of the proposed cost-sensitive ranking model.

4.4 Discussions of the Results

In our work, we do not use cross-validation to build and evaluate the proposed approach. Instead, we do online prediction - using the data before a certain date to train the model and use the data after the date to test the model. Existing work on failure prediction such as [9, 26] uses cross-validation to evaluate their machine-learning based models. In our scenario, cross-validation can lead to much better results than online prediction, as shown in Figure 7. For example, on Dataset 1, using cross-validation we can obtain TPR value of 91.64% (when FPR is 0.1%), while using online prediction the TPR value is only 36.50%. However, our experiences show that cross-validation may not always reflect the actual effectiveness of a prediction model. Online prediction should be used in practice.

In cross validation, the dataset is randomly divided into training and testing sets. Therefore, it is possible that the training set contains parts of future data, and the testing set contains parts of past data. However, in real-world online prediction, training and testing sets are divided by time. The past data is used to train the model and the future data is used to test the model.

The gap is magnified when there are time-sensitive features and environment-sensitive features. In disk error prediction, some features have temporal nature and their values vary drastically over time. Some features may be easily affected by environmental changes to the cloud system. For example, the disks on the same rack or the same motherboard encounter similar attribute changes caused by unstable voltage. However, such changes may not happen before the time of prediction. Using cross-validation we may utilize the knowledge that should not be known at the time of prediction, thus obtaining better evaluation results. Therefore, cross-validation is not suitable for evaluating our model in practice. The problem of cross-validation in evaluating an online prediction model is also observed by others [36].

4.5 Threats to Validity

We have identified the following threats to validities:

Subject systems: In our experiments, we only collect data from one cloud service system of one company. Therefore, our results might not be generalizable to other systems. However, the system we studied is a typical, large-scale cloud service system, from which sufficient data can be collected. Furthermore, we have applied our approach in the maintenance of the cloud system. In future, we will reduce this threat by evaluating CDEF on more subject systems and report the evaluation results.

Data noise: After a disk is identified to be faulty, it could be sent to repair. After that, some disks could be returned and used again. Therefore, a small degree of noise may exist in the labeling of a disk.

Evaluation metrics: We used the FPR/TPR metrics to evaluate the prediction performance. These metrics have been widely used to evaluate the effectiveness of a disk fault prediction mode [32]. Prior work [38] points out that a broader selection of metrics should be used in order to maximize external validity. In our future work, we will reduce this threat by experimenting with more evaluation measures such as Recall/Precision.

5 Lessons Learned from Practice

We have successfully applied CDEF to the maintenance of Microsoft Azure, which is a large-scale cloud service system that allows IT professionals to build, deploy, and manage applications. The cloud service achieves global scale on a worldwide network of data centers across many regions. Due to the unreliable nature of the underlying commodity hardware, various issues occur in Azure every day. Without proper handling of these issues, Azure service availability could be seriously affected. We found disk error is the most severe one among all hardware issues.

CDEF is currently used by Azure to preferentially select healthier disks for VM allocation and live migration. After deploying CDEF, in average, we successfully saved around 63k minutes of VM downtime per month. Note that 99.999% service availability means that only 26 seconds per month of VM downtime is allowed. Therefore, CDEF has significantly improved service availability of Microsoft Azure.

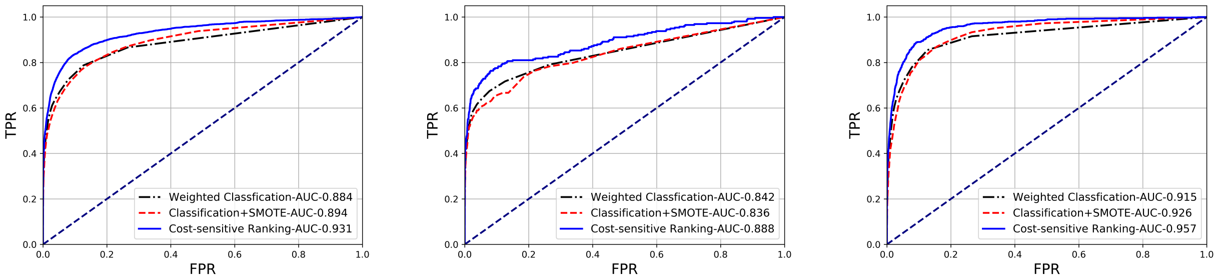
Currently the training is performed daily over the past 90-day data, and keeps a moving window of 90 days. The cutting point *r* in the ranking model is set along with the training process. When a disk is predicted as faulty, we mark the host node unallocable and trigger live migration process. We also run disk stress test on the predicted disks before they are taken out for replacement.

We have learned the following lessons from our industrial practice:

- **Continuous training**. Many factors could affect the distribution of disk error data, such as bugs in OS driver/firmware, workload on clusters, platform maintenance, etc. A model trained in the past will not always work in the future. Therefore, we build a continuous training pipeline. For every predicted disk error, we also let the disk go through a disk

Table 4: The cost and TPR values (when FPR is 0.1%) achieved by the proposed cost-sensitive ranking model

	Random Guess		Cost-sensitive ranking		Weighted Classfication		Classification+SMOTE	
	Cost	TPR	Cost	TPR	Cost	TPR	Cost	TPR
Dataset 1	1447986	0.1%	2508	36.50%	2910	26.52%	9442	24.63%
Dataset 2	1146662	0.1%	234	41.09%	717	27.91%	7812	27.94%
Dataset 3	1446929	0.1%	760	29.67%	1234	17.42%	8239	17.68%



(a) Dataset 1

(b) Dataset 2

(c) Dataset 3

Figure 6: ROC of cost-sensitive ranking and classification

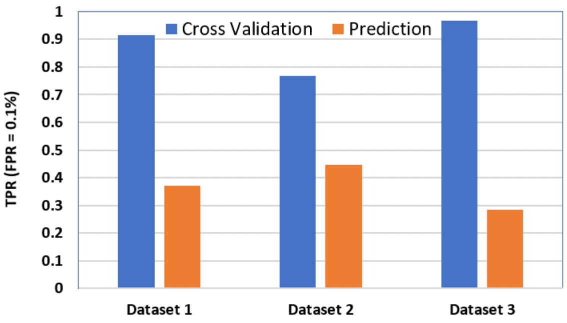


Figure 7: Evaluation results - cross validation vs. online prediction

stress test to check if it is really faulty. This forms a continuous feedback loop between disk error prediction and disk stress test.

- **Cost-effectiveness**. Prediction alone may not make much impact if the cost of recovery operation is really high (because the cost of leaving the host node as it is might be cheaper than the cost of taking the recovery operation). Furthermore, the cost to recover a node with one VM on top is much cheaper than the cost of recovery with 10 VMs in terms of VM availability. Thus, the cost of recovery could vary depending on the state of the host node, the recovery operation, etc. The prediction could be even more useful if we can better estimate the cost.

- **Faulty disks will get even worse.** Our experience shows that before a disk completely fails, it may already start emitting errors that affect upper-layer applications and services. That is why incorporating the system-level signals is better than using SMART alone. We found that disk errors, in average, occur 15.8 days earlier than complete disk failure. Our experience also shows that, before completely fails, the status of a disk will actually get worse over time. For example, for faulty disks, the value of the feature *ReallocatedSectors* increases by 3 times during the last week of its operation. The value of system-level signal *DeviceReset* even increases by 10 times during the same period. This finding confirms our intention to detect disk error earlier before it makes severe impact on application usage.

6 Related Work

6.1 Disk Failure Prediction

There are a large amount of related work on predicting disk failures. For example, BackBlaze publishes quarterly report [6] for users to keep track of reliability of popular hard drives in the market. Most of the modern hard drives support Self-Monitoring, Analysis and Reporting Technology (SMART), which can monitor internal attributes of individual drives. SMART is used by some manufacturers to predict impending drive failure by simple threshold-based method [31, 34].

As the prediction performance of the thresholding algorithm is disappointing, researchers have proposed various machine learning models for predicting disk failures. For example, Zhu et al. [42] predicted disk failure based on raw SMART attributes and their change rates, and neural network and SVM model are applied. Ganguly et al. [16] utilized SMART and hardware-level features such as node performance counter to predict disk failure. Ma et al. [25] investigate the impact of disk failures on RAID storage systems and designed RAIDShield to predict RAID-level disk failures.

Tan et al. [37] proposed an online anomaly prediction method to foresee impending system anomalies. They applied discrete-time Markov chains (DTMC) to model the evolving patterns of system features, then used tree-augmented naive Bayesian to train anomaly classifier. Dean et al. [11] proposed an Unsupervised Behavior Learning (UBL) system, which leverages an unsupervised method Self Organizing Map to predict performance anomalies. Wang et al. [41] also proposed an unsupervised method to predict drive anomaly based on Mahalanobis distance. There are also other work [19, 40] in online machine learning [7], which aims to update the best predictor at each step for steaming data (as opposed to batch learning techniques). While our "online prediction" focuses on the prediction workflow: always using a batch of historical data to predict the future (as opposed to cross-validation). Furthermore, unlike [37], we deal with the evolving features by proactively selecting the consistently predictive features. Unlike [11, 41] that can be used even when label data is difficult to get, we adopt a supervised method as we have quality labeled data. We will compare our method with unsupervised-learning based methods in our future work.

For feature selection, Botezatu et al. [9] selected the most relevant features based on statistical measures. Gaber et al. [15] used machine learning algorithms to extract features representing the behavior of the drives and predict the failure of the drives. However, these feature selection methods are not able to prune non-predictive features in online prediction scenario.

All these related work focus on disk failure prediction based on SMART and other hardware-level attributes. While our work focuses on predicting disk errors that affect the availability of virtual machines, before complete disk failure happens. We incorporate both SMART and system-level signals, which proves better than using SMART data alone. Also, most of the related work evaluate their prediction model in a cross validation manner, which is not appropriate in real-world practice. In our work, we perform online prediction and propose a novel algorithm to select stable and predictive features.

6.2 Failures in Cloud Service Systems

Although tremendous effort has been made to maintain high service availability, in reality, there are still many unexpected system problems caused by software or platform failures (such as software crashes, network outage, misconfigurations, memory leak, hardware breakdown, etc.). There have been some previous studies in the literature on failures of a data center. For example, Ford et al. studied [13] the data availability of Google distributed storage systems, and characterized the sources of faults contributing to unavailability. Their results indicate that cluster-wide failure events should be paid more attention during the design of system components, such as replication and recovery policies. Vishwanath and Nagappan [39] classified server failures in a data center and found that 8% of all servers had at least one hardware incident in a given year. Their studies could be helpful to reduce the hardware faults, especially the networking faults. Huang et al. [22] also found that the major availability breakdowns and performance anomalies we see in cloud environments tend to be caused by subtle underlying faults, i.e., gray failure rather than fail-stop failure. The above-mentioned related work shows that failures in cloud systems can be triggered by many software or hardware issues. In our work, we only focus on disk error prediction. In particular, disk errors can be also seen as a form of *gray failures*: the system's failure detectors may not notice them even when applications are afflicted by them.

7 Conclusion

Disk error is one of the most important reasons that cause service unavailability. In this paper, we propose CDEF, an online disk error prediction approach that can predict disk errors proactively before they cause more severe damage to the cloud system. We collect both SMART and system-level signals, perform feature engineering, and develop a cost-sensitive ranking model. We evaluate our approach using real-world data collected from a cloud system. The results confirm that the proposed approach is effective and outperforms related methods. The ability to predict faulty disks enables the live migration of existing virtual machines and allocation of new virtual machines to the healthy disks, thus improving service availability. We have also successfully applied the proposed approach to Microsoft Azure.

There are many viable ways of extending this work. We have applied our approach to hard disk drives in production. In the future, we will apply it to other disk types such as Solid State Drive. We will also explore the synergy between disk error prediction and other cloud failure detection techniques such as [22], and propose an integrated solution to service availability improvement.

Abstract

Data reliability and availability, and serviceability (RAS) of erasure-coded data centers are highly affected by data repair induced by node failures. Compared to the recovery phase of the data repair, which is widely studied and well optimized, the failure identification phase of the data repair is less investigated. Moreover, in a traditional failure identification scheme, all chunks share the same identification time threshold, thus losing opportunities to further improve the RAS.

To solve this problem, we propose *RAFI*, a novel risk-aware failure identification scheme. In RAFI, chunk failures in stripes experiencing different numbers of failed chunks are identified using different time thresholds. For those chunks in a high risk stripe (a stripe with many failed chunks), a shorter identification time is adopted, thus improving the overall data reliability and availability. For those chunks in a low risk stripe (one with only a few failed chunks), a longer identification time is adopted, thus reducing the repair network traffic. Therefore, the RAS can be improved simultaneously.

We use both simulations and prototyping implementation to evaluate RAFI. Results collected from extensive simulations demonstrate the effectiveness and efficiency of RAFI on improving the RAS. We implement a prototype on HDFS to verify the correctness and evaluate the computational cost of RAFI.

1 Introduction

In large-scale erasure-coded data centers, node failures are the norm rather than the exception [1]. Those frequent node failures can result in numerous chunk failures (a chunk is the basic unit to organize data). The *RAS* (*R*eliability, *A*vailability, and *S*erviceability) of data centers are highly affected by repairing those failed chunks, which is known as *data repair*. Many solutions [2–19] are proposed to improve the RAS, i.e., reduce data loss, unavailability, and repair network traffic (a typical repair cost), through optimizing the data repair. However, existing solutions typically focus on the *recovery phase*, which is from the time when a chunk failure is identified to the time when the failed chunk is recovered. In contrast, the *identification phase*, which is from the time when a chunk failure occurs to the time when the chunk failure is identified, has not been explored yet. Consequently, the potential to further improve the RAS is not fully explored.

Traditionally, the failure identification of a chunk depends on the failure identification of its host node. When a node fails, its failure is not identified until a certain time threshold. When the node failure is identified, the failures of all the chunks on that node are identified, and the states of those chunks transition to *lost*. In summary, all chunks share the same time threshold with nodes in a traditional failure identification (TFI) scheme.

Under the TFI scheme, it is hard to simultaneously improve the RAS through adjusting the time threshold. On one hand, higher data reliability and availability could be achieved by lowering the failure identification time threshold, because of the shortened data repair time. On the other hand, the data center might suffer from increasing repair network traffic, because more transient node failures might be identified. In contrast, by increasing the failure identification time threshold, the repair network traffic could be reduced but the data reliability and availability might be suffer.

In this paper, we posit that the RAS can be simultaneously improved through optimizing the identification phase. This is rooted in the following dedicated observation on stripes. Each stripe consists of data chunks and parity chunks generated from those data chunks. A stripe is the basic unit for ensuring data reliability and availability. According to the number of failed chunks in a stripe, failed stripes can be classified into two types. One is a stripe which has many failed chunks, e.g., by default two or more failed chunks in a stripe with three parity chunks. This type of failed stripes is referred to as a high risk stripe. The other is referred to as a low risk stripe, which has a few failed chunks, e.g., by default one failed chunk in a stripe with three parity chunks. The more failed chunks a stripe has, the lower the data reliability and availability of the stripe are. Hence, most of the data loss and unavailability occur in high risk stripes. On the other hand, low risk stripes are much more common than high risk stripes, and thus induce most of the repair network traffic.

There already exist solutions that improve the RAS in the failure recovery phase, are rooted in being aware of the risk of stripes, e.g., prioritizing the recovery of the chunks in the stripes with multiple lost chunks [3, 7], or canceling the recovery of the chunks in the stripes with a few lost chunks [14]. Inspired by these approaches, we propose a novel *R*isk-*A*ware *F*ailure *I*dentification scheme, named *RAFI*, to improve the RAS of erasure-coded data centers. More specifically, RAFI is aware of not only lost chunks, which are focused on the traditional risk-aware wisdom, but also *unidentified failed* chunks, whose failure has not been identified yet. The key principle of RAFI is that the more failed chunks a stripe has, the shorter failure identification time threshold those chunks take. As a result, the aforementioned conflict between the data reliability and availability, and the repair network traffic is resolved, and the RAS are improved simultaneously.

We make the following contributions in this paper.

(1) We propose a risk-aware failure identification scheme RAFI to simultaneously improve the RAS of erasure-coded data centers. By deploying RAFI, a chunk failure is identified through multiple independent identification thresholds. Therefore, for chunks in high risk stripes, their failure identification is expedited, thus improving the data reliability and availability. For chunks in low risk stripes, their failure identification is postponed, thus reducing the repair network traffic. As a result, the RAS are improved simultaneously.

(2) A simulator is developed to verify our RAFI. The simulation results demonstrate that RAFI is very effective and efficient. For example, cooperating with all types of the state-of-the-art optimizations on the failure recovery phase, RAFI can further improve the data reliability by a factor of 9.3, and reduce the data unavailability and repair network traffic by 43% and 36%, respectively, at the cost of degraded reads increased by 1.7%.

(3) A prototype of RAFI is implemented in HDFS to verify the correctness and computational cost of our RAFI. The experimental results demonstrate that, in the worst case scenario, the computational cost of RAFI is still negligible.

The rest of this paper is organized as follows: Section 2 presents a model to analyze the relevance among the data reliability, repair network traffic, and failure identification. In Section 3, we give the design of RAFI. The results of prototype experiments and simulations are illustrated in Section 4 and 5, respectively. Section 6 reviews related work on optimizing the failure recovery phase, and Section 7 concludes the paper.

2 Background and Motivation

In this section, we first define the terms used in this paper. Then, we review the background materials of erasure-coded data centers, and summarize the existing methods to improve the RAS. Finally, we illustrate our motivation to propose RAFI.

2.1 Terms

Some terms to facilitate our discussion are summarized as follows.

A failed node: a node whose heartbeats have been lost. When a node fails, its heartbeat is lost immediately and it becomes a failed node. In TFI, the failure of a node is not identified until its heartbeats have been lost for over a certain time threshold.

A failed chunk: a chunk whose host node fails. When a node fails, all chunks on that node become failed. A failed chunk can be further classified into an unidentified failed chunk and a lost chunk as described below.

An unidentified failed chunk: a failed chunk whose failure has not been identified yet. Between the chunk failure occurs and that failure is identified, the chunk is treated as unidentified failed.

A lost chunk: a failed chunk whose failure is identified. After the failure of a chunk is identified, the chunk is treated as lost.

S^i and S^{i+}: a stripe S^i is a stripe with i lost chunks, and a stripe S^{i+} is a stripe with i and more lost chunks.

2.2 Erasure-coded Data Centers

To tolerate node failures, data redundancy techniques are usually deployed in data centers. Traditional data redundancy techniques, e.g., replication, suffer from high spatial cost. Hence, erasure coding techniques (e.g., Reed-Solomon coding) which have a much lower spatial cost compared to replication techniques, are widely used in data centers [7, 12, 20, 21].

To apply the erasure coding in data centers, data is first divided into fixed size data chunks. Then, parity chunks are generated from those data chunks. To prevent data loss or unavailability from node failures, all those data and parity chunks together form a stripe and are distributed to different nodes.

Table 1: Methods to Improve the RAS

	Time Threshold ↓	Recovery Penalty Factor ↑	Network Bandwidth ↑	Queue Time ↓
Reliability/Availability	↑	↑	↑	↑
Repair Network Traffic	↑	↓	→	→

Node failures are monitored through frequent heartbeats, e.g., every 3 seconds [3]. However, a node failure is not immediately identified when the heartbeats are lost, because most node failures are transient and those failed nodes can come back in a short period, e.g., 10 minutes [20]. In order to reduce the repair network traffic, only when the heartbeats have been lost over a certain time threshold, e.g., 15 minutes [20] or 30 minutes [7], a node failure is identified (a misidentification occurs if the node comes back).

Traditionally, when a node failure is identified, all the chunk failures due to that node failure are treated as identified failures. Surviving data and parity chunks (on other nodes) of the lost chunks would be fetched to repair those lost chunks (data repair), thus ensuring the data availability and reliability.

2.3 Methods to Improve the RAS

It is cost-effective to improve the RAS by optimizing the data repair process. Many solutions are proposed following this way which are explained below and also summarized in Table 1.

(1) Decreasing the time threshold reduces the repair time, and thus improves the reliability; however, it increases the repair network traffic;

(2) In erasure-coded data centers, multiple available chunks are transmitted over the network to recover lost chunks in the stripe. Recovery penalty factor is a factor which is between the amount data transmitted for recovering a stripe S^i and the size of a chunk. Decreasing the recovery penalty factor [2, 4, 5, 7–13, 16, 17, 22, 23] reduces the repair time, and thus improves the reliability; in the meanwhile, it reduces the repair network traffic;

(3) Increasing the network bandwidth [6, 24–26] of each storage node reduces the repair time, and thus improves the reliability; in the meanwhile, the repair network traffic stays almost the same.

(4) The queue time (waiting for recovery) of failed stripes is affected by recovery schemes. Giving high priority to S^i $(i > 1)$ [7, 27], the queue time of S^i $(i > 1)$ is decreased, and thus the reliability is improved; in the meanwhile, this method has little effect on the repair network traffic.

According to the above analysis and simulation results demonstrated in Figure 9a in Section 5.3, the RAS cannot be improved simultaneously by adjusting the failure identification time threshold. Therefore, a novel risk-aware failure identification scheme RAFI is proposed to explore the huge potential of simultaneously improving the RAS within the failure identification phase.

2.4 Motivation

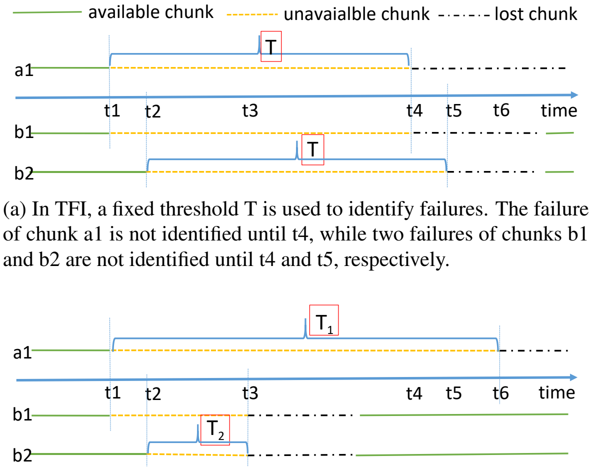
When some nodes fail, many stripes are affected, i.e., have failed chunks. Due to the randomized chunk layout, only a small fraction of those affected stripes have many failed chunks, and the remaining affected stripes only have a few failed chunks. Hence, most repair network traffic is induced by repairing the latter type of stripes.

On the other hand, the failure identification time of an arbitrary affected stripe having i failed chunks is equal to the failure identification time of its ith failed chunk, i.e., all the affected stripes share the same failure identification time. The stripes with many lost chunks usually entitle high recovery priority, i.e., a short queuing time. Hence, the repair time of those stripes are usually dominated by the failure identification time. In contrast, the stripes with a few identified failed chunks usually have a long queuing time. Hence, the repair time of those stripes are usually dominated by the recovery time.

If the failure identification of those two types of stripes can be handled separately, the RAS of data centers can be improved simultaneously. More specifically, for the stripes having many failed chunks, we tune down the failure identification time threshold of those failed chunks, and thus improving the data availability and reliability at the cost of slightly increasing repair network traffic. For the stripes having a few failed chunks, we tune up the failure identification time threshold of those failed chunks, and thus reducing the repair network traffic without significantly reducing data reliability and availability. More importantly, the benefit induced by the above two operations would be dominant compared to the associated cost. Hence, the RAS of data centers can be improved simultaneously.

3 RAFI: Design and Analysis

In this section, we first present the design of RAFI; followed by a discussion on the benefit and cost of deploying RAFI.



(a) In TFI, a fixed threshold T is used to identify failures. The failure of chunk a1 is not identified until t4, while two failures of chunks b1 and b2 are not identified until t4 and t5, respectively.

(b) In RAFI, the failure of chunk a1 is identified through the threshold T_1 at t6, which is later than t4. On the other hand, the failures of chunks b1 and b2 are identified through the threshold T_2 at t3, which is ahead of t4 and t5.

Figure 1: Identification of chunk failures using TFI and RAFI. We use three sample chunks, where a1 is a random chunk of a stripe A while b1 and b2 are two random chunks of a stripe B. Assume chunk a1 fails at time t1 while chunks b1 and b2 fail at t1 and t2, respectively.

3.1 Design of RAFI

As we discussed above, the key problem of the traditional failure identification (TFI) scheme is that all chunks share the same failure identification time threshold. To simultaneously improve the RAS, we propose *RAFI* to identify chunk failures according to the risk level of their host stripes and apply different time thresholds accordingly. More specifically, dedicated chunk failure identification time thresholds are set for stripes in different risk levels, which are determined by the *total failed chunks* in the stripes. For chunks in low risk stripes, long failure identification time thresholds are adopted, thus reducing the repair cost. For chunks in high risk stripes, short failure identification time thresholds are adopted, thus improving the data reliability and availability. As a result, the RAS are simultaneously improved.

In summary, the key design principle of RAFI is that the more failed chunks a stripe has, the shorter failure identification threshold those chunks take. For a failed chunk in a stripe with i failed chunks, there are at most i identification thresholds to identify the failure of this chunk, and the jth ($0 < j \leq i$) identification threshold is described as follows. If there are j failed chunks and the failure durations of these j failed chunks are all longer than a preset time threshold T_j, all these j chunk failures are identified and these chunks are denoted as lost immediately. The state of an unidentified failed chunk in these j chunks transitions to lost, and a lost chunk in these j chunks remains lost. The states of the remaining $(i-j)$ chunks do not transition.

In RAFI, a chunk failure is identified by independent identification thresholds, which is quite different from the traditional single identification threshold described in Section 1. For example, in a (6,3)-coded data center, stripe A has one failed chunk and is a low risk stripe, stripe B has two failed chunks and is a high risk stripe. A time threshold T_1 which is larger than the original time threshold T is set to identify failures of chunks in the low risk stripe; while a time threshold T_2, which is shorter than the T is set to identify failures of chunks in the high risk stripe. As shown in Figure 1, using RAFI, the failure identification of chunk a1 in the stripe A is postponed; in the meanwhile, the failure identification of chunks b1 and b2 in the stripe B is expedited.

RAFI is flexible. First, all the time thresholds can be set independently to get proper trade-offs between the data reliability and availability, and the repair network traffic for a certain type of stripes. Second, the identification thresholds can be merged to get proper trade-offs between the RAS and the computation cost of RAFI. When the time thresholds in all identification thresholds are set to the same T, RAFI becomes TFI.

3.2 Benefit and Cost

Improving the RAS: Using RAFI, we can independently set different time thresholds to identify failures. First, short thresholds are used to expedite the identification of failed chunks in high risk stripes, thus improving the data reliability and availability. At the same time, long thresholds are used to postpone the failure identification of chunks in low risk stripes, thus reducing the repair network traffic and improve the serviceability. Because the identification time is dominant in the repair time of chunks in high risk stripes, the expedition is effective in improving the data reliability and availability thus compensates the negative impacts induced by the postponement. Because most repair network traffic is induced by recovering chunks in low risk stripes, the repair network traffic is significantly reduced, even under the consideration of the extra repair network traffic induced by the expedition, thus improving the serviceability.

Compatibility: Because RAFI focuses on the failure identification phase, it can work together with existing optimizations which focus on the failure recovery phase.

Increasing Degraded Reads: Degraded read is an operation to read unavailable but recoverable chunks in a stripe. Because we postpone the failure identification of chunks in low risk stripes, more failed chunks might be generated, thus increasing degraded reads. However, the simulation results in Section 5 show that degraded reads increase by less than 1.7% due to RAFI. Because degraded reads are much fewer than normal reads, the overhead is very small.

4 Prototyping Evaluation

In this section, we first present the evaluation methodology; then we illustrate implementation details of our prototype RAFI-HDFS; finally we demonstrate results of prototyping experiments.

4.1 Evaluation Methodology

To verify the effectiveness of RAFI, we propose a hybrid methodology to comprehensively evaluate RAFI via both simulation and prototype implementation. The reason is explained below.

It is difficult to evaluate a technique targeting at the RAS of data centers because the data loss and unavailability events are very rare and not evenly distributed. The accuracy problem induced by that uneven distribution can be mitigated by high accurate simulation, which is run thousands to millions of iterations, although the simulator itself might be not that accurate. However, pure simulation cannot verify the correctness of design details and might cover fatal defects of the technique.

In our hybrid evaluation, the design details and computational cost of RAFI are verified through prototyping running on a real distributed storage system; the effectiveness and efficiency of RAFI on the RAS are evaluated through high accurate Monte-Carlo simulation.

In this section, we evaluate the identification time and computational cost of RAFI in real world environments. The simulator and simulation results are discussed in Section 5.

4.2 RAFI-HDFS

To evaluate the effectiveness of RAFI, we implement a prototype named RAFI-HDFS on HDFS [27], a representative distributed file system widely deployed in the data centers. Because erasure coding is supported by HDFS in version 3.0.0, our implementation is based on HDFS 3.0.0-alpha2. The implementation of RAFI-HDFS follows the design in Section 3. We only add about 200 lines of codes to HDFS.

Figure 2 demonstrates the overall architecture of RAFI-HDFS consisting of two modules: one is a classification module and the other is an identification module.

The classification module is responsible for converting the node failures into appropriate input for the identification thresholds. More specifically, the classification module receives a node list that contains all failed nodes and their failure durations from the node monitor module. Only those nodes whose failure durations are larger

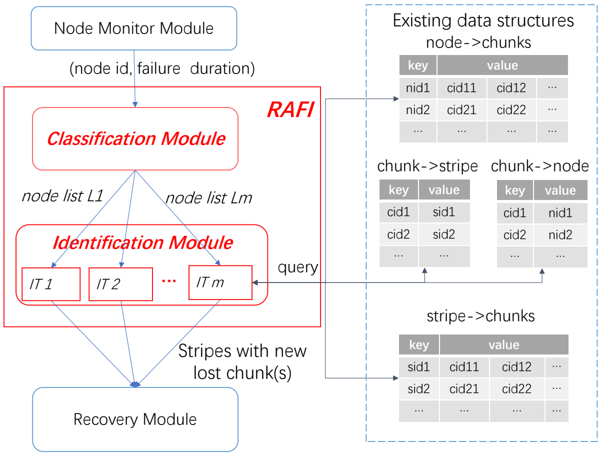


Figure 2: Architecture of RAFI-HDFS. The right side is existing data structures which are used in RAFI. The node monitor module reports failed nodes and their failure durations. The classification module inserts nodes to different identification thresholds in the identification module according to their failure durations. The identification thresholds (IT) in the identification module are used to identify chunk failures.

than T_i ($1 \leq i \leq m$) are inserted into the node hash list L_i for the *identification threshold (IT) i*, thus reducing the computation cost of that identification threshold. It is worth noting that the classification module replaces failed chunk lists with failed node lists. In such a manner, the memory usage of maintaining the numerous failed chunks is saved.

The identification module is a universal set of all the identification thresholds in RAFI. When *IT i* receives its node list L_i, it begins to calculate the *count* of failed chunks in stripes. First, the identification threshold calculates the *count* of unidentified failed chunks in stripes through querying the node-chunk mapping table and the chunk-stripe mapping table, which typically reside in the main memory of the manager nodes of the data centers. Second, through querying the stripe-chunk mapping table and chunk-node mapping table, the *count* of lost chunks is obtained. If the count of failed chunks (unidentified failed chunks and lost chunks) is larger than or equal to i, those failed chunks which belong to nodes in L_i, transition to lost.

After working through all identification thresholds, if new chunk failures are identified, the recovery module is called to recover stripes containing those lost chunks. Particularly, for nodes which enter *IT* 1, the failures of these nodes are identified and these nodes are removed from the system at the end of the *IT* 1.

Complexity. RAFI-HDFS only checks chunks on failed nodes which newly enter L_i to reduce the computation cost. Assume there are j nodes in L_i ($2 \leq i \leq m$) and there are an average of d chunks to be checked on the node. Each stripe has $k+m$ chunks. Because we use a hash list to track the failed nodes, the total comparison time is about $(k+m)\times d$. The time complexity of identifying chunk failures is $\mathcal{O}(d)$.

4.3 Results of Prototyping Experiments

Experimental Setups. The experimental system consists of ninety-seven servers running on the Alibaba Cloud [28]. One server served as a NameNode contains an Intel Xeon E5-2682v4 @ 2.5 GHZ CPU (4 vCPU), 16 GB DDR4 memory, 1.5 Gbps network and 40 GB SSD. The remaining 96 servers are used as DataNodes, each of which has an Intel Xeon E5-2680v3 @ 2.5 GHZ CPU (1 vCPU), 1 GB DDR4 memory, 1 Gbps network and 40 GB SSD. The operating system running on all these servers is Ubuntu 14.04. Each DataNode sends heartbeats to the NameNode every 3 seconds and the NameNode checks the states of all DataNodes every 5 minutes. As default in HDFS, the time threshold $T=10.5$ minutes and the erasure coding scheme RS(6,3) is used.

Identification Time of Chunks: The identification time of a chunk is the period from the time when a chunk becomes failed to the time when the chunk is identified as a lost chunk. In order to evaluate the real identification time, we collect the identification times by randomly killing two DataNodes. In order to evaluate the real identification time of chunks, we collect the identification times by randomly killing DataNodes in 0, 5, 10, and 20 minutes. Each experiment is conducted 20 times. In RAFI, T_2 is set to 1 minute and T_1 is set to 60 minutes. The results are consistent with our analysis in Section 3.2. The results demonstrate that TI_2 is expedited and TI_1 is postponed. When we simultaneously kill two storage nodes, TI_1 and TI_2 under TFI are 13.1 minutes; however, TI_2 under RAFI is 3.6 minutes, while TI_1 under RAFI is 62.6 minutes. Moreover, TI_1 and TI_2 are not relevant to the time between the failure arrivals.

Burden on the NameNode: Because the computations run on the NameNode, we record the time spent to identify chunk failures when nodes fail to further estimate the impact on the NameNode. The chunk size is shrunk to $1KB$ in our cluster to generate enough number of chunks. In the experiments, each DataNode stores about 68,000 chunks. In the experiments, there is no I/O workloads because the time spent to identify chunk failures under no I/O workloads is sufficient to indicate the overhead caused by RAFI on the NameNode. For each result, we concurrently kill DataNodes. Each experiment is conducted 10 times and we calculate the average results.

We evaluate the time spent to identify chunk failures from two aspects: the number of DataNodes in the cluster and the number of concurrent node failures.

First, as shown in Figure 3, the time spent to identify all 68,000 chunk failures on one failed DataNode increases from 74 to 137 milliseconds when the number of DataNodes increases from 12 to 96. Compared to time thresholds and check intervals (by default 10.5 and 5 minutes, respectively), the time spent to identify chunk failures can be negligible in the identification time.

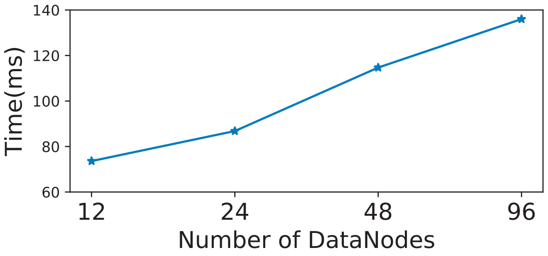

Figure 3: Time spent to identify chunk failures when when a DataNode fails. The number of DataNodes in the cluster changes from 12 to 96. E.g., the NameNode takes 87 ms to identify 68,000 chunk failures in a cluster of 24 DataNodes.

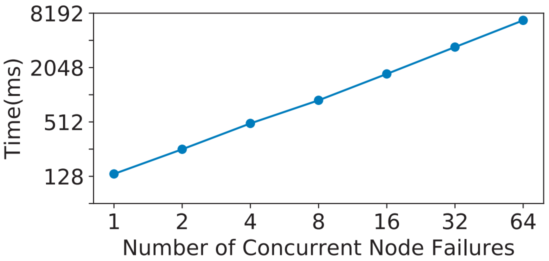

Figure 4: Time spent to identify chunk failures when DataNodes fail. The cluster consists of 96 DataNodes. E.g., the NameNode spends 889 ms to identify 544,000 chunk failures when eight DataNodes fail concurrently .

Second, as illustrated in Figure 4, the time spent to identify chunk failures increases linearly as concurrent node failures increase. The experiment results are consistent with the analysis in Section 4.2. It is worth noting that there are no failed nodes in most check time. Thus, our method has minimal impact on the NameNode.

Moreover, in our evaluation, only one single thread is used to check all chunks on failed nodes. In fact, we can use multi-threading technologies to check all chunks on failed nodes, e.g., each thread is responsible for checking all chunks on one failed node. Therefore, the time spent to identify all chunks on failed nodes can be dramatically reduced when multiple nodes fail concurrently.

5 Simulations and Results Analysis

In this section, we discuss our simulator and simulation results to evaluate the effectiveness and efficiency of RAFI on the RAS.

5.1 DR-SIM

We developed a simulator called DR-SIM which is written in the R language because it easily runs in parallel. The source code is approximately 1400 lines [29].

Event-driven simulators are widely used to study the RAS of data centers [14, 20, 30]. However, those simulators cannot be used in our simulations due to the following two reasons. First, some simulators are not open source, e.g., the Google's Cell Simulator [20]. Second, the RAS cannot be all simulated by some simulators. For example, limited by performance, the data reliability cannot be studied by the ds-sim [14]. As a result, we develop our own simulator, named DR-SIM, to study the effect of the data repair on the RAS in data centers.

We summarize important features of DR-SIM as follows. (1) The trade-off between the performance and accuracy of DR-SIM is carefully tuned. A simulation iteration (typically represents five years) can be finished in tens of seconds. Therefore, we run hundreds of thousands iterations for each simulation configuration, to accurately measure the RAS. (2) Many state-of-the-art optimizations on the data repair are integrated into DR-SIM, and important parameters of the data repair are considered as variants in DR-SIM. Through modifying the configuration of DR-SIM, we study the effectiveness and efficiency of RAFI upon various combinations of the state-of-the-art optimizations under various typical environments of the data centers.

Figure 5 shows the architecture of DR-SIM which includes four modules: a configuration manager, a failure generator, a repair calculator, and an event collector.

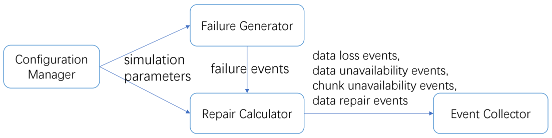

Figure 5: Architecture of DR-SIM

The configuration manager loads parameters used in the simulations. The parameters are explained as follows. (1) *System parameters*: The target erasure-coded data center consists of N independent storage nodes. Each node has d chunks. The chunk size is s. (2) *Coding parameters*: Data are coded with (k, m) erasure codes, i.e., k data chunks and m parity chunks are in a stripe. The $k+m$ chunks in the same stripe are distributed to $k+m$ distinct nodes. A random placement policy is used because it is usually adopted in practice. The recovery penalty factor of S^i ($1 \le i \le m$) is r_i which is between the amount data transmitted for recovery of S^i and s. The recovery network bandwidth is b on each node. (3) *Failure parameters*: Assume node failure arrivals are independent. Let $f(x)$ and $F(x)$ be the probability and cumulative distribution functions of the failure arrivals, respectively. Assume failure durations are independent. Let $g(x)$ and $G(x)$ be the probability and cumulative distribution functions of the failure durations, respectively. ρ is the ratio of permanent node failures to all node failures. τ denotes the additional proportion of correlated node failures. (4) *Identification parameters*: Storage nodes periodically send heartbeats to dedicated manager nodes, e.g. the NameNode [27, 31] or the metadata manager [32]. The manager nodes check states of all nodes at regular time intervals of T_h. The time thresholds for identifying chunk failures are T_i ($1 \le i \le m$). (5) *Simulation runtime parameters*: N_i denotes the number of iterations. T_d is the simulation duration for each iteration.

The failure generator is responsible for generating failure arrivals and failure durations of node failures at the beginning of a simulation iteration. The failure arrivals are generated according to the distribution function $f(x)$. Permanent failures and transient failures are generated by their durations. For the transient failures, their durations are generated according to the distribution function $g(x)$. For permanent failures, they are generated according to the parameter ρ. Technically, failure durations of the permanent failures are set to zero (only for handling but not calculating). In DR-SIM, additional correlated failures are explicitly generated by adding a random value between 0 to 120 seconds [20] to existing failure arrivals according to the parameter τ. It is worth noting that the comeback of transient failed nodes has been already considered in DR-SIM.

The repair calculator simulates the data repair process for lost chunks when failures occur. The repair calculator identifies the chunk failures according to the T_h and T_i ($1 \le i \le m$) and calculates the repair time for lost chunks based on the recovery network bandwidth, the recovery penalty factors and the recovery priority. The recovery processes of lost chunks are scheduled depending on the number of lost chunks in their stripes. For stripes have the same number of lost chunks, the repair calculator uses first come first scheduled rule to manage the recovery of those chunks. Moreover, lost chunks are recovered in parallel by utilizing all available nodes [33, 34].

The event collector is responsible for collecting data loss events, data unavailability events, chunk unavailability events, and data repair events. At the end of each iteration, DR-SIM calculates metrics according to the collected events. The mean time to data loss in the whole data center (referred as ***MTTDL***) is the metric to evaluate the data reliability. All the data loss events are recorded to calculate the *MTTDL*. The cumulative unavailable time of all stripes (referred as T_{us}) is the metric to evaluate the data availability. All the data unavailability events are recorded to calculate the T_{us}. The total repair network traffic (referred as ***RNT***) is the metric to evaluate the serviceability. All the data repair events are recorded to calculate the *RNT*. The cumulative unavailable time of all chunks (referred as T_{uc}) is the metric to evaluate the degraded reads. All the chunk unavailability events are recorded to calculate the T_{uc}. The former three metrics are widely used in evaluation of the RAS in the data centers [6, 7, 12, 14, 15, 20, 30, 35, 36]. The latter one is roughly in proportion to the number of degraded reads. It is worth noting that chunks and stripes are actually not simulated in DR-SIM under the consideration of computation complexity. In fact, the cumulative unavailability time of stripes and cumulative unavailability time of chunks are estimated from the generated node failures and data repair events.

5.2 Simulation Testbed

Comparisons between RAFI and TFI are made upon the testbed described as follows.

The following three state-of-the-art optimizations are always considered in the testbed. (1) The network adopts CLOS topologies [24–26]. (2) All lost chunks are parallel recovered via using available recovery network bandwidth on all nodes. (3) The chunks in stripes with more lost chunks have the higher priority to be recovered.

Three kinds of erasure codes are chosen in the simulations to understand the sensitivity to different erasure codes. RS codes are are a set of popular erasure codes which are widely used in real world distributed storage systems [12, 20, 21]. Zigzag codes [10] represent MDS (Maximum Distance Separable) codes with optimal recovery penalty factors. LRC codes [7] are representative non-MDS codes deployed in Windows Azure Storage.

The 1 Gbps network is chosen as the baseline in the testbed under the consideration of the cost-effectiveness in the erasure-coded data center, although we have found that RAFI is more efficient in reducing the *RNT* under the 40 Gbps network during studying the sensitivity of RAFI to the recovery network bandwidth.

Because chunks in low risk stripes are the optimization objects of both RAFI and *Lazy* [14], Lazy is considered in the testbed when we made dedicated comparisons between these two techniques in Section 5.3.4.

Default values of most parameters used in the simulations are listed in Table 2. The failure arrivals are assumed to be independent and exponentially distributed with the mean time to failure (MTTF = 7.1 days) [12,20]. The failure durations are assumed to be independent and Weibull distributed. We get sample values from [20] and model the failure durations with Weibull(113 seconds, 0.54), which is shown in Figure 6. The model fits well starting from 0.5 minutes.

Table 2: Symbols and Their Definitions

Symbol	Definition	Default Value
N	# of storage nodes in a data center	1000
d	# of chunks on a node	125,000
s	Chunk size	128 MB
T_h	Check interval of node states	5 minutes
b	Recovery network bandwidth on each node	0.1 Gbps
T_d	Duration of each iterations	5 years
N_i	# of iterations	500,000

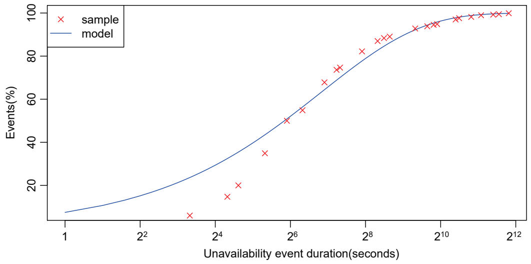

Figure 6: Unavailability Event Duration

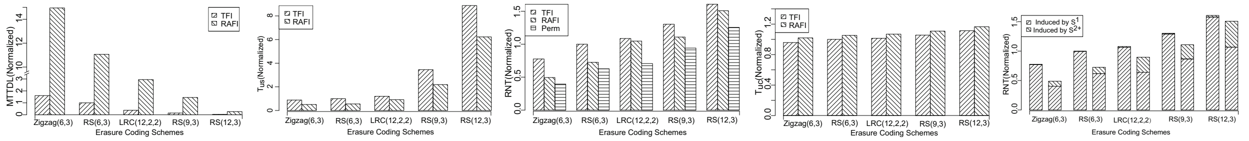
In our simulations, to simplify the comparison complexity, the identification thresholds *identification threshold i* ($i > 1$) are merged to one by sharing the same threshold value. The features of the erasure codes, and two time threshold values (one for T_1, and the other for T_i ($i > 1$)) are represented by an abbreviation, e.g., RS(6,3)-15-2 denotes a data center employed RS(6,3) with T_1 = 15 minutes and T_2 = T_3 = 2 minutes. r_1, r_2 and r_3 of an RS(6,3)-coded stripe are 6, 7, and 8, respectively. All measured metrics including the *MTTDL*, T_{us}, *RNT* and T_{uc}, are normalized to that of the RS(6,3)-15-15 (it denotes a TFI configuration when the latter two values are the same). The *MTTDL*, T_{us}, and *RNT* are the metrics to evaluate the RAS.

5.3 Simulation Results

5.3.1 RAS as Functions of T_i

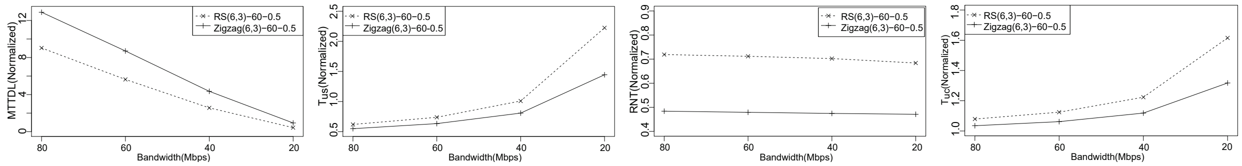
First of all, we run simulations to find the proper two threshold values for RAFI. Let $T_3 = T_2 = T_1$. Figure 9a illustrates that the data reliability and availability get worse while the repair network traffic is improved when T_1 increase. The *RNT* reduces slowly when T_1 is larger than 60 minutes. Thus, T_1 of RAFI is set to 60 minutes in the rest simulations.

Then, to study the impact of T_2, let $T_3 = T_2$. T_2 ranges from 0.5 to 8 minutes. The results in Figure 9b demonstrate that RAFI simultaneously improves the RAS in most configurations. More specifically, the *MTTDL* is improved by a factor up to 11. The T_{us} is reduced by up to 45%. The *RNT* is reduced by up to 27%. The *RNT* increases with the reduction of T_2 because reducing T_2 increases the number of S^{2+}, and results in unnecessary



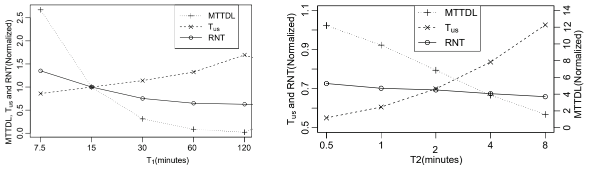
(a) Reliability (b) Availability (c) Serviceability (d) Degraded Reads (e) *RNT* induced by S^1 v.s. *RNT* induced by S^{2+}.

Figure 7: Impacts of different erasure coding schemes on the RAS. The results are normalized to RS(6,3)-15-15.



(a) Reliability (b) Availability (c) Serviceability (d) Degraded Reads

Figure 8: Impacts of constrained recovery network bandwidth on the RAS. RS(6,3) and Zigzag(6,3) are considered in the simulations. The results are normalized to RS(6,3)-15-15.



(a) The *MTTDL*, T_{us}, and *RNT* with different T_1.

(b) The *MTTDL*, T_{us}, and *RNT* with different T_2. T_1 is set to 60 minutes.

Figure 9: Impacts of T_1 and T_2. The erasure coding scheme is RS(6,3), and the results are normalized to RS(6,3)-15-15.

repair network traffic to repair those S^{2+}. Only when T_2 is 8 minutes, which is close to the original T of 15 minutes, RAFI does not take effect on the data availability.

From the results, we find that the data reliability and availability are sensitive to the decrease of T_2 but the repair network traffic is not sensitive to the decrease of T_2. As a result, *both* T_2 *and* T_3 *are set to 0.5 minutes* in the rest simulations.

5.3.2 RAS as Functions of Erasure Coding Schemes

In this section, we examine the effectiveness and efficiency of RAFI under five typical kinds of erasure coding schemes, RS(6,3), RS(9,3), RS(12,3), Zigzag(6,3) [10], and LRC(12,2,2) [7]. These erasure coding schemes represent various recovery penalty factors. T_1, T_2 and T_3 are 60 minutes, 0.5 minutes and 0.5 minutes, respectively. All results are normalized to RS(6,3)-15-15 and presented in Figure 7. In general, RAFI can cooperate with all the five kinds of erasure coding schemes, and simultaneously further improve the RAS at the cost of the slightly increased degraded reads.

Improving Reliability: Figure 7a shows that RAFI improves the *MTTDL* of Zigzag(6,3), RS(6,3), LRC(12,2,2), RS(9,3), and RS(12,3) by a factor of 9.3, 11, 7.7, 9.8, and 7.7, respectively. When the recovery penalty factor increases, the improvements diminish a little. The reason is that the higher recovery penalty factor lengthens the recovery time, thus weakens the effect of the reduction of the identification time.

Improving Availability: Figure 7b illustrates that RAFI improves the data availability under various erasure coding schemes. The T_{us} of Zigzag(6,3), RS(6,3), LRC(12,2,2), RS(9,3), and RS(12,3) is reduced by 43%, 45%, 24%,37%, and 30%, respectively.

Improving Serviceability: Figure 7c shows that RAFI reduces the *RNT* under various erasure coding schemes. The *Perm* represents the *RNT* induced only by permanent node failures. Figure 7e shows the composition of the *RNT*. In TFI, over 99% of the *RNT* is induced by the repair of S^1. In RAFI, about 15%-30% of the *RNT* is induced by the repair of S^{2+}.

Degraded Reads: When RAFI postpones the recovery of S^1, the amount of unidentified failed chunks increases. Figure 7d shows that the degraded reads increase by 1.7% at most, which is very slight.

5.3.3 RAS as Functions of Recovery Network Bandwidth

Network bandwidth is very valuable in the data centers. In this section, simulations are performed to understand the effect of RAFI under a limited recovery network bandwidth b. Both RS(6,3) and Zigzag(6,3) codes are considered in the simulations. T_1, T_2 and T_3 are 60 minutes, 0.5 minutes and 0.5 minutes, respectively. The simulation results are normalized to RS(6,3)-15-15 and presented in Figure 8.

Figure 8 shows that the RAS are still improved even when b is 40 Mbps. However, at the same time, the T_{uc} increases by 22%, because a small b significantly extends the repair time of the lost chunks, thus leads to longer chunk unavailability time. When b reduces, the reduction of *RNT* increases a little.

Table 3: The RAS improvements under 40 Gbps network

Erasure Coding Schemes	RS(6,3)	Zigzag(6,3)
Improvement of *MTTDL*	3.4	3.7
Reduction of T_{us}	54%	56%
Reduction of *RNT*	79%	86%

40 Gbps network: Nowadays, some data centers are equipped with 40 Gbps network for each node [26, 37]. In such a scenario, the recovery network bandwidth b is 4 Gbps for each node. Table 3 shows that RAFI still improves the RAS when b is 4 Gbps. When b increases from 100 Mbps to 4 Gbps, the recovery time reduces. Because the ratio between the recovery time and the repair time decreases, the improvement of *MTTDL* decreases. However, when the repair rate increases, there will be more unnecessary repair network traffic. Therefore, RAFI is very effective in reducing the repair network traffic.

5.3.4 Comparisons with *Lazy*

To comprehensively compare RAFI with *Lazy*, the comparisons are made in the form of TFI + *Lazy* v.s. RAFI + *Lazy* v.s. RAFI. RS(6,3) and Zigzag(6,3) codes are considered in the simulations. *Lazy* [14] recovers lost chunks if their host stripes have at least two lost chunks. In TFI + *Lazy*, we use the parameters: T_1 = T_2 = T_3 = 15 minutes. In RAFI + *Lazy*, T_1 = T_2 = 15 minutes, T_3 = 1 minutes. In RAFI, T_1 = 60 minutes and T_2 = T_3 = 15 minutes. The comparison results are shown in Figure 10.

Cooperating with *Lazy*, compared to TFI, RAFI improves the *MTTDL* by a factor of 5.1, at the cost of increasing the *RNT* by 2.5%. Because *Lazy* even does not recover some permanent failed chunks, RAFI cannot further reduce the *RNT*.

Compared to TFI + *Lazy*, RAFI without *Lazy* increases the *MTTDL* by over two orders of magnitude at a higher *RNT* cost. An interesting thing is that, RAFI suffers a much lower increase of the *RNT* when cooperating with the Zigzag codes. The reason is that the recovery penalty factor of a Zigzag(6,3)-coded S^1 is only 63% of that of an RS(6,3)-coded S^1. In fact, as mentioned in Section 6, many codes [6, 7] are proposed to reduce the recovery penalty factor of stripes with one lost chunk.

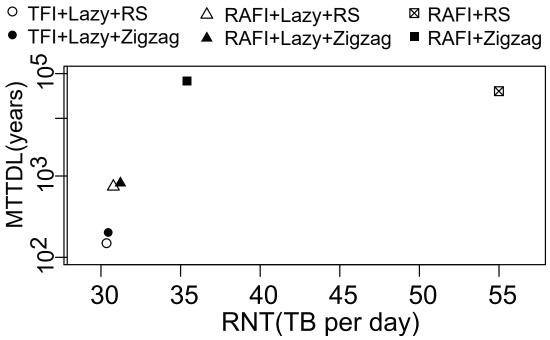


Figure 10: The *MTTDL* and *RNT* under TFI+*Lazy*, RAFI+*Lazy*, and RAFI. The erasure coding schemes are RS(6,3) and Zigzag(6,3). X axis is the repair network traffic, Y axis is the *MTTDL*.

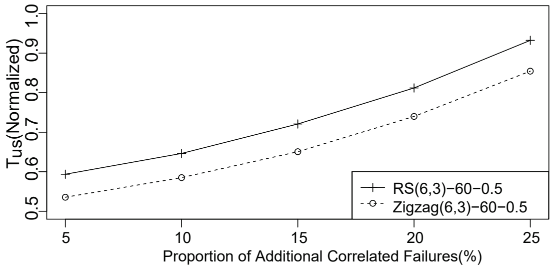

Figure 11: Impact of correlated failures on availability. The results are normalized to RS(6,3) with no additional correlated failures.

5.3.5 Availability under Correlated Failures

Because transient failures may happen concurrently [20], we desire to see how data availability is affected by correlated failures. From Figure 11, we can see that, as the proportion of additional correlated failures increases, RAFI still reduces about 40% of the T_{us}, demonstrating that RAFI is very resilient to correlated failures.

6 Related Work

Existing solutions which are proposed to improve the RAS focus on optimizing the failure recovery phase, such as reducing recovery penalty factors [2, 4, 5, 7–13, 16, 17, 22, 23], improving recovery rates [6, 18, 19], and risk-aware recovery scheduling [3, 7, 14].

Reducing recovery penalty factors: Both the recovery time and repair network traffic are improved through reducing the recovery penalty factors of erasure codes. Two types of techniques are proposed. One is to design MDS and non-MDS erasure codes with low recovery penalty factors [2, 6–12, 15–17, 38]. The other is to design recovery algorithms to reduce recovery penalty factors of existing erasure codes [4, 5, 13].

Regenerating Codes [22, 23, 38, 39] are a family of MDS codes. The recovery penalty factors of the Regenerating Codes are much lower than that of the traditional RS (Reed-Solomon) codes [40]. However, the Regenerating Codes are not systematic codes, thus suffer from high read cost. To maintain low recovery penalty factors and read cost, systematic MDS codes, such as Zigzag and Butterfly codes [10, 17] are proposed. Zigzag codes [10] are proved to be with optimal recovery penalty factors in all systematic MDS codes. One significant drawback of Zigzag codes is that the implementation depends on non-binary algebra.

New trade-off points between storage overheads and recovery penalty factors are found through non-MDS codes, such as LRC [7, 11, 16]. Compared to MDS codes, non-MDS codes dramatically reduce the recovery penalty factors. However, the cost of non-MDS codes cannot be ignored, particular when the scale of the data center is very large, i.e., even 1% extra storage overhead usually means millions of dollars [41, 42].

Recovery algorithms, such as [4,5,13], are proposed to reduce recovery penalty factors of existing erasure codes. The biggest drawback of those recovery algorithms is that their efficiency on reducing recovery penalty factors are much lower than that of designing novel codes.

Improving the recovery rate: Another approach to shorten the recovery time is improving the recovery rate.

It is common to improve the recovery rate through deploying high-speed networks, i.e., increasing the recovery network bandwidth. For example, CLOS networks [24–26] are deployed in FDS [6] to provide non-oversubscribed full bisection bandwidth networks at the scale of a data center. As a result, the recovery is dramatically accelerated.

The recovery rate is also improved through increasing the recovery parallelism. Mitra et al. propose a parallel chunk recovery method PPR [18] to improve the recovery parallelism. Li et al. propose a pipelined chunk recovery method ECPipe [19] to further improve that recovery parallelism. However, both PPR and ECPipe take effect when there are only a few chunks be recovered.

Risk-aware recovery scheduling: Besides accelerating the recovery of all chunks, high data reliability and availability can also be achieved through scheduling the recovery of chunks according to the *number of lost chunks* in their host stripes, which indicates the data reliability and availability risk of those stripes.

The recovery of the chunks in high risk stripes is prioritized in HDFS [3] and WAS [7]. In such a manner, the repair time of high risk stripes is dramatically reduced. Meanwhile, the increase of the repair time is relatively small. Therefore, the data reliability and availability are improved. It is worth noting that, after being scheduled, the failure identification time becomes dominant in the repair time of high risk stripes, because those chunks in high risk stripes are usually very few. **As a result, the reduction in the identification time of high risk stripes is very effective in improving the data reliability and availability.**

Silberstein et al. propose a technique *Lazy* [14] to reduce the repair network traffic. Because chunks in low risk stripes, e.g., S^1, are dominant in all chunks be recovered, most of the repair network traffic is generated by recovering those chunks. Canceling the recovery of chunks in low risk stripes dramatically reduces the repair network traffic. However, the data reliability and availability dramatically decrease.

7 Conclusions

In this paper, we present a risk-aware failure identification scheme, named RAFI, to simultaneously improve the data reliability, availability, and serviceability (RAS) of erasure-coded data centers. The basic idea of RAFI is identifying a chunk failure not only according to its failure duration, but also based on the data reliability and availability of its host stripe. The benefits of RAFI are: (1) the identification of failed chunks in high risk stripes is expedited to improve the data reliability and availability; and (2) the identification of failed chunks in low risk stripes is postponed to reduce the repair network traffic, thus improving the serviceability. Our results based on both simulations and prototyping have demonstrated the effectiveness and efficiency of RAFI in terms of reduced data loss, unavailability, and repair network traffic.

Siphon: Expediting Inter-Datacenter Coflows in Wide-Area Data Analytics

Shuhao Liu, Li Chen and Baochun Li
Department of Electrical and Computer Engineering, University of Toronto

Abstract

It is increasingly common that large volumes of production data originate from geographically distributed datacenters. Processing such datasets with existing data parallel frameworks may suffer from significant slowdowns due to the much lower availability of inter-datacenter bandwidth. Thus, it is critical to optimize the delivery of inter-datacenter traffic, especially *coflows* that imply application-level semantics, to improve the performance of such geo-distributed applications.

In this paper, we present *Siphon*, a building block integrated in existing data parallel frameworks (*e.g.,* Apache Spark) to expedite their generated inter-datacenter coflows at runtime. Specifically, Siphon serves as a transport service that accelerates and schedules the inter-datacenter traffic with the awareness of workload-level dependencies and performance, while being completely transparent to analytics applications. Novel intra-coflow and inter-coflow scheduling and routing strategies have been designed and implemented in Siphon, based on a software-defined networking architecture.

On our cloud-based testbeds, we have extensively evaluated Siphon's performance in accelerating coflows generated by a broad range of workloads. With a variety of Spark jobs, Siphon can reduce the completion time of a single coflow by up to 76%. With respect to the average coflow completion time, Siphon outperforms the state-of-the-art scheme by 10%.

1 Introduction

Big data analytics applications are typically developed with modern data parallel frameworks, such as Apache Hadoop [1] and Spark [25], taking advantage of their out-of-the-box features of scalability. With the trend of further scaling out, it has been reported that these applications are deployed across the globe, with their raw input data generated from different locations and stored in geographically distributed datacenters [19, 24]. When processing such geo-distributed data, computation tasks in different datacenters would transfer their intermediate results across the inter-datacenter network, which has much lower bandwidth, typically by an order of magnitude [12], than that within a datacenter. As such, applications that involve heavy inter-datacenter traffic easily suffer from significantly degraded performance, known as the *wide-area data analytics* [23].

To alleviate such performance degradation, existing work in the literature has largely focused on rearranging the pattern of inter-datacenter traffic, with the hope of relieving network bottlenecks. Specifically, one category of such efforts [19, 23, 24] attempted to design optimal mechanisms of assigning input data and computation tasks across datacenters, to reduce or balance the network loads. Another category of the existing work [12, 22] tried to adjust the application workloads towards reducing demands on inter-datacenter communications.

However, given particular traffic from an application, improving its performance by directly accelerating the completion of its inter-datacenter data transfers has been largely neglected. To fill this gap, we propose a deliberate design of a fast delivery service for data transfers across datacenters, with the goal of improving application performance from an orthogonal and complementary perspective to the existing efforts. Moreover, it has been observed that an application cannot proceed until all its flows complete [7], which indicates that its performance is determined by the collective behavior of all these flows, rather than any individual ones. We incorporate the awareness of such an important application semantic, abstracted as *coflows* [8], into our design, to better satisfy application requirements and further improve application-level performance.

Existing efforts have investigated the scheduling of coflows within a single datacenter [6, 8, 17, 27], where the network is assumed to be congestion free and abstracted as a giant switch. Unfortunately, such an assumption no longer holds in the wide area inter-datacenter network, yet the requirement for optimal coflow scheduling to improve application performance becomes even more critical.

In this paper, we present three inter-datacenter coflow scheduling strategies that can significantly improve application-level performance. *First*, we have designed a novel and practical inter-coflow scheduling algorithm to minimize the average coflow completion time, despite the unpredictable available bandwidth in wide-area networks. The algorithm is based on Monte Carlo simulations to handle the uncertainty, with several optimizations to ensure its timely completion and enforcement. *Second*, we have proposed a simple yet effective intra-coflow scheduling policy. It tries to prioritize a subset of flows such that the potential straggler tasks can be accelerated. *Finally*, we have designed a greedy multi-path routing algorithm, which detours a subset of the traffic on a bottlenecked link to an alternate idle path, such that the slowest flow in a shuffle can be finished earlier.

Further, to enforce these scheduling strategies, we have designed and implemented *Siphon*, a new building block for data parallel frameworks that is designed to provide a transparent and unified platform to expedite inter-datacenter coflows.

From the perspective of data parallel frameworks, Siphon decouples *inter-datacenter* transfers from *intra-datacenter* traffic, serving as a transport with full coflow awareness. It can be easily integrated to existing frameworks with minimal changes in source code, while being completely transparent to the analytics applications atop. We have integrated Siphon to Apache Spark [25].

With Siphon, the aforementioned coflow scheduling strategies become feasible thanks to its software-defined networking architecture. For the datapath, it employs *aggregator* daemons on all (or a subset of) workers, forming a virtual overlay network atop the inter-datacenter WAN, aggregating and forwarding inter-datacenter traffic efficiently. At the same time, a *controller* can make centralized routing and scheduling decisions on the aggregated traffic and enforce them on aggregators. Also, the controller can work closely with the resource scheduler of the data parallel framework, to maintain a global and up-to-date knowledge about ongoing inter-datacenter coflows at runtime.

We have evaluated our proposed coflow scheduling strategies with Siphon. Across five geographical regions on Google Cloud, we have evaluated the performance of Siphon from a variety of aspects, and the effectiveness of intra-coflow scheduling in accelerating several real Spark jobs. Our experimental results have shown an up to 76% reduction in the shuffle read time. Further experiments with the Facebook coflow benchmark [8] have shown an $\sim$ 10% reduction on the average coflow completion time as compared to the state-of-the-art schemes.

We make three original contributions in this paper:

- We have proposed a novel and practical inter-coflow scheduling algorithm for wide-area data analytics. Starting from analyzing the network model, new challenges in inter-datacenter coflow scheduling have been identified and addressed.
- We have designed an intra-coflow scheduling policy and a multi-path routing algorithm that improve WAN utilization in wide-area data analytics.
- We have built Siphon, a transparent and unified building block that can easily extend existing data parallel frameworks with out-of-box capability of expediting inter-datacenter coflows.

2 Motivation and Background

In modern big data analytics, the network stack traditionally serves to deliver *individual flows* in a timely fashion [3, 4, 26], while being oblivious to the application workload. Recent work argues that, by leveraging workload-level knowledge of flow interdependence, the proper scheduling of coflows can improve the performance of applications in datacenter networks [8].

As an application is deployed at an inter-datacenter scale, the network is more likely to be a system bottleneck [19]. Existing efforts in wide-area data analytics [12, 19, 22] all seek to avoid this bottleneck, rather than mitigating it. Therefore, it is necessary to enforce a systematic way of scheduling inter-datacenter coflows for better link utilization, given the fact that the timely completion of coflows can play an even more significant role in application performance.

However, new challenges arise in inter-datacenter networks, which have quite different characteristics as compared to datacenter networks [11, 14]. Such unique characteristics can invalidate the assumptions made by existing coflow scheduling algorithms.

First, inter-datacenter networks have a different network model. Networks are usually modeled as a big switch [8] or a fat tree [20] in the recent coflow scheduling literature, where the ingress and egress ports at the workers are identified as the bottleneck. This is no longer true in wide area data analytics, as the available bandwidth on inter-datacenter links are magnitudes lower than the edge capacity (see Table 1).

Second, the available inter-datacenter bandwidth fluctuates over time. Unlike in datacenter networks, the completion time of a given flow can hardly be predictable, which makes the effectiveness of existing deterministic scheduling strategies (*e.g.*, [8, 27]) questionable. The reason is easily understandable: though the aggregated link bandwidth between a pair of datacenters might be abundant, it is shared among tons of users and their

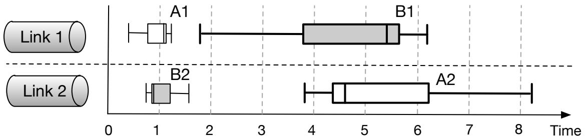

Figure 1: An example with two coflows, A and B, being sent through two inter-datacenter links. Based on link bandwidth measurements and flow sizes, the duration distributions of four flows are depicted with box plots. Note that the expected duration of $A1$ and $B2$ are the same.

launched applications, with varied, unsynchronized and unpredictable networking patterns.

Third, our ability to properly schedule and route inter-datacenter flows is limited. We may gain full control via software-defined networking within a datacenter [28], but such a technology is not readily available in inter-datacenter WANs. Flows through inter-datacenter links are typically delivered with best effort on direct paths, without the intervention of application developers.

To summarize, it calls for a redesigned coflow scheduling and routing strategy for wide-area data analytics, as well as a new platform to realize in existing data analytics frameworks. In this paper, Siphon is thus designed from the ground up for this purpose. It is an application-layer, pluggable building block that is readily deployable. It can support a better WAN transport mechanism and transparently enforce a flexible set of coflow scheduling disciplines, by closely interacting with the data parallel frameworks. A Spark job with tasks across multiple datacenters, for example, can take advantage of Siphon to improve its performance by reducing its inter-datacenter coflow completion times.

3 Scheduling Inter-Datacenter Coflows

3.1 Inter-Coflow Scheduling

Inter-coflow scheduling is the primary focus of the literature [6, 8, 21, 27]. In this section, we first analyze the practical network model of wide-area data analytics. Based on the new observations, we propose the details of a Monte Carlo simulation-based scheduling algorithm.

3.1.1 Goals and Non-Goals

Our major objective is to *minimize the average coflow completion time*, in alignment with the existing literature. However, we focus on inter-datacenter coflows, which are constrained by a different network model. In particular, based on the measurement in Table 1, we conclude that inter-datacenter links are the only bottlenecked resources, and congestion can hardly happen at the ingress or egress port. For convenience, we call it a *dumb bell* network structure. In addition, we consider the availability of inter-datacenter bandwidth as a dynamic resource. Scheduling across coflows should take runtime variations into account, making a scheduling decision that has a higher probability of completing coflows faster.

Similar to [8, 28], we assume the complete knowledge of ongoing coflows, *i.e.,* the source, the destination and the size of each flow are known as soon as the coflow arrives. Despite recent work [6, 27] which deals with zero or partial prior knowledge, we argue that this assumption is practical in modern data parallel frameworks. It is conceivable that the task scheduler is fully aware the potential cross-worker traffic before launching the tasks in the next stage and triggering the communication stage [1, 7, 25]. We will elaborate further on its feasibility in Sec. 4.3.

3.1.2 Schedule with Bandwidth Uncertainty

Coflow scheduling in a big switch network model has been proven to be NP-hard, as it can be reduced to an instance of the concurrent open shop scheduling with coupled resources problem [8]. With a dumb bell network structure, as contention is removed from the edge, each inter-datacenter link can be considered an independent resource that is used to service the coflows (jobs). Therefore, it makes sense to perform fully preemptive coflow scheduling, as resource sharing always results in an increased average [10].

The problem may seem simpler with this network model. However, it is the sharing nature of inter-datacenter links that complicates the scheduling. The real challenge is, being shared among tons of unknown users, the available bandwidth on a certain link is not predictable. In fact, the available bandwidth a random variable whose distribution can be inferred from history measurements. Thus, the flow durations are also random variables. The coflow scheduling problem in wide-area data analytics can be reduced to the *independent probabilistic job shop scheduling problem* [5], which is also NP-hard.

We seek a heuristic algorithm to solve this online scheduling problem. An intuitive approach is to make an estimation of the flow completion times, *e.g.,* based on the expectation of recent measurements, such that we can solve the problem by adopting a deterministic scheduling policy such as Minimum-Remaining Time First (MRTF) [8, 27].

Unfortunately, this naive approach fails to model the

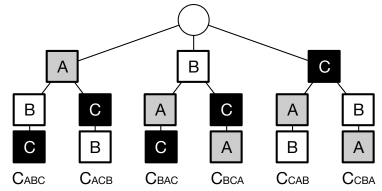

Figure 2: The complete execution graph of Monte Carlo simulation, given 3 ongoing coflows, A, B and C. The coflow scheduling order is determined by the distributions at the end of all branches.

probabilistic distribution of flow durations. Fig. 1 shows a simple example in which deterministic scheduling does not work. In this example, the available bandwidth on Link 1 and 2 have distinct distributions because users sharing the link have distinct networking behaviors. With Coflow A and B competing, the box plots depict the skewed distributions of flow durations if the corresponding coflow gets all the available bandwidth.

With a naive, deterministic approach that considers average only, scheduling either A or B will result in a minimum average coflow completion time. However, it is an easy observation that, with a higher probability, the duration of flow $A1$, will be shorter than $B2$. Thus, prioritizing Coflow A over B should yield an optimum schedule.

3.1.3 Monte Carlo Simulation-based Scheduling

To incorporate such uncertainty, we propose an online Monte Carlo simulation-based inter-coflow scheduling algorithm, which is greatly inspired by the offline algorithm proposed in [5].

The basic idea of Monte Carlo simulation is simple and intuitive: For every candidate scheduling order, we repeatedly simulate its execution and calculate its *cost*, *i.e.,* the simulated average coflow completion time. With enough rounds of simulations, the cost distribution will approximate the actual distribution of average coflow completion time. Based on this simulated cost distribution, we can choose among all candidate scheduling orders at a certain confidence level.

As an example, Fig. 2 illustrates an algorithm execution graph with 3 ongoing coflows. There are 6 potential scheduling orders, corresponding to the 6 branches in the graph. To perform one round of simulation, the scheduler generates a flow duration for each of the node in the graph, by randomly drawing from their estimated distributions. By summing up the cost for each branch, it yields a best scheduling decision instance, which results in a counter increment. After plenty of rounds, the best scheduling order will converge to the branch with the maximum counter value.

One major concern of this algorithm is its high complexity. With n ongoing coflows, there will be up to $n!$ branches in the graph of simulation. Luckily, thanks to the nature of coflow scheduling, we can apply the following techniques to limit the simulation search space.

Bounded search depth. In online coflow scheduling, all we care about is *the* coflow that should be scheduled *next*. This property makes a full simulation towards all leaf nodes unnecessary. Therefore, we set an upper bound, d, to the search depth, and simulate the rest of branches using MRTF heuristic and the median flow durations. This way, the search space is limited to a polynomial time $\Theta(n^d)$.

Early termination. Some "bad" scheduling decisions can be identified easily. For example, scheduling an elephant coflow first will always result in a longer average. Based on this observation, after several rounds of full simulation, we cut down some branches where performances are always significantly worse. This technique limit the search breath, resulting in a $O(n^d)$ complexity.

Online incremental simulation. As an online simulation, the scheduling algorithm should quickly react to recent events, such as coflow arrivals and completions. Whenever a new event comes, the previous job execution graph will be updated accordingly, by pruning or creating branches. Luckily, the existing useful simulation results (or partial results) can be preserved to avoid repetitive computation.

These optimizations are inspired by similar techniques adopted in Monte Carlo Tree Search (MCTS), but our algorithm differs from MCTS conceptually. In every simulation, MCTS tends to reach the leave of a single branch in the decision tree, where the outcome can be revealed. As a comparison, our algorithm has to go though all branches at a certain depth, otherwise we cannot figure out the optimal scheduling for the particular instance of available bandwidth.

3.1.4 Scalability

In wide-area data analytics, a centralized Monte Carlo simulation-based scheduling algorithm may be questioned with respect to its scalability, as making and enforcing a scheduling decision may experience seconds of delays.

We can exploit the parallelism and staleness tolerance of our algorithm. The beauty of Monte Carlo simulation is that, by nature, the algorithm is infinitely parallelizable and completely agnostic to staled synchronization. Thus, we can potentially scale out the implementation to a great number of scheduler instances placed in all worker datacenters, to minimize the running time of the scheduling algorithm and the propagation delays in enforcing scheduling decisions.

3.2 Intra-Coflow Scheduling

To schedule flows belonging to the same coflow, we have designed a preemptive scheduling policy to help flows share the limited link bandwidth efficiently. Our schedul-

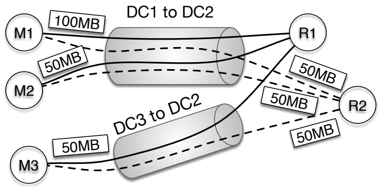

Figure 3: Network flows across datacenters in the shuffle phase of a simple job.

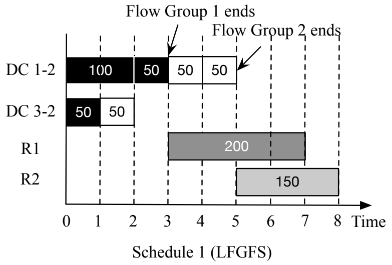

Figure 4: Job timeline with LFGF scheduling.

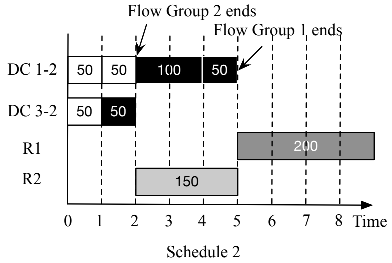

Figure 5: Job timeline with naive scheduling.

ing policy is called *Largest Flow Group First (LFGF)*, whose goal is to minimize *job* completion times. A *Flow Group* is defined as a group of all the flows that are destined to the same reduce task. The size of a flow group is the total size of all the flows within, representing the total amount of data received in the shuffle phase by the corresponding reduce task. As suggested by its name, LFGF preemptively prioritizes the flow group of the largest size.

The rationale of LFGF is to coordinate the scheduling order of flow groups so that the task requiring more computation can start earlier, by receiving their flows earlier. Here we assume that the task execution time is proportional to the total amount of data it received for processing. It is an intuitive assumption given no prior knowledge about the job.

As an example, we consider a simple Spark job that consists of two reduce tasks launched in datacenter 2, both requiring to fetch data from two mappers in datacenter 1 and one mapper in datacenter 3, as shown in Fig. 3. Corresponding to the two reducers *R1* and *R2*, two flow groups are sharing both inter-datacenter links, with the size of 200 MB and 150 MB, respectively. For simplicity, we assume the two links have the same bandwidth, and the calculation time per unit of data is the same as the network transfer time.

With LFGF, Flow Group 1, corresponding to *R1*, has a larger size and thus will be scheduled first. As is illustrated in Fig. 4, the two flows (*M1-R1*, *M2-R1*) in Flow Group 1 are scheduled first through the link between datacenter 1 and 2. The same applies to another flow (*M3-R1*) of Flow Group 1 on the link between datacenter 3 and 2. When Flow Group 1 completes at time 3, *i.e.*, all its flows complete, *R1* starts processing the 200 MB data received, and finishes within 4 time units. The other reduce task *R2* starts at time 5, processes the 150 MB data with 3 units of time, and completes at time 8, which becomes the job completion time.

If the scheduling order is reversed as shown in Fig. 5, Flow Group 2 will complete first, and thus *R2* finishes at time 5. Although *R1* starts at the same time as *R2* in Fig. 4, its execution time is longer due to its larger flow group size, which results in a longer job completion time. This example intuitively justifies the essence of LFGF — for a task that takes longer to finish, it is better to start it earlier by scheduling its flow group earlier.

3.3 Multi-Path Routing

Beyond ordering the coflows, we design a simple and efficient multi-path routing algorithm to utilize available link bandwidth better and to balance network load. The idea is similar to water-filling — it identifies the bottleneck link, and shifts some traffic to the alternative path with the lightest network load in an iterative fashion.

The bottleneck link is identified based on the time it takes to finish all the passing flows. In the first iteration, we calculate all the link load and the time it takes to finish all the passing flows, given that all the flows go through their direct links. To be particular, for each link l, the link load is represented as $D_l = d_i$, where d_i represents the total amount of data of the fetch i whose direct path is link l. The completion time is thus calculated as $t_l = D_l/B_l$, where B_l represents the bandwidth of link l. We identify the most heavily loaded link l^*, which has the largest t_{l^*}, and choose one of its alternative paths which has the lightest load for traffic re-routing. In order to compute the percentage of traffic to be rerouted from l^*, represented by α, we solve the equation $D_{l^*}(1-\alpha)/B_{l^*} = (D_{l^*}\alpha + D_{l'})/B_{l'}$, where l' is the link with the heaviest load on the selected detour path.

4 Siphon: Design and Implementation

4.1 Overview

To realize any coflow scheduling strategies in wide-area data analytics, we need a system that can flexibly enforce the scheduling decisions. Traditional traffic engineering [11, 14] techniques can certainly be applied, but they are not yet available to common cloud users. As is concluded in Sec. 2, Siphon is designed and implemented as a host-based building block to achieve this goal.

Fig. 6 shows a high-level overview of Siphon's architecture. Processes, called *aggregator daemons*, are deployed on all (or a subset of) workers, interacting with the worker processes of the data parallel framework directly. Conceptually, all these aggregators will form

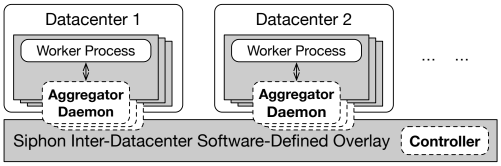

Figure 6: An architectural overview of *Siphon*.

an overlay network, which is built atop inter-datacenter WANs and supports the data parallel frameworks.

In order to ease the development and deployment of potential optimizations for inter-datacenter transfers, the Siphon overlay is managed with the software-defined networking principle. Specifically, aggregators operate as application-layer switches at the data plane, being responsible for efficiently aggregating, forwarding and scheduling traffic within the overlay. Network and flow statistics are also collected by the aggregators actively. Meanwhile, all routing and scheduling decisions are made by the central Siphon *controller*. With a flexible design to accommodate a wide variety of flow scheduling disciplines, the centralized controller can make fine-grained control decisions, based on coflow information provided by the resource scheduler of data parallel frameworks.

4.2 Data Plane

Siphon's data plane consists of a group of aggregator daemons, collectively forming an overlay that handles inter-datacenter transfers requested by the data parallel frameworks. Working as application-layer switches, the aggregators are designed with two objectives: it should be simple for data parallel frameworks to use, and supports high switching performance.

4.2.1 Software Message Switch

The main functionality of an aggregator is to work as a software switch, which takes care of fragmentizing, forwarding, aggregating and prioritizing the data flows generated by data parallel frameworks.

After receiving data from a worker in the data parallel framework, an aggregator will first divide the data into fragments such that they can be easily addressable and schedulable. These data fragments are called *messages*. Each data flow will be split into a sequence of messages to be forwarded within Siphon. A minimal header, with a flow identifier and a sequence number, will be attached to each message. Upon reaching the desired destination aggregator, they will be again reassembled and delivered to the final destination worker.

The aggregators can *forward* the messages to any peer aggregators as an intermediate nexthop or the final destination, depending on the forwarding decisions made by the controller. Inheriting the design in traditional OpenFlow switches, the aggregator looks up a forwarding table that stores all the forwarding rules in a hash table, to ensure high performance. Fortunately, wildcards in forwarding rule matching are also available, thanks to the hierarchical organizations of the flow identifiers. If neither the flow identifier nor the wildcard matches, the aggregator will consult the controller. A forwarding rule includes a nexthop to enforce routing, and a flow weight to enforce flow scheduling decisions.

Since messages forwarded to the same nexthop share the same link, we use a priority queue to buffer all pending outbound messages to support *scheduling* decisions. Priorities are allowed to be assigned to individual flows sharing a queue, when it is backlogged with a fully saturated outbound link. The control plane will be responsible for assigning priorities to each flows.

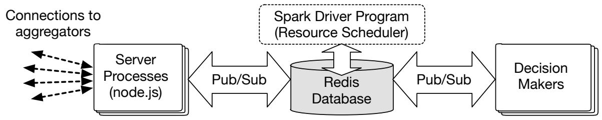
4.2.2 Performance-Centric Implementation

Since an aggregator is I/O-bounded, it is designed and implemented with performance in mind. It has been implemented in C++ from scratch with the event-driven asynchronous programming paradigm. Several optimizations are adopted to maximize its efficiency.

Event-driven design. events are raised and handled asynchronously, including all network I/O events. All the components are loosely coupled with one another, as each function in these components is only triggered when specific events it is designed to handle are raised. As examples of such an event-driven design, the switch will start forwarding messages in an input queue as soon as the queue raises a `PacketIn` event, and the output queue will be consumed as soon as a corresponding worker TCP connection raises a `DataSent` event, indicating that the outbound link is ready.

Coroutine-based pipeline design pattern. Because an aggregator may communicate with a number of peers at the same time, work conservation must be preserved. In particular, it should avoid head-of-line blocking, where one congested flow may take all resources and slow down other non-congested flows. An intuitive implementation based on input and output queues cannot achieve this goal. To solve this problem, our implementation takes advantage of a utility called "stackful coroutine," which can be considered as a procedure that can be paused and resumed freely, just like a thread whose context switch is controlled explicitly. In an aggregator, each received message is associated with a coroutine, and the total number of active coroutines is bounded for the same flow. This way, we can guarantee that non-congested flows can be served promptly, even coexisting with resource "hogs."

Minimized memory copying. Excessive memory copying is often an important design flaw that affects performance negatively. We used smart pointers and reference counting in our implementation to avoid memory



Connections to aggregators
Server Processes (node.js)

Decision Makers

Figure 7: The architecture of the Siphon Controller.

copying as messages are forwarded. In the lifetime of a message through an aggregator, it is only copied between the kernel socket buffers for TCP connections and the aggregator's virtual address space. Within the aggregator, a message is always accessed using a smart pointer, and passed between different components by copying the pointer, rather than the data in the message itself.

4.3 Control Plane

The controller in Siphon is designed to make flexible control plane decisions, including flow scheduling and routing.

Although the controller is a logically centralized entity, our design objective is to make it highly scalable, so that it is easy to be deployed on a cluster of machines or VMs when needed. As shown in Fig. 7, the architectural design of the controller completely decouples the decision making processes from the server processes that directly respond to requests from Siphon aggregators, connecting them only with a Redis database server. Should the need arises, the decision making processes, server processes, and the Redis database can be easily distributed across multiple servers or VMs, without incurring additional configuration or management cost.

The Redis database server provides a reliable and high-performance key-value store and a publish/subscribe interface for inter-process communication. It is used to keep all the states within the Siphon datapath, including all the live statistics reported by the aggregators. The publish/subscribe interface allows server processes to communicate with decision-making processes via the Redis database.

The server processes, implemented in `node.js`, directly handle the connections from all Siphon aggregators. These server processes are responsible for parsing all the reports or requests sent from the aggregators, storing the parsed information into the Redis database, and responding to requests with control decisions made by the decision-making processes. It is flexible how the decision-making processes are implemented, depending on requirements of the scheduling algorithm.

In inter-coflow scheduling, the controller requires the full knowledge of a coflow before it starts. This is achieved by integrating the resource scheduler of the data parallel framework to the controller's Pub/Sub interface. Particularly in Spark, the task scheduler running in the driver program have such knowledge as soon as the reduce tasks are scheduled and placed on workers. We have modified the driver program, such that whenever there are new tasks being scheduled, the generated traffic information will be published to the controller. The incremental Monte Carlo simulations will then be triggered on the corresponding parallel decision makers.

5 Performance Evaluation

In this section, we present our results from a comprehensive set of experimental evaluations with Siphon, organized into three parts. First, we provide a coarse-grained comparison to show the application-level performance improvements by using Siphon. A comprehensive set of machine learning workloads is used to evaluate our framework compared with the baseline Spark. Then, we try to answer the question how Siphon expedite a single coflow by putting a simple shuffle under the microscope. Finally, we evaluate our inter-coflow scheduling algorithm, by using the state-of-the-art heuristic as a baseline.

5.1 Macro-Benchmark Tests

Experimental Setup. In this experiment, we run 6 different machine learning workloads on a 160-core cluster, which spans across 5 geographical regions. Performance metrics such as application runtime, stage completion time and shuffle read time are to be evaluated. The shuffle read time is defined as the completion time of the slowest data fetch in a shuffle. It reflects the time needed for the last task to start computing, and it determines the stage completion time to some extent.

The Spark-Siphon cluster. We set up a 160-core, 520 GB-memory Spark cluster. Specifically, 40 `n1-highmem-2` instances are evenly disseminated in 5 Google Cloud datacenter (N. Carolina, Oregon, Belgium, Taiwan, and Tokyo). Each instance provides 2 vCPUs, 13 GB of memory, and a 20 GB SSD of disk storage. Except for one instance in the N. Carolina region works as both Spark master and driver, all instances serve as Spark standalone executors. All instances in use are running Apache Spark 2.1.0.

The Siphon aggregators run on 10 of the executors, 2 in each datacenter. An aggregator is responsible for handling Pub/Sub requests from 4 executors in the same datacenter. The Siphon controller runs on the same instance as the Spark master, in order to minimize the communication overhead between them.

Note that we do not launch extra resources for Siphon aggregators to make the comparison fair. Even though they occupy some computation resource and system I/Os with their co-located Spark executors, the consumption is minimal.

Workload specifications. 6 machine learning workloads, with multiple jobs and multiple stages, are used

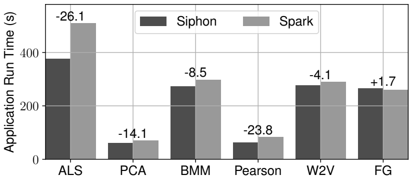

Figure 8: Average application run time.

Workload	# Shuffles	Total Bandwidth Usage(GB)	Extra Bandwidth Usage(MB)	Siphon Shuffle Read Time (s)	Spark Shuffle Read Time (s)	Runtime Reduction (%)	Cost Difference (¢)
ALS	18	40.47	2186.3	46.8	90.5	**48.3**	**-26.56**
PCA	2	0.51	37.6	3.3	13.7	**76.1**	**-6.80**

for evaluation.

- *ALS:* Alternating Least Squares.
- *PCA:* Principle Component Analysis.
- *BMM:* Block Matrix Multiplication.
- *Pearson:* Pearson's correlation.
- *W2V:* Word2Vec distributed presentation of words.
- *FG:* FP-Growth frequent item sets.

These workloads are the representative ones from Spark-Perf Benchmark[1], the official Spark performance test suite created by Databricks[2]. The workloads that are not evaluated in this paper share the same characteristics with one or more selected ones, in terms of the network traffic pattern and computation intensiveness. We set the scale factor to 2.0, which is designed for a 160-core, 600 GB-memory cluster.

Methodologies. With different workloads, we compare the performance of job executions, with or without Siphon integrated as its cross-datacenter data transfer service.

Note that, without Siphon, Spark works in the same way as the out-of-box, vanilla Spark, except one slight change on the `TaskScheduler`. Our modification eliminates the randomness in the Spark task placement decisions. In other words, each task in a given workload will be placed on a *fixed* executor across different runs. This way, we can guarantee that the impact of task placement on the performance has been eliminated.

Performance. We run each workload on the same input dataset for 5 times. The average application run time comparisons across 5 runs are shown in Fig. 8. Later we focus on job execution details, taking the run with median application run time for example. Table 2 summarizes the total shuffle size and shuffle read time of each workload. Further, Fig. 9 breaks down the time for network transfers and computation in each stage, providing more insight.

Among the 6 workloads, BMM, the most network-intensive workload, benefits most from Siphon. It enjoys a 23.6% reduction in average application run time. The reason is that it has one huge shuffle — sending more than 40 GB of data in one shot — and Siphon can help significantly. The observation can be proved by Fig. 9(c), which shows that Siphon manages to reduce around 50 seconds of shuffle read time.

Another network-intensive workload is ALS, an iterative workload. The average run time has been reduced by 13.2%. The reason can be easily seen with the information provided in Table 2. During a single run of the application, 40.47 GB of data is shuffled through the network, in 18 stages. Siphon collectively reduces the shuffle time by more than 30 seconds. Fig. 9(a) shows the CDFs of shuffle completion times and stage comple-

[1] `https://github.com/databricks/spark-perf`
[2] `https://databricks.com/`.

tion times, using Spark and Siphon respectively (note the *x*-axis is in log scale). As we observe, the long tail of the stage completion time distribution is reduced because Siphon has significantly improved the performance of all shuffle phases.

The rest of the workloads generate much less shuffled traffic, but their shuffle read time have also been reduced (5.4%∼76.1%).

PCA and Pearson are two workloads that have network-intensive stages. Their shuffle read time constitutes a significant share in some of the stages, but they also have computation intensive stages that dominate the application run time. For these workloads, Siphon greatly impacts the job-level performance, by minimizing the time used for shuffle (Table 2).

W2V and FG are two representative workloads whose computation time dominates the application execution. With these workloads, Siphon can hardly make a difference in terms of application run time, which is mostly decided by the computation stragglers. An extreme example is shown in Fig. 9(e). Even though the shuffle read time has been reduced by 4 seconds (Table 2), the computation stragglers in Stage 4 and Stage 6 will still slow down the application by 0.7% (Fig. 8). Siphon is not designed to accelerate these computation-intensive data analytic applications.

Cost Analysis. As the acceleration of Spark shuffle reads in Siphon is partially due to the relay of traffic through intermediate datacenters, it is concerned how it affects the overall cost for running the data analytics jobs. On the one hand, the relay of traffic increases the total WAN bandwidth usage, which is charged by public cloud providers. On the other hand, the acceleration of jobs reduces the cost for computation resources.

We present the total cost of running the machine learning jobs in Table 2, based on Google Cloud pricing[3]. Each instance used in our experiment costs \$1.184 per hour, and our cluster costs ¢ 0.6578 per second. As a comparison, the inter-datacenter bandwidth only costs 1 cent per GB.

As a result, Siphon actually reduced the total cost of running all workloads (Table 2). On the one hand, a small portion of inter-datacenter traffic has been relayed. On the other hand, the idle time of computing resources has been reduced significantly, which exceeds the extra bandwidth cost.

5.2 Single Coflow Tests

Experimental Setup. In the previous experiment, Siphon works well in terms of speeding up the coflows in complex machine learning workloads. However, one question remains unanswered: how does each component of Siphon contribute to the overall reduction on the coflow completion time? In this experiment, we use a smaller cluster to answer this question by examining a single coflow more closely.

The cross-datacenter Spark cluster consists of 19 workers and 1 master, spanning 5 datacenters. The Spark master and driver is on a dedicated node in Oregon. The geographical location of worker nodes is shown in Fig. 13, in which the number of executors in different datacenters is shown in the black squares. The same instance type (`n1-highmem-2`) is used.

Most software configurations are the same as the settings used in Sec. 5.1, including the Spark patch. In other words, the cluster still offers a fixed task placement for a given workload.

In order to study the system performance that generates a single coflow, we decided to use the `Sort` application from the HiBench benchmark suite [13]. `Sort` has only two stages, one map stage of sorting input data locally and a reduce stage of sorting after a full shuffle. The only coflow will be triggered at the start of the reduce stage, which is easier to analyze. We prepare the benchmark by generating 2.73 GB of raw input in HDFS. Every datacenter in the experiment stores an arbitrary fraction of the input data without replication, but the distribution of data sizes is skewed.

We compare the shuffle-level performance achieved by the following 4 schemes, with the hope of providing a comprehensive analysis of the contribution of each component of Siphon:

- *Spark:* The vanilla Spark framework, with fixed task placement decisions, as the baseline for comparison.
- *Naive:* Spark using Siphon as its data transfer service, without any flow scheduling or routing decision makers. In this case, messages are scheduled in a round-robin manner, and the inter-datacenter flows are sent directly through the link between the source to the destination aggregators.
- *Multi-path:* The *Naive* scheme with the multi-path routing decision maker enabled in the controller.
- *Siphon:* The complete Siphon evaluated in Sec. 5.1. Both LFGF intra-coflow scheduling and multi-path routing decision makers are enabled.

Job and stage level performance. Fig. 10 illustrates the performance of sort jobs achieved by the 4 schemes aforementioned across 5 runs, with respect to their job completion times, as well as their stage completion times for both map and reduce stages. As we expected, all 3 schemes using Siphon have improved job performance by accelerating the reduce stage, as compared to *Spark*. With *Naive*, the performance improvement is due to a higher throughput achieved by pre-established parallel TCP connections between Siphon aggregators.The im-

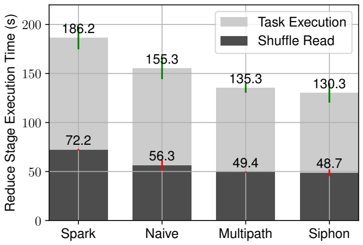

Figure 11: Breakdowns of the reduce stage execution across 5 runs.

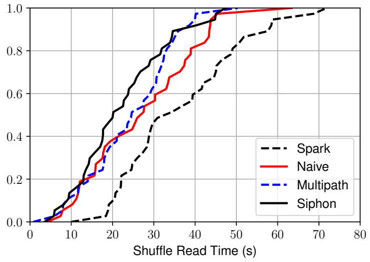

Figure 12: CDF of shuffle read time (present the run with median job completion time).

provement of *Multi-path* over *Naive* is attributed to a further reduction of reduce stage completion times — with multi-path routing, the network load can be better balanced across links to achieve a higher throughput and faster network transfer times. Finally, it is not surprising that *Siphon*, benefiting the advantages of both intra-coflow scheduling and *Multi-path* routing, achieves the best job performance.

To obtain fine-grained insights on the performance improvement, we break down the reduce completion time further into two parts: the shuffle read time (*i.e.,* coflow completion time) and the task execution time. As is shown in Fig. 11, the improvement of *Naive* over *Spark* is mainly attributed to a reduction of the shuffle read time.*Multi-path* achieves a substantial improvement of shuffle read time over *Naive*, since the network transfer completes faster by mitigating the bottleneck through multi-path routing. *Siphon* achieves a similar shuffle read time with *Multi-path*, with a slight reduction in the task execution time. This implies that multi-path routing is the main contributing factor for performance improvement, while intra-coflow scheduling helps marginally on the straggler mitigation as expected.

Shuffle: Spark v.s. Naive. To allow a more in-depth analysis of the performance improvement achieved by the baseline Siphon (*Naive*), we present the CDFs of shuffle read times achieved by *Spark* and *Naive*, respectively, in Fig. 12. Compared with the CDF of *Spark* that exhibits a long tail, all the shuffle read times are reduced by ∼10 s with *Naive*, thanks to the improved throughput achieved by persistent, parallel TCP connections between aggregators.

Shuffle: intra-coflow scheduling and multi-path routing. We further study the effectiveness of the decision makers, with *Multi-path* and *Siphon*'s CDFs presented in Fig. 12.

With multi-path routing enabled, both *Multi-path* and *Siphon* achieve shorter completion times (∼50 s) for their slowest flows respectively, compared to *Naive* (>60 s) with direct routing. Such an improvement is contributed by the improved throughput with a better balanced load across multiple paths. It is also worth noting that the percentage of short completion times achieved with *Multi-path* is smaller than *Naive* — 22% of shuffle reads complete within 18 s with *Multi-path*, while 35% complete with *Naive*. The reason is that by rerouting flows from bottleneck links to lightly loaded ones via their alternative paths, the network load, as well as shuffle read times, will be better balanced.

It is also clearly shown that with LFGF scheduling, the completion time of the slowest shuffle read is almost the same with that achieved by *Multi-path*. This meets our expectation, since the slowest flow will always finish at the same time in spite of the scheduling order, given a fixed amount of network capacity.

We further illustrate the inter-datacenter traffic during the sort job run time in Fig. 13, to intuitively show the advantage of multi-path routing. The sizes of the traffic between each pair of datacenters are shown around the bidirectional arrow line, the thickness of which is proportional to the amount of available bandwidth shown in Table 1.

The narrow link from Taiwan to S. Carolina becomes the bottleneck, which needs to transfer the largest amount of data. With our multi-path routing algorithm, part of the traffic will be rerouted through Oregon. We can observe that the original traffic load along this path is not heavy (only 149 MB from Taiwan to Oregon and 170 MB from Oregon to S. Carolina), and both alternate links have more available bandwidth. This demonstrates that our routing algorithm works effectively in selecting optimal paths to balance loads and alleviate bottlenecks.

5.3 Inter-Coflow Scheduling

In this section, we evaluate the effectiveness of Monte Carlo simulation-based inter-coflow scheduling algorithm, by comparing the average and the 90th-percentile Coflow Completion Time (CCT) with existing heuristics.

Testbed. To make the comparison fair, we set up a testbed on a private cloud, with 3 datacenters located in **V**ictoria, **T**oronto, and **M**ontreal, respectively. We have conducted a long-term bandwidth measurement among them, with more than 1000 samples collected for each link. Their distributions are depicted in Fig. 14, which are further used in the online Monte Carlo simulation.

Benchmark. We use the Facebook benchmark [8] workload, which is a 1-hour coflow trace from 150 work-

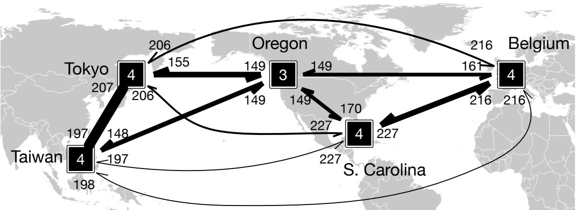

Figure 13: The summary of inter-datacenter traffic in the shuffle phase of the sort application.

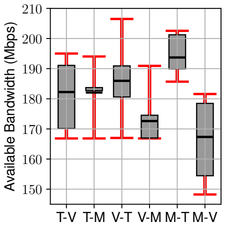

Figure 14: Bandwidth distribution among datacenters.

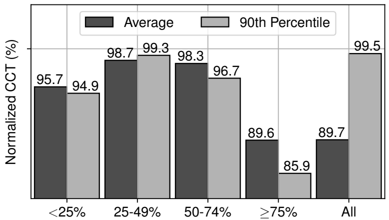

Figure 15: Average and 90th percentile CCT comparison.

ers. We assume workers are evenly distributed in the 3 datacenters, and generate aggregated flows on inter-datacenter links. To avoid overflow, the flow sizes are scaled down, with the average load on inter-datacenter links reduced by 30%.

Methodology. A coflow generator, together with a Siphon aggregator, is deployed in each datacenter. All generated traffic goes through Siphon, which can enforce proper inter-coflow scheduling decisions on inter-datacenter links. As a baseline, we experiment with the Minimum Remaining Time First (MRTF) policy, which is the state-of-the-art heuristic with full coflow knowledge [27]. The metrics CCTs are then normalized to the performance of the baseline algorithm.

Performance. Fig. 15 shows that Monte Carlo simulation-based inter-coflow scheduling outperforms MRTF in terms of both average and tail CCTs. Considering all coflows, the average CCT is reduced by ∼10%. Since the coflow size in the workload follows a long-tail distribution, we further categorize coflows in 4 bins, based on the total coflow size. Apparently, the performance gain mostly stems from expediting the largest bin – elephant coflows that can easily overlap with each other. Beyond MRTF, Monte Carlo simulations can carefully study all possible near-term coflow ordering with respect to the unpredictable flow completion times, and enforce a decision that is statistically optimal.

6 Related Work

Wide-Area Data Analytics. For data analytics spanning across datacenters, wide area network links easily become the performance bottleneck. To reduce the usage of inter-datacenter bandwidth, existing works either tweak applications to generate different workloads [12, 16, 23, 24], or assign input datasets and tasks to datacenters optimally [19, 22]. However, all these efforts focus on adding wide-area network awareness to the computation framework, without tackling the lower-level inter-datacenter data transfers directly. Orthogonal and complementary to these efforts, Siphon is designed for the inter-datacenter network optimization — it delivers the inter-datacenter traffic with better efficiency, regardless of the upper-layer decisions on task placement or execution plan.

Software-Defined Networking (SDN). The concept of SDN has been proposed to facilitate the innovation in network control plane [2, 18].In the inter-datacenter wide-area network, SDN has been recently adopted to provide centralized control with elegantly designed traffic engineering strategies [11, 14, 15]. Different from these efforts, our work realizes the SDN principle in the application layer, without requiring hardware support. Moreover, our work focuses on improving performance for data analytics jobs with more complex communication patterns, controlling flows at a finer granularity.

Network Optimization for Data Analytics. Accounting for the job-level semantics, coflow scheduling algorithms (*e.g.*, [6, 8, 9]) are proposed to minimize the average coflow completion time within a datacenter network, which is assumed to be free of congestion. Without such assumptions, joint coflow scheduling and routing strategies [17, 28] are proposed in the datacenter network, where both the core and the edge are congested. Different from these models, the network in the wide area has congested core and congestion-free edge, since the inter-datacenter links have much lower bandwidth than the access links of each datacenter. Apart from the different network model, our coflow scheduling handles the uncertainty of the fluctuating bandwidth in the wide area, while the existing efforts assume that the bandwidth capacities remain unchanged.

7 Concluding Remarks

To address the performance degradation of data analytics deployed across geographically distributed datacenters, we have designed and implemented Siphon — a building block that can be seamlessly integrated with existing data parallel frameworks — to expedite coflow transfers. Following the principles of software-defined networking, a controller implements and enforces several novel coflow scheduling strategies.

To evaluate the effectiveness of Siphon in expediting coflows as well as analytics jobs, we have conducted extensive experiments on real testbeds, with Siphon deployed across geo-distributed datacenters. The results have demonstrated that Siphon can effectively reduce the completion time of a single coflow by up to 76% and improve the average coflow completion time.

Abstract

Large commercial latency-sensitive services, such as web search, run on dedicated clusters provisioned for peak load to ensure responsiveness and tolerate data center outages. As a result, the average load is far lower than the peak load used for provisioning, leading to resource under-utilization. The idle resources can be used to run batch jobs, completing useful work and reducing overall data center provisioning costs. However, this is challenging in practice due to the complexity and stringent tail-latency requirements of latency-sensitive services. Left unmanaged, the competition for machine resources can lead to severe response-time degradation and unmet service-level objectives (SLOs).

This work describes *PerfIso*, a performance isolation framework which has been used for nearly three years in Microsoft Bing, a major search engine, to colocate batch jobs with production latency-sensitive services on over 90,000 servers. We discuss the design and implementation of *PerfIso*, and conduct an experimental evaluation in a production environment. We show that colocating CPU-intensive jobs with latency-sensitive services increases average CPU utilization from 21% to 66% for off-peak load without impacting tail latency.

1 Introduction

New server acquisition contributes to over half of the total cost of ownership (TCO) of modern data centers [8]. However, server utilization is low in data centers hosting large latency-sensitive services for two main reasons: First, latency-sensitive services are typically provisioned for the peak load, which occurs only for a fraction of the total running time [18]. Second, business-continuity plans dictate tolerating multiple major data center outages, such as tolerating the failure of two data centers out of three data centers within a continent while remaining capable of processing peak load. The high degree of over-provisioning is imperative: a livesite incident causing brief downtime results in lost revenue and frustrated users, while an extended downtime comes with negative headline news and irreparable business damage. Even slightly higher response times decrease user satisfaction and impact revenues [29, 10, 17].

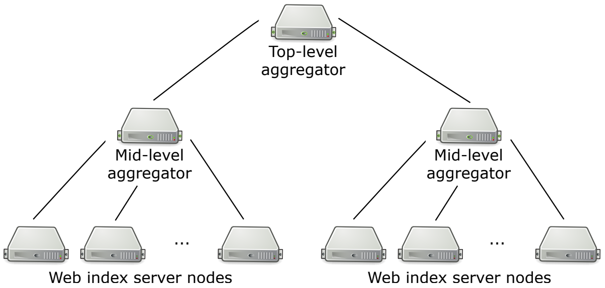

Figure 1: Architecture of index serving system of Web search engine with two aggregation levels (MLA and TLA). The user query is processed on index servers, which send responses to MLAs, which send aggregated responses to TLA.

Over-provisioning means that resource utilization is low, offering the opportunity to colocate batch jobs alongside latency-sensitive services [32, 18]. Colocation must be managed carefully lest it degrades performance due to competition on machine resources. Our main goal is to ensure that the end-to-end service-level objectives (SLOs) are met while increasing the work done by batch jobs. The main technical challenges arise from maintaining short tail latency (e.g., the 99^{th} latency percentile also called P99 latency) for the latency-sensitive services coupled with the complexity of commercial software and large deployments.

Oftentimes the service-level-objectives are not known explicitly for each individual component. For example, large commercial search engines contain tens of plat-

[*] Work done while authors were at Microsoft Research.

forms: to serve the web index, to build and update the web index, to manage user data and transaction history, to serve the most relevant advertisements, and to bill advertisers among many others. Modeling these components or assuming all their target latency values are known is not realistic.

Production environments are complex. A large data center comprising over 100,000 machines spans several generations of hardware. The generation gap can be up to 6 years, effectively constraining which hardware features can be used for performance isolation. Changes to the software stack running in a production environment are often infeasible. To be deployed on a large scale, the performance isolation framework must be robust, modular, and easy to debug. A good solution must provide the same performance guarantees seamlessly across all hardware and software configurations.

We describe our experiences in developing and deploying *PerfIso*, the performance isolation framework used in Microsoft's Bing clusters for over three years. We show how to colocate batch jobs with online services even when the tail response-latency requirements are within the order of milliseconds. We describe *CPU blind isolation* which dynamically restricts the cores that batch jobs use to protect the bursty interactive services even under high load. Depending on the load, batch jobs are given more or fewer resources to make progress.

Existing colocation approaches [20, 16, 34, 38] measure server-level performance metrics (e.g., query response times), and adjust resource allocation when the target is not met. This is not a good fit because if a query misses its target, it is already too late [17], and only end-to-end response time constraints are specified; per-layer service time limits are not.

We take a different approach: we ensure that there is always some slack in available resources such that abrupt changes in load do not impact response times. In contrast, traditional resource management polices focus on high resource-utilization while enforcing fair-sharing (most operating systems employ work-conserving scheduling algorithms). This works well for batch jobs, but does not account for factors such as the response-time latency of an interactive service. By using non-work-conserving resource management, we are able to adapt to changes in load and resource demands while treating the latency-sensitive service as a "black-box".

We focus on a concrete example: IndexServe — the Web index serving platform — because it is one of the largest in terms of machine count and has some of the strictest latency requirements. The web index is partitioned across hundreds or thousands of servers, and a user search query is processed in parallel on all servers. Responses are aggregated from the IndexServe machines on multiple levels (see Fig. 1). In such multi-layered systems, the slowest server dictates the response time [15].

To handle high load while meeting the strict latency requirements, many services are implemented as highly-optimized multi-threaded servers. The low query servicing-times make them highly bursty in nature: in several Bing services we find that, under high load, up to 15 threads become ready to run in just $5\mu s$. Due to the stringent tail-latency constraints, it is imperative to avoid scheduling delays, making the CPU the main bottleneck in our approach. We show that statically restricting CPU cores or CPU cycles does not fully solve the problem and fails to take advantage of idle cores during off-peak.

Our key goal is to ensure that interactive services perform equally well with batch jobs colocated as when they run alone. We show that CPU blind isolation successfully protects IndexServe while increasing average CPU utilization from 21% to 66% by colocating it with CPU-intensive jobs.

The main contributions of this work are as follows:

i. Identifying the key challenges of colocating batch jobs with large production latency-sensitive services and analyzing the effectiveness of operating system mechanisms to monitor and control resources.

ii. Introducing *CPU Blind Isolation* — a technique to mitigate harmful CPU-level interference between tenants.

iii. Designing and implementing the *PerfIso* performance isolation framework which allows batch jobs to be run alongside latency-sensitive services without any tail latency degradation.

iv. Evaluating *PerfIso* on a single machine to compare it to other alternatives, and on a 75-node production cluster, both running a real-world commercial online interactive service.

2 Background

We refer to the latency-sensitive user-facing services as *primary tenants*. All resources of a machine need to be available for them, since they generate the revenue that pays for the actual machines. The main goal of our system is to colocate batch jobs with a latency-sensitive user-facing service without impacting its response times. Thus, the primary always runs <u>unrestricted</u> and <u>unmodified</u>.

Batch jobs that run on these machines are *secondary tenants* and are treated in a best-effort manner — any resources they use are released to the system whenever the *primary* needs them. If the primary does not utilize all available resources, the secondary will be allowed to use some of them.

2.1 Applications and Services

Primary tenants comprise the latency-sensitive services which are governed by strict response-time SLOs. They are characterized by the following:

1. **a complex layered architecture** – hard to model or predict, since responses are computed in parallel and then aggregated.

2. **short tail latency** – any layer can severely impact query response times.

3. **highly bursty nature** – the service frequently spawns a large number of workers in a short period of time (order of microseconds).

Example primary tenant. We take the IndexServe component of **Bing** search as an example. IndexServe receives user queries and fetches potential matches from a search index. It can perform a variety of lookup and ranking operations. Its response times are within the order of milliseconds, and SLOs dictate that the 99^{th} percentile must stay within a 1-millisecond limit of its expected value (i.e., without colocation). Fig. 1 shows a simplified description of the layered architecture of IndexServe. Our measurements indicated that during a time frame of $5\mu s$, up to 15 threads became ready for execution.

Example secondary tenants. Non-latency-sensitive, big-data applications run alongside the primary. Popular big-data frameworks such as Hadoop [1], YARN [31], Apache Spark [35, 7], or Apache Flink [9] allow running a wide-range of compute-intensive (e.g., machine learning), and disk-bound (e.g., search index preparation and aggregation) jobs. Additionally, each server needs to run an *HDFS DataNode* process (for data replication), and a *YARN NodeManager* process (to handle individual task creation/destruction).

Both classes of tenants require access to several resources: CPU, disk, memory, network, etc. Accounting for potential resource bottlenecks is paramount in maintaining the performance of the primary. However, that alone is not sufficient, as our system needs to ensure that the secondary can make adequate progress, increasing the amount of work done when the primary is underutilized.

2.2 Driving Forces and Constraints

We focus on the performance requirements of the primary, without making any assumptions about its implementation. This enables wide-spread deployment, but makes it difficult to identify when the secondary interferes with the primary. Although we consider the CPU the main bottleneck, other resources also need to be monitored for contention.

Another key aspect is controlling resource access. Most operating systems already offer static mechanisms to restrict or prioritize access to a certain resource. While comprehensive, these are insufficient when dealing with bursty latency-sensitive workloads.

Given the complexity of production systems, it is hard to change the primary or the operating system (especially the kernel) due to the high costs of development, testing and deployment. Rather, our solution relies on features readily-available, and makes very few assumptions about the primary workload. In a nutshell, we treat the primary and the OS as a “black-box”.

3 System Design

3.1 CPU Blind Isolation

CPU is a prevalent bottleneck resource for most low-latency services and big-data frameworks [27]. Modern OSes implement effective means to statically manage CPU time across tenants [3, 4], such as throttling CPU cycles or restricting CPU cores. However, in Section 6.1.4 we show that they are ineffective because they cannot automatically adapt to the bursty workloads.

We propose a new technique called *CPU Blind Isolation*, which restricts which cores secondary tenants use based on core utilization information read from the OS. The key idea is to ensure that the primary *always has some headroom* (i.e., **buffer idle cores**), to absorb any primary worker-threads that wake up. The number of buffer cores is computed after offline-profiling of the primary using a sufficiently-heavy workload.

As the primary must always run unrestricted, we *restrict the secondary* to run only on a subset of cores. The secondary is allocated the cores remaining after subtracting the cores used by the primary and the number of buffer idle cores.

For example, consider a machine with 48 (physical) cores running a primary that needs 4 buffer cores to absorb bursts. If the primary uses 20 cores, the secondary would be restricted to 24 cores. If the primary goes up to 24 cores, the secondary is immediately restricted to 20.

Why not change the OS scheduler? We recognize that this solution can be implemented at the scheduler level. We argue that this is impractical and imposes significant overhead in large-scale deployment. Bugs introduced to the scheduler by seemingly-trivial changes are laborious to track down and can cause unexpected performance degradation. For example, the well-established Linux Completely-Fair-Scheduler has been found to have had bugs which caused threads to wait even when idle cores were available [21]. These bugs persisted in the codebase for several years. Our approach achieves performance isolation without interfering with the scheduler or the scheduling policy.

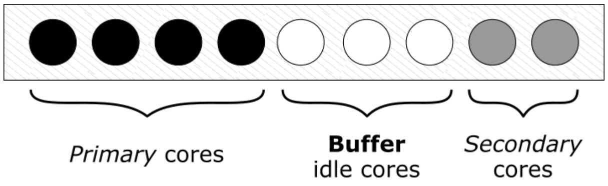

Figure 2: Conceptual representation of *CPU blind isolation*. The primary is unrestricted, and can run on any core, while the secondary is restricted to a subset of cores such that the primary always has a buffer of idle cores.

Non-work conserving scheduling In contrast to most OS schedulers, *blind isolation* is non-work conserving by nature. It deliberately chooses to leave several cores idle in order to properly measure and react to changes in the amount of work done by the primary. It is known that non-work conserving schedulers can improve performance in multi-processor scenarios [13]. We find that, similarly, blind isolation helps improve CPU utilization in the case of colocation.

3.1.1 Counting Idle Cores

An important requirement of our solution is a *low-latency*, *low-overhead* means of obtaining CPU utilization information. More specifically, we need to know how many cores are idle. We consider a core to be idle if the *idle thread* is running there.

The Windows scheduler keeps track of idle cores and provides this information through a system call. This system call returns a bit mask with the bits corresponding to the idle CPUs' ids set. We tested several other approaches relying on different metrics (e.g., recorded idle times, counting active threads), but found this solution to be best in terms of latency, overhead, and accuracy.

3.1.2 Allocating Cores to the Secondary

Once we know how many cores are idle we can detect whether the secondary needs to give up cores to the primary, or if the primary is not using all available cores. We assume that the secondary is CPU-intensive, and thus will fully occupy all cores allocated to it. If **I** is the number of idle cores in the system, **B** is the number of buffer cores, and **S** is the number of cores allocated to the secondary, then: if $\mathbf{I} < \mathbf{B}$, **S** is decreased, and if $\mathbf{I} > \mathbf{B}$, **S** is increased.

3.2 Managing Other Resources

Disk. We *choose which disks* are best suited for the primary and secondary. We find that it is necessary to separate the disks which are on the critical path of the primary from those used by the secondary. This is motivated by the nature of the tenants: the primary is highly-tuned towards read-only random accesses, so it is assigned to a striped set of solid-state disks (SSDs). In contrast, batch jobs often perform both reads and writes and mostly sequential in nature, so they are assigned to a striped set of hard-disks (HDDs).

Memory. Most low-latency services will manage their caches explicitly, loading data from disk as necessary depending on incoming queries. Furthermore, primary services are engineered to have a fixed working set and a stable memory footprint. We cannot compromise on this, and must guarantee the primary's ability to make full use of the memory. This is achieved by *limiting the memory footprint* of the secondary. When memory runs very low, secondary processes are killed.

Egress network packets. We *throttle* the outbound traffic of the secondary, marking it as low-priority and allowing the primary to maintain its throughput and response latency. This prevents the secondary from affecting the responsiveness of the primary.

4 Implementation and Deployment

We implemented *PerfIso* as a user-mode service based on the techniques and OS mechanisms described. Most of the static limits that *PerfIso* enforces are read from cluster-wide configuration files distributed through the Autopilot [14] environment. The resource limits can be altered independently at runtime by issuing a command to *PerfIso*. A client-application can also be used locally for debugging.

Although it is possible to obtain the unique process identifiers (PIDs) of the secondary tenants, Autopilot eases this task by keeping a list of running services and their respective information. Each secondary tenant process is placed in a unified *Job Object* configured dynamically by *PerfIso*.

4.1 Isolation Algorithm

The dynamic limits set by *PerfIso* need to be adjusted often. The state of the system needs to be read and the control knobs updated accordingly. Polling is important because the state of the primary can change quickly. Unfortunately, constantly updating certain settings can become harmful to the performance of all services. Thus, *polling and updating are separated* in *PerfIso*. We poll utilization data (e.g., CPU) continuously in a tight loop and we update the dynamic limits of the system on-demand based on the measured change in resource requirements.

Choosing the number of buffer cores. *CPU blind isolation* uses buffer cores to ensure that tail latency is protected while the system adjusts to changes in load. This requires that sufficient buffer cores are allocated to absorb bursty workloads. A one-off measurement of the primary under its provisioned peak load is needed to find how many threads can become ready for execution.

We evaluate different buffer core values in Section 6.1.3, and find that 8 cores are enough for IndexServe to maintain its 99th percentile SLO on our servers.

I/O throttling. The monitoring mechanisms provide only per-device I/O statistics, without discerning which processes originated the operations. In order to provide per-process throttling of I/O, we use *Deficit-Weighted-Round-Robin* [19]. Each process is assigned an I/O priority and one or more limits that need to be enforced (e.g., bandwidth, IOPS). Based on its priority, each process is assigned a weight – the higher the priority, the larger the weight. We then measure the number of completed I/O requests per second (or IOPS) per drive, and use a moving average.

We compute the portion of the requests a given process is responsible for based on its weight. Considering w_i^t the weight of process i at time t, and $curr^t$ the IOPS value measured at time t, then the demand of process i is:

$$D_i^t = \sum_{t'=t-\Delta}^{t} \frac{w_i^{t'} \times curr^{t'}}{\sum_{\forall j} w_j^{t'}}$$

We mark the lower limit of process i with lim_i, which represents the minimum amount of IOPS that process i is guaranteed. The deficit of this process with regard to the limit is:

$$\mathrm{Def}_i^t = \frac{curr^t - min(lim_i, D_i^t)}{min(lim_i, D_i^t)}$$

The I/O priorities of processes are adjusted based on the computed deficit values.

4.2 Deployment in Production Clusters

All machines run under a management framework such as Autopilot [14]. This provides machine wiping, imaging, backup, and monitoring functionality. Autopilot provides a stable service management interface to start, stop, and configure software. *PerfIso* is run as an additional service in Autopilot, making it easy to deploy, and to configure across various different environments.

PerfIso is designed to have a “kill-switch”, so that it can be quickly deactivated. This is useful when debugging production issues, and it allows quickly excluding *PerfIso* as a potential cause.

PerfIso is fully recoverable, since all parameters are stored in the cluster-wide configuration files. In the event of a crash, Autopilot will bring it up again, and *PerfIso* will resume its function by loading its state from disk.

PerfIso ensures that its settings do not affect those employed by the primary. For example, if the primary uses core affinitization for performance reasons, then *PerfIso* would not override these settings when attempting to accommodate the secondary.

5 Experimental Evaluation

5.1 Objectives

1. How is tail latency impacted by colocating batch jobs with the primary without *PerfIso*?

2. How effective is *PerfIso* in maintaining tail latency when a batch job is colocated with the primary?

3. How does CPU *blind isolation* compare to static isolation mechanisms provided by modern OSes?

5.2 Machine Configuration

We evaluate our solution on typical production hardware. Each server has two Intel Xeon E5-2673 v3 processors with 12 physical cores per die (a total of 48 cores with hyper-threading), 128 GB of RAM, and a 10 GbE Ethernet card. Storage is provided by 2 striped volumes: 4× 500 GB SSD drives, and 4× 2 TB HDD drives. The servers run Microsoft Windows Server 2016.

5.3 Experiment Setup

We use Bing IndexServe as the **primary** tenant in our experiments. IndexServe processes a search query to find a match using a large index partitioned across machines and replicated for performance.

IndexServe is setup with an index slice of 569 GB, and uses approximatively 110 GB of memory to cache recently accessed web index data. The index slice is stored on the striped SSD volume which IndexServe uses exclusively. IndexServe relies on the SSDs’ low I/O latency to maintain its tail latency requirements. The HDD volume is only used by IndexServe for logging, being shared with the secondary. The service is configured to return the most relevant matches.

Primary workload. We use a trace of 500k real-world queries from early 2017 to put load on the primary. A separate client machine is used to submit queries from the trace. We first replay a warm-up trace of 100k queries at a rate of 300 queries / second (QPS) so that IndexServe ramps up and reaches a steady-state. The warm-up is not reported as part of our measurements.

We vary the load by changing the query arrival rate, *i.e.*, we replay our trace at different query rates. The following represent a reasonable approximation of query arrival rates that an IndexServe machine might receive at the time that this paper was written:

- 2,000 QPS - approximating average load

- 4,000 QPS - approximating peak load

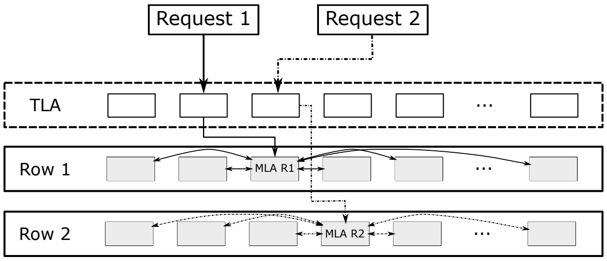

Figure 3: Request processing on the 75 machine IndexServe cluster described in Section 5.3. All gray machines run IndexServe and hold a slice of the index.

The client application replays the query trace in an open loop and sends queries according to a Poisson process distribution.

Secondary workload. We use a synthetic microbenchmark as the **secondary** to stress the CPU by actively utilizing as many CPU cycles as the system permits, pushing *blind isolation* to its limits. This **CPU bully** is a multi-threaded program with each worker thread computing the sum of several integer values. The number of worker threads is configurable and we vary it up to the total number of logical cores present on the system. The bully maximizes CPU utilization since there are very few memory or external storage accesses.

Single-machine experiments. We run IndexServe on a single machine configured as described above. We measure the impact of CPU contention on tail query response time, the most important metric being the 99th percentile.

Cluster experiments. We setup IndexServe across 75 machines, in the following manner: the index is split into 22 partitions (or *columns*), and each column is replicated by a factor of 2 (total of 2 *rows*). Each IndexServe server holds a partition of the index similarly to the single-box runs. The top-level aggregator (TLA) runs on 31 separate machines than the ones that hold the index. The mid-level aggregator (MLA) runs on IndexServe machines, and each request may get forwarded to a different MLA based on the TLA load-balancing. Fig. 3 shows an example of the system processing 2 incoming requests.

Each IndexServe machine also runs an HDFS client because many batch jobs that are used in production run on top of frameworks such as Hadoop and, thus, rely on HDFS for storage access. In addition to other experiment-specific *PerfIso* settings, we also set the following static disk bandwidth limits: data replication is limited to 20MB/s, and HDFS clients are limited to 60 MB/s. All I/O operations done by HDFS are unbuffered.

A client is setup on a separate machine and configured to submit queries to the TLA machines. We then run a trace of 200k queries at a total rate of 8,000 QPS. The TLAs will load-balance these queries across the 2 rows, resulting in an average workload of 4,000 QPS for each IndexServe machine.

Additionally, we use a **Disk bully** to ensure that I/O generated by HDFS does not cause any server to straggle. We setup DiskSPD [5] to create an I/O bound workload on the HDD strip of each machine. We perform a mixed read-write workload, with 33% reads and 67% writes, with sequential accesses and synchronous I/O operations.

6 Experimental Results

We first evaluate *PerfIso* on a single machine and measure the effectiveness of CPU blind isolation. We then move on to a 75-machine cluster and analyze CPU isolation mechanisms, measuring latency end-to-end and at each component level. The main metric used is the 99th percentile of query response latency.

6.1 Single-machine Experiments

Going further, we analyze the baseline (or standalone) behaviour of IndexServe and three colocation scenarios:

- **No isolation** – The primary and secondary are colocated without any isolation.
- **Blind isolation** – The secondary is dynamically restricted in terms of CPU cores using our technique.
- **Alternative isolation** – The secondary is successively restricted in terms of CPU cores, and CPU cycles using OS-specific mechanisms.

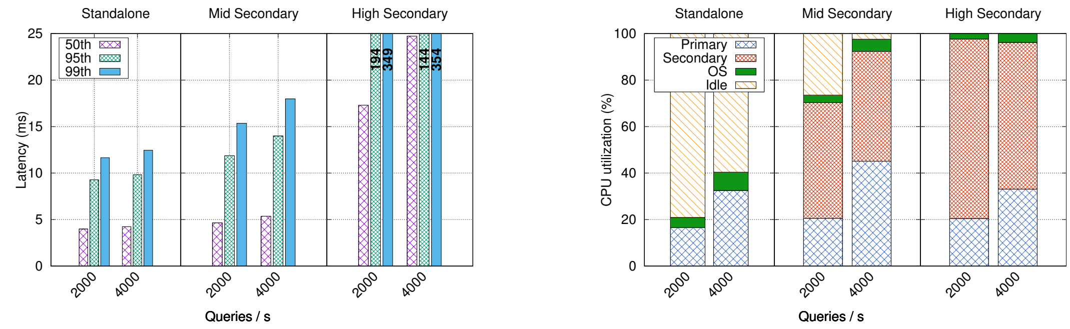
Our goal is to also maximize the amount of work done by the secondary, so we first configure each isolation technique with "relaxed" settings. We then successively restrict the secondary until either the SLO is met, or until the secondary no longer gets any work done.

6.1.1 Baseline

First, we measure how IndexServe performs when it runs standalone (i.e., no colocation). The 1st bar groups of Figs. 4a and 4b report the query latency and CPU utilization, respectively. The median query time is 4ms, and the 99th percentile is 12ms, both for 2,000 and 4,000 QPS. The average CPU utilization is low, with the CPU remaining idle for 80% and 60% of time, respectively.

6.1.2 No Isolation

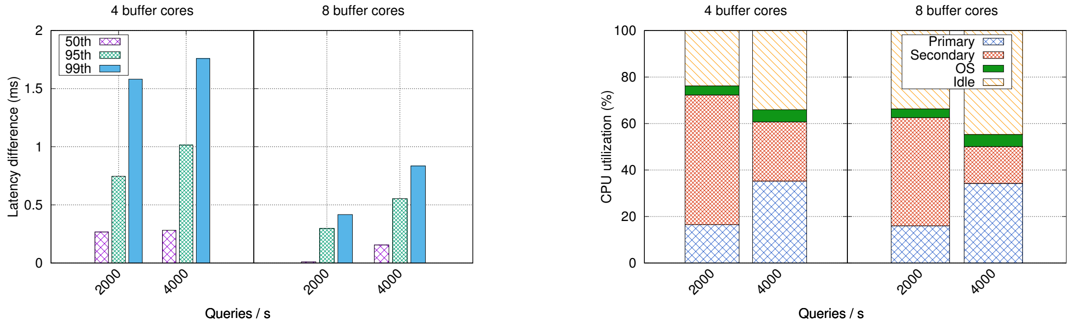
We colocate the primary and secondary, configuring the bully to use either *mid* (24 threads) or *high* (48 threads). The 2nd and 3rd columns of Figs. 4a and 4b report query latency and CPU utilization for the *mid* and



(a) Query response latency

(b) CPU utilization

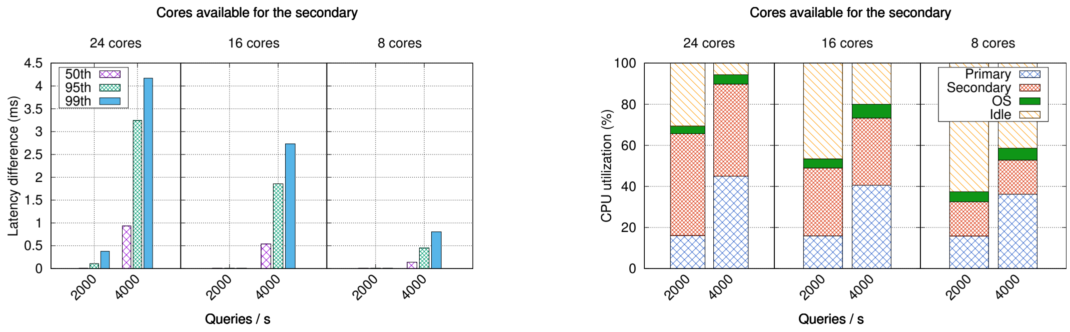
Figure 4: Single machine run of IndexServe standalone (no colocation) vs. colocated with an unrestricted secondary. A *mid* secondary increases the 99th percentile query latency by up to 42%, while a *high* increases same by up to 29×.



(a) Query latency degradation

(b) CPU utilization

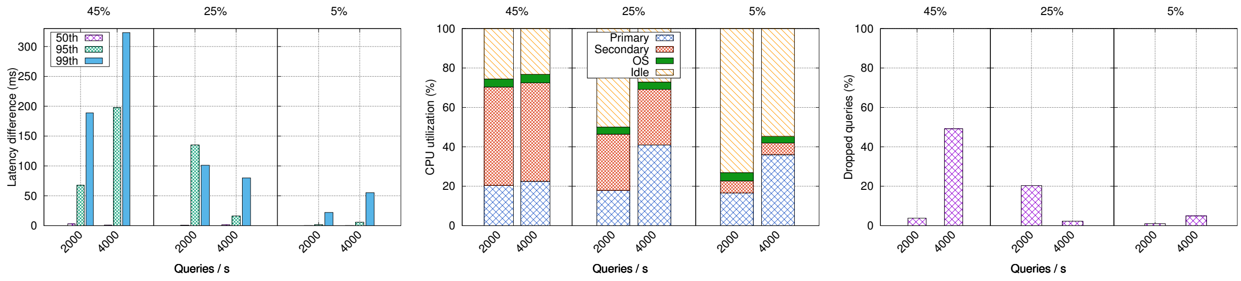
Figure 5: Single machine run of IndexServe colocated with a secondary restricted using blind isolation. Using a buffer of 8 CPU cores, the 99th percentile query latency is less than 1 ms off from the standalone case.



(a) Query latency degradation

(b) CPU utilization

Figure 6: Single machine run of IndexServe colocated with a secondary with CPU cores statically restricted.

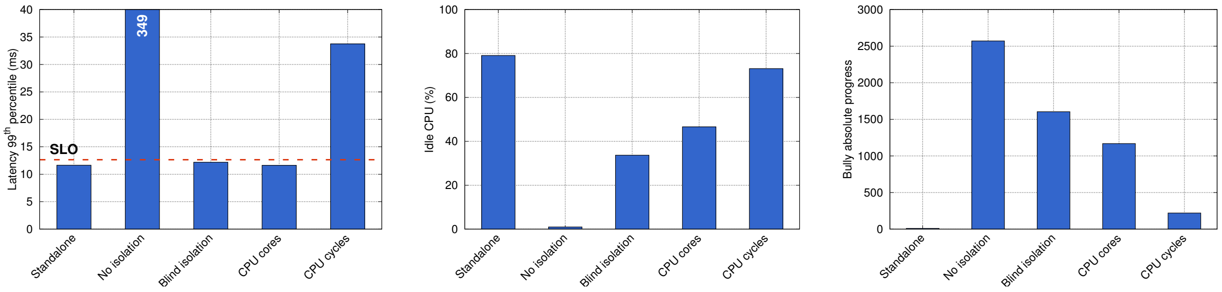


(a) Query latency degradation

(b) CPU utilization

(c) Dropped queries

Figure 7: Single machine run of IndexServe colocated with a secondary with CPU cycles statically restricted.



(a) Query latency

(b) Idle CPU

(c) Secondary progress

Figure 8: Comparison of isolation approaches on a single machine run of IndexServe at 2,000 QPS colocated with a secondary running in *high*-mode. CPU blind isolation uses 8 buffer cores, CPU cores allows the secondary to use 8 cores, and CPU cycles restricts the secondary to 5% of CPU time.

high configurations, respectively. The impact of colocation is substantial. The *mid* case reaches 15ms and 18ms in the 99th percentile for 2,000 and 4,000 QPS (higher than the baseline by 3-5ms). For *high*, these values reach 349ms and 354ms (a 29× degradation). Between 11% and 32% of queries timeout.

Fig. 4b shows the CPU utilization for the primary and secondary, and idle CPU. Interestingly, when colocated with the *mid* secondary, the CPU utilization of the primary increases up to 40% — IndexServe tries to compensate for the increase in pending queries by starting more workers. While this successfully prevents dropped queries, it ultimately aggravates CPU contention, and the latency SLO is not met. Another consequence is that the secondary gets less CPU time overall, since the primary will push it out from the only cores where it can run.

In the case of the *high* secondary, more than 32% of queries submitted at *peak* primary load are dropped due to the longer processing times, causing a decrease in primary CPU utilization.

6.1.3 Blind Isolation

We further use the 48 worker variant (*high*) secondary to evaluate the efficiency of isolation mechanisms.

We evaluate the blind isolation mechanism by reserving 4 and 8 buffer logical-cores, respectively. The insight here is to allow the primary to have a buffer of cores to start new worker threads when load increases.

Fig. 5a and Fig. 5b report our findings in terms of latency degradation and CPU utilization. We find that provisioning 8 idle logical cores is enough to ensure less than 1ms of degradation for the 99th latency percentile of the *high* workload.

6.1.4 Comparison to Alternative Isolation Methods

We next analyze the effectiveness of two common methods of static CPU resource management which are available in most modern OSes: *restricting CPU cores* and *restricting CPU cycles*. Windows provides these mechanisms through the *Job Object* abstraction [3], while Linux does so through the *cgroups* framework [4].

Restricting CPU cores. We successively restrict the secondary to use only 24, 16, and 8 cores of all 48 available logical cores. The primary is guaranteed exclusive and unimpeded access to the remainder, but can also compete for the secondary's cores. Fig. 6a shows the degradation of query response latency for each case.

Fig. 6b shows the overall CPU utilization breakdown when the bully is restricted to a subset of cores. When IndexServe is under average load, the secondary can claim up to 33% of the CPU time. While this is an important gain, the servers need to be provisioned for *peak* load, thereby reducing the subset of cores allocated to the secondary to 8 cores. With IndexServe under *peak* load, the secondary can only use up to 17% of the CPU time.

Restricting CPU cycles. We successively restrict the secondary to 45%, 25% and 5% of the overall CPU time.

Fig. 7a reports the measured degradation of latency, and Fig. 7c shows the percentage of queries that were dropped (because of increased processing times). Giving the bully even as little as 5% of CPU time still produces degradation. Furthermore, as opposed to restricting CPU cores, there is always some percentage of queries that get dropped, ranging from 50% to around 1% (in the best case). Fig. 7b shows that using this method less CPU time goes to the secondary.

The main reason this technique yields results worse than restricting CPU cores is that multi-threaded services such as IndexServe launch short-lived worker threads to process incoming requests. If these threads end up being queued for execution instead of being launched right away, it creates a cascading effect which impacts all incoming queries. Despite the secondary not utilizing more than its share of CPU time, IndexServe worker threads get delayed, leading to considerable degradation.

Progress of the secondary. Finally, we analyze the amount of work that the secondary gets done under isolation, as a percentage of the total work done when unrestricted. We report for each IndexServe workload the point where latency degradation was lowest for that experiment. Blind Isolation allows the secondary to achieve 62% and 25% of the work it did unrestricted, for 2,000 and 4,000 QPS, respectively. Restricting CPU cores yields a more modest 45% and a similar 30%, respectively. Restricting CPU cycles fares worst, yielding only 9% in both cases.

6.2 Cluster Experiments

We next look at how *PerfIso* performs in a production cluster. We evaluate at an approximation of peak load to stress the system, attempting to impact tail latency. This makes *PerfIso* throttle the secondary more aggressively to accommodate the primary.

As described in Fig. 3, requests arrive at one of many top-level aggregator (TLA) machines, which forwards the request in a round-robin fashion to one of the two rows of IndexServe machines (each row holds a partitioned copy of the search index). The TLA chooses an IndexServe machine from the row to act as the mid-level aggregator (MLA) for a particular request. The MLA queries all the other IndexServe instances in its row (including the local one), aggregates all results, and formulates the final query response.

We run each experiment 8 times, and measure query latency at a) each server, b) at each layer, and c) end-to-end. Fig. 9a reports the baseline query response latency, averaged across IndexServe machines, across MLAs, and across TLAs. The HDFS client takes up to 5% of total CPU time.

We start our CPU bully and configure *PerfIso* on each IndexServe machine for blind isolation in the same manner as the singlebox runs. Fig. 9b shows the query response latency for this CPU-bound workload. Compared to the baseline, the 99th percentile reported by IndexServe, MLA, and TLA instances increases by at most 0.8, 0.4, and 1.1 milliseconds, respectively.

We configure *PerfIso* to throttle disk I/O to either 100MB/s, or 20 IOPS/s, for a given operation data chunk size of 8KB. Fig. 9c shows the query response latency for this Disk-bound workload. Compared to the baseline, the 99th percentile reported by IndexServe, MLA, and TLA instances increases by at most 0.8, 1.2, and 1.1 milliseconds, respectively.

Progress results with larger cluster. Finally, we show production results for a cluster of 650 IndexServe machines processing live user queries while colocated with a large batch job executing the training phase of a machine-learning computation. Fig. 10 shows key performance metrics: load in QPS, 99th percentile latency of query response times measured at the TLA, and server CPU utilization averaged across all machines. Importantly, CPU utilization averages 70% over 1 hour.

6.3 Takeaways

We now present a sum-up of our evaluation, referring to the objectives established in Section 5.1:

1. Fig. 8a shows that a CPU-bound batch job can importantly affect the 99th percentile query latency of the primary, reaching up to 29× degradation. Fig. 4a shows that even a mildly CPU-intensive job can cause interference and can increase tail latency by up to 42%.

2. Fig. 8a shows that *blind isolation* successfully protects tail latency under medium load (2,000 QPS), and Fig. 4a shows that this holds for *peak* loads (4,000 QPS) as well. In the latter case, the 99th percentile is within 1 ms of the standalone case. Fig. 9 reports the results for 8 runs of an approximated *peak* load (4,000 QPS) on a production cluster, showing that *PerfIso* successfully protects tail latency. The query response latency tail for CPU and Disk-bound jobs (Figs. 9b and 9c) is within 1.2 milliseconds of the standalone case (Fig. 9a). Fig. 10 shows that *blind isolation* raises CPU utilization to 70% through colocation over the course of 1 hour on a 650-machine IndexServe cluster.

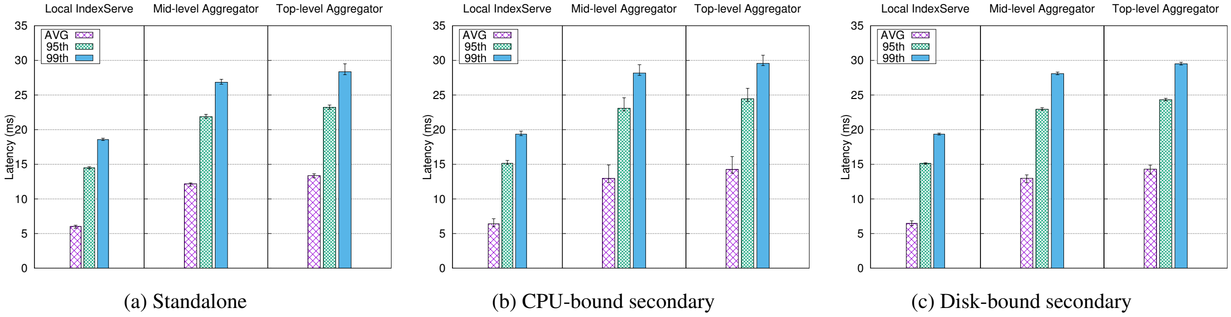
3. Fig. 8 reports a full comparison of all our evaluated techniques, showing that *blind isolation* and *cpu cores* both protect tail latency. However *blind isolation* manages to reduce idle cpu time by a further 13% compared to *cpu cores*, and allows the secondary to perform 17% more work. *CPU cycles* fails to protect tail latency.

We conclude that *PerfIso* successfully protects tail latency across all IndexServe machines, ultimately preserving the end-to-end SLOs.

7 Related Work

Many existing solutions propose colocation to increase data center utilization, but rely on information about the primary tenant's SLO and workload, or on specific hardware support. The complexity and performance characteristics (e.g., tail latency requirements and bursty nature) of primary tenants pushed our design into a different direction, adopting a black-box model with few assumptions on hardware for large-scale deployment.

MS Manners [12] provides CPU-level performance isolation on single-core machines by restricting the CPU



(a) Standalone

(b) CPU-bound secondary

(c) Disk-bound secondary

Figure 9: Latency values for IndexServe running on a production cluster: Fig. 9a shows the baseline, Figs. 9b and 9c show the result of colocation with CPU-bound and Disk-bound secondary tenants, respectively.

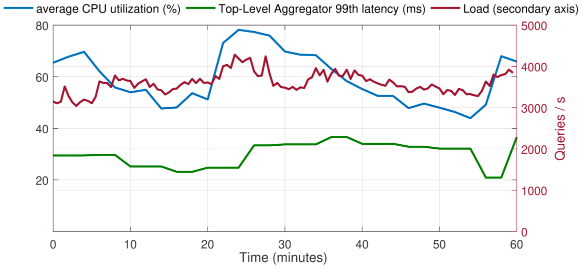


Figure 10: Production results for a cluster of 650 IndexServe machines colocated with a secondary running a machine learning training computation over 1 hour.

cycles available to the secondary, based on job progress information. Our experimental evaluation shows that managing CPU cycles per tenant severely impacts tail latency, and we manage the number of CPU cores of the secondary tenants dynamically instead.

TEMM [38] proposes a throttling-based management technique to configure CPU duty cycles and DVFS settings to meet SLOs. TEMM requires the latency SLOs of the primary, and assumes that the bottleneck is either the last-layer caches or off-chip bandwidth, whereas any of several other resources can be the bottleneck.

MIMP [36] considers tenants in a virtualized environment. It defines a new priority in the hypervisor scheduler to meet the performance requirements of the primary tenant, focusing on CPU-level interference.

Quasar [11] is a cluster manager that reduces resource over-provisioning and increases utilization while meeting quality of service constraints. It uses profiling information and collaborative filtering to infer the tenants' resource requirements. It additionally monitors service performance and adjusts allocations when target latencies are not met. In contrast, *PerfIso*, ensures some slack is always available to accommodate the bursty demands of the primary tenant without assuming explicit server-level performance requirements or tail latency targets.

Heracles [20] uses a feedback mechanism to adjust the secondary tenants' resources based on the tail latency of the primary tenant. Heracles needs the latency SLOs of the primary and exploits hardware mechanisms such as Intel's Cache Allocation Technology [2]. *Heracles* is complementary to this work since the knowledge of primary tenant SLOs and availability of specific hardware mechanisms limits wider deployment.

Jail [28] is Google's cache partitioning performance isolation mechanism. It incorporates Intel CMT and CAT [2] support into Linux cgroups, but allows only static partitioning of resources. In contrast our experiments show dynamic isolation techniques (such as *blind isolation*) provide more resources to the secondary while protecting the primary's tail latency. Additionally, data center machines span multiple hardware generations, not all of which supporting CAT.

RubikColoc [16] configures per-core DVFS to compensate for the overhead of multiplexing primary and secondary tenants on the same core. RubikColoc needs server-level latency SLOs and per-core DVFS support.

Elfen [34] provides CPU-level performance isolation for primary and secondary tenants running on the same core using Simultaneous Multi-Threading (SMT) technology available on modern CPUs. Effectively, the secondary is colocated with the primary on the same physical core only when the primary's measured performance is within its SLO. Elfen needs latency SLOs for the primary, OS support to query SMT-to-process mappings, and application-level instrumentation for the secondary.

BatchDB [23] is a database system that handles both OLTP and OLAP queries, providing good performance isolation for the former. Our approach instead focuses on the scenario where the tenants are distinct applications.

Leverich et al. [18] advocate using colocation to improve cluster throughput-per-TCO, and identify queuing delay, scheduling delay, and worker-thread load imbalance as the challenges in providing service-level QoS. They propose better cluster provisioning and custom OS schedulers to mitigate tenant interference. However, given the complexity of large commercial services, we cannot make changes, neither at the hardware nor kernel level, which is why we adopt a "black-box" model.

CPI^2 [37] is a performance isolation mechanism which uses Clock Per Instruction (CPI) data to build probabilistic distribution models and to find stragglers (victims of resource interference). CPI^2 identifies the antagonists of latency-sensitive tasks by matching CPI patterns, and restricts their CPU cycle-share. We show that restricting CPU cores is significantly more effective in protecting primary tail latency.

HipsterCo [26] is a task scheduler for latency-sensitive workloads running on heterogeneous multi-core systems. HipsterCo colocates batch jobs with latency-sensitive workloads to increase resource utilization. HipsterCo uses reinforcement learning to build the CPU and DVFS configuration required to meet target SLOs. All remaining CPU cores are allocated to batch jobs. However, HipsterCo requires performance feedback from latency-sensitive workloads which is not available in our environment. Furthermore, we argue that for complex commercial latency-sensitive services, some buffer cores are required to prevent performance degradation.

Bubble-Up [24] and *Bubble-Flux* [33] focus on memory bandwidth and last-level cache interference as the main actors in colocation performance degradation. The former proposes a static profiling technique to accurately estimate the expected degradation, while the later uses an online approach, both assuming live performance information from the latency-sensitive service is available.

Zhang et al. [39] use historical resource utilization data and disk re-imaging patterns of tenants in task scheduling and data placement. The primary has resource-priority, meaning that a load-surge kills off secondary tasks. Thus, the scheduling algorithm places secondaries as to minimize the likelihood of termination. *Misra et al.* [25] improved upon this work by proposing a scalable distributed file system design which maximizes data availability for secondary tenants. Due to the highly spiking and unpredictable nature of the primary services we target, relying on historical data is insufficient to insure that performance guarantees are met.

Pisces [30] achieves fairness and per-tenant performance isolation in shared key-value storage. Pisces uses deficit-weighted-round-robin (DWRR) to schedule requests at server-level, thus mediating resource contention. In our case secondary tasks are batch jobs, and therefore do not lend themselves to request scheduling, so we only employ DWRR for I/O throttling.

2DFQ [22] proposes a new weighted fair queuing algorithm to ensure fairness for multi-tenant services that use thread pools inside a single process. This technique benefits the primary tenants and could reduce the burstiness of their execution, which complements *PerfIso* and potentially reduces the number of buffer cores required.

Alizadeh et. al [6] propose HULL — a system which leaves 'bandwidth headroom' to mitigate the problem of packet queuing in low-latency networked systems. This is similar in spirit to our non-work-conserving resource management approach, but focuses on avoiding network congestion rather than performance isolation.

8 Conclusions

Machines hosting large commercial latency-sensitive services are often underutilized because important services are provisioned for peak load as to meet business availably and fault-tolerance constraints.

Colocating batch jobs with latency-sensitive services is an important way of increasing utilization and data center efficiency, but comes with key challenges. Large latency-sensitive services are complex, and follow a layered architecture and therefore require short tail latencies. The diversity of commercial systems prevents us from using explicit knowledge of their latency targets, motivating us to adopt an approach in which we assume limited information about the primary tenant.

This paper presents the design and implementation of *PerfIso*, a performance isolation framework that makes use of idle resources to run batch jobs without affecting the primary tenant. It uses *CPU blind isolation* to meet the requirements of commercial large latency-sensitive services. The key insight is ensuring that the primary tenant always has idle cores available to accommodate its bursty workload, while allowing the secondary tenant to make progress.

We evaluate *PerfIso* experimentally on a single machine and on a cluster of machines using Bing IndexServe as the primary workload. We compare existing CPU isolation techniques (such as rate limiting and static core affinitization) to our approach, and we find that under the latter the 99^{th} percentile of the tail latency values remain largely unchanged compared to running standalone. *PerfIso* allows compute-intensive batch jobs to use up to 47% of CPU cycles for off-peak loads which would have otherwise remained idle.

Abstract

Six years ago, Google released an invaluable set of scheduler logs which has already been used in more than 450 publications. We find that the scarcity of other data sources, however, is leading researchers to overfit their work to Google's dataset characteristics. We demonstrate this overfitting by introducing four new traces from two private and two High Performance Computing (HPC) clusters. Our analysis shows that the private cluster workloads, consisting of data analytics jobs expected to be more closely related to the Google workload, display more similarity to the HPC cluster workloads. This observation suggests that additional traces should be considered when evaluating the generality of new research.

To aid the community in moving forward, we release the four analyzed traces, including: the longest publicly available trace spanning *all* 61 months of an HPC cluster's lifetime and a trace from a 300,000-core HPC cluster, the largest cluster with a publicly available trace. We present an analysis of the private and HPC cluster traces that spans job characteristics, workload heterogeneity, resource utilization, and failure rates. We contrast our findings with the Google trace characteristics and identify affected work in the literature. Finally, we demonstrate the importance of dataset plurality and diversity by evaluating the performance of a job runtime predictor using all four of our traces and the Google trace.

1 Introduction

Despite intense activity in the areas of cloud and job scheduling research, publicly available cluster workload datasets remain scarce. The three major dataset sources today are: the Google cluster trace [58] collected in 2011, the Parallel Workload Archive [19] of High Performance Computing (HPC) traces collected since 1993, and the SWIM traces released in 2011 [10]. Of these, the Google trace has been used in more than 450 publications making it the most popular trace by far. Unfortunately, this 29-day trace is often the only one used to evaluate new research. By contrasting its characteristics with newer traces from different environments, we have found that the Google trace alone is insufficient to accurately prove the generality of a new technique.

Our goal is to uncover overfitting of prior work to the characteristics of the Google trace. To achieve this, our first contribution is to introduce four new traces: two from the private cloud of Two Sigma, a hedge fund, and two from HPC clusters located at the Los Alamos National Laboratory (LANL). Our Two Sigma traces are the longest, non-academic private cluster traces to date, spanning 9 months and more than 3 million jobs. The two HPC traces we introduce are also unique. The first trace spans the entire 5-year lifetime of a general-purpose HPC cluster, making it the longest public trace to date, while also exhibiting shorter jobs than existing public HPC traces. The second trace originates from the 300,000-core current flagship supercomputer at LANL, making it the largest cluster with a public trace, to our knowledge. We introduce all four traces, and the environments where they were collected, in Section 2.

Our second contribution is an analysis examining the generality of workload characteristics derived from the Google trace, when our four new traces are considered. Overall, we find that the private Two Sigma cluster workloads display similar characteristics to HPC, despite consisting of data analytics jobs that more closely resemble the Google workload. Table 1 summarizes all our findings. For those characteristics where the Google workload is an outlier, we have surveyed the literature and list affected prior work. In total, we surveyed 450 papers that reference the Google trace study [41] to identify popular workload assumptions, and we constrast them to the Two Sigma and LANL workloads to detect violations. We group our findings into four categories: job characteristics (Section 3), workload heterogeneity (Section 4), resource utilization (Section 5), and failure analysis (Section 6).

Our findings suggest that evaluating new research using the Google trace alone is insufficient to guarantee generality. To aid the community in moving forward, our third contribution is to publicly release the four traces introduced and analyzed in this paper. We further present a case study on the importance of dataset plurality and diversity when evaluating new research. For our demonstration we use JVuPredict, the job runtime predictor of the JamaisVu scheduling system [51]. Originally, JVuPredict was evaluated using only the Google trace [51]. Evaluating its performance with our four new traces, however, helped us identify features that make it easier to detect related and recurring jobs with predictable behavior. This enabled us to quantify the importance of individual trace fields in runtime prediction.

Section	Characteristic	Google	Two Sigma	Mustang	OpenTrinity
Job Characteristics (§3)	Majority of jobs are small	✔	✘	✘	✘

	Jobs with unsuccessful outcomes consume significant fraction of resources	✔	✔	✘	✘
	Longer/larger jobs often terminate unsuccessfully	✔	✘	✘	✘

Table 1: Summary of the characteristics of each trace. Note that the Google workload appears to be an outlier.

We describe our findings in Section 7.

Finally, we briefly discuss the importance of trace length in accurately representing a cluster's workload in Section 8. We list related work studying cluster traces in Section 9, before concluding.

2 Dataset information

We introduce four sets of job scheduler logs that were collected from a general-purpose cluster and a cutting-edge supercomputer at LANL, and across two clusters of Two Sigma, a hedge fund. The following subsections describe each dataset in more detail, and the hardware configuration of each cluster is shown in Table 2.

Users typically interact with the cluster scheduler by submitting commands that spawn multiple processes, or *tasks*, distributed across cluster nodes to perform a specific computation. Each such command is considered to be a *job* and users often compose scripts that generate more complex, multi-job schedules. In HPC clusters, where resources are allocated at the granularity of physical nodes similar to Emulab [4, 16, 27, 57], tasks from different jobs are never scheduled on the same node. This is not necessarily true in private clusters like Two Sigma.

2.1 Two Sigma clusters

The private workload traces we introduce originate from two datacenters of Two Sigma, a hedge fund firm. The workload consists of data analytics jobs processing financial data. A fraction of these jobs are handled by a Spark [49] installation, while the rest are serviced by home-grown data analytics frameworks. The dataset spans 9 months of the two datacenters' operation starting in January 2016, covering a total of 1313 identical compute nodes with 31512 CPU cores and 328TB RAM. The logs contain 3.2 million jobs and 78.5 million tasks, collected by an internally-developed job scheduler running on top of Mesos [28]. Because both datacenters experience the same workload and consist of homogeneous nodes, we collectively refer to both data sources as the *TwoSigma* trace, and analyze them together.

Platform	Nodes	CPUs	RAM	Length
LANL Trinity	9408	32	128GB	3 months
LANL Mustang	1600	24	64GB	5 years
TwoSigma A	872	24	256GB	9 months
TwoSigma B	441	24	256GB	
Google B	6732	0.50*	0.50*	29 days
Google B	3863	0.50*	0.25*	
Google B	1001	0.50*	0.75*	
Google C	795	1.00*	1.00*	
Google A	126	0.25*	0.25*	
Google B	52	0.50*	0.12*	
Google B	5	0.50*	0.03*	
Google B	5	0.50*	0.97*	
Google C	3	1.00*	0.50*	
Google B	1	0.50*	0.06*	

Table 2: Hardware characteristics of the clusters analyzed in this paper. For the Google trace [41], (*) signifies a resource has been normalized to the largest node.

We expect this workload to resemble the Google cluster more closely than the HPC clusters, where long-running, compute-intensive, and tightly-coupled scientific jobs are the norm. First, unlike LANL, job runtime is not budgeted strictly; users of the hedge fund clusters do not have to specify a time limit when submitting a job. Second, users can allocate individual cores, as opposed to entire physical nodes allocated at LANL. Collected data include: timestamps for job stages from submission to termination, job properties such as size and owner, and the job's return status.

2.2 LANL Mustang cluster

Mustang was an HPC cluster used for *capacity computing* at LANL from 2011 to 2016. Capacity clusters such as Mustang are architected as cost-effective, general-purpose resources for a large number of users. Mustang was largely used by scientists, engineers, and software developers at LANL and it was allocated to these users at the granularity of physical nodes. The cluster consisted of 1600 identical compute nodes, with a total of 38400 AMD Opteron 6176 2.3GHz cores and 102TB RAM.

Our Mustang dataset covers the entire 61 months of the machine's operation from October 2011 to November 2016, which makes this the longest publicly available cluster trace to date. The Mustang trace is also unique because its jobs are shorter than those in existing HPC traces. Overall, it consists of 2.1 million multi-node jobs submitted by 565 users and collected by SLURM [45], an open-source cluster resource manager. The fields available in the trace are similar to those in the TwoSigma trace, with the addition of a time budget field per job, that if exceeded causes the job to be killed.

2.3 LANL Trinity supercomputer

In 2018, Trinity is the largest supercomputer at LANL and it is used for *capability computing*. Capability clusters are a large-scale, high-demand resource introducing novel hardware technologies that aid in achieving crucial computing milestones, such as higher-resolution climate and astrophysics models. Trinity's hardware was stood up in two pre-production phases before being put into full production use and our trace was collected before the second phase completed. At the time of data collection, Trinity consisted of 9408 identical compute nodes, a total of 301056 Intel Xeon E5-2698v3 2.3GHz cores and 1.2PB RAM, making this the largest cluster with a publicly available trace by number of CPU cores.

Our Trinity dataset covers 3 months from February to April 2017. During that time, Trinity was operating in OpenScience mode, i.e., the machine was undergoing beta testing and was available to a wider number of users than it is expected to have after it receives its final security classification. We note that OpenScience workloads are representative of a capability supercomputer's workload, as they occur roughly every 18 months when a new machine is introduced, or before an older one is decommissioned. The dataset, which we will henceforth refer to as *OpenTrinity*, consists of 25237 multi-node jobs issued by 88 users and collected by MOAB [1], an open-source cluster scheduling system. The information available in the trace is the same as that in the Mustang trace.

2.4 Google cluster

In 2012, Google released a trace of jobs that ran in one of their compute clusters [41]. It is a 29-day trace consisting of 672074 jobs and 48 million tasks, some of which were issued through the MapReduce framework, and ran on 12583 heterogeneous nodes in May 2011. The workload consists of both long-running services and batch jobs [55]. Google has not released the exact hardware specifications of each cluster node. Instead, as shown in Table 2, nodes are presented through anonymized platform names representing machines with different combinations of microarchitectures and chipsets [58]. Note that the number of CPU cores and RAM for each node in the trace have been normalized to the most powerful node in the cluster. In our analysis, we estimate the total number of cores in the Google cluster to be 106544. We derive this number by assuming that the most popular node type (Google B with 0.5 CPU cores) is a dual-socket server, carrying quad-core AMD Opteron Barchelona CPUs that Google allegedly used in their datacenters at the time [26]. Unlike previous workloads, jobs can be allocated fractions of a CPU core [46].

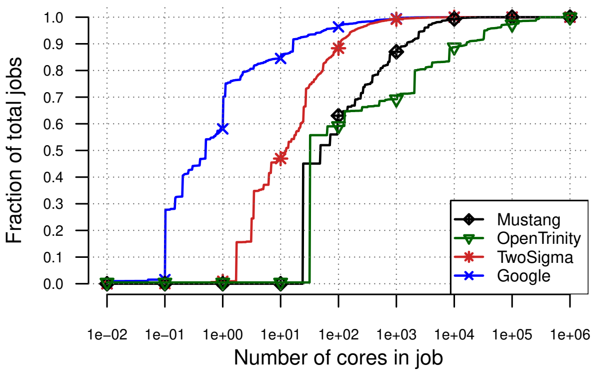

Figure 1: CDF of job sizes based on allocated CPU cores.

3 Job characteristics

Many instances of prior work in the literature rely on the assumption of heavy-tailed distributions to describe the size and duration of individual jobs [2, 8, 13, 14, 40, 50]. In the LANL and TwoSigma workloads these tails appear significantly lighter.

Observation 1: *On average, jobs in the TwoSigma and LANL traces request 3 - 406 times more CPU cores than jobs in the Google trace. Job sizes in the LANL traces are more uniformly distributed.*

Figure 1 shows the Cumulative Distribution Functions (CDFs) of job requests for CPU cores across all traces, with the x-axis in logarithmic scale. We find that the 90% of smallest jobs in the Google trace request 16 CPU cores or fewer. The same fraction of TwoSigma jobs request 108 cores, and 1-16K cores in the LANL traces. Very large jobs are also more common outside Google. This is unsurprising for the LANL HPC clusters, where allocating thousands of CPU cores to a single job is not uncommon, as the clusters' primary use is to run massively parallel scientific applications. It is interesting to note, however, that while the TwoSigma clusters contain fewer cores than the other clusters we examine (3 times fewer

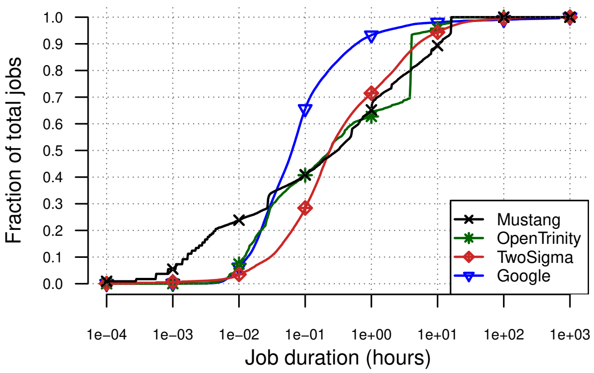

Figure 2: CDF of the durations of individual jobs.

than the Google cluster), its median job is more than an order of magnitude larger than a job in the Google trace. An analysis of allocated memory yields similar trends.

Observation 2: *The median job in the Google trace is 4-5 times shorter than in the LANL or TwoSigma traces. The longest 1% of jobs in the Google trace, however, are 2-6 times longer than the same fraction of jobs in the LANL and TwoSigma traces.*

Figure 2 shows the CDFs of job durations for all traces. We find that in the Google trace, 80% of jobs last less than 12 minutes *each*. In the LANL and TwoSigma traces jobs are at least an order of magnitude longer. In TwoSigma, the same fraction of jobs last up to 2 hours and in LANL, they last up to 3 hours for Mustang and 6 hours for OpenTrinity. Surprisingly, the tail end of the distribution is slightly shorter for the LANL clusters than for the Google and TwoSigma clusters. The longest job is 16 hours on Mustang, 32 hours in OpenTrinity, 200 hours in TwoSigma, and at least 29 days in Google (the duration of the trace). For LANL, this is due to hard limits causing jobs to be indiscriminately killed. For Google, the distribution's long tail is likely attributed to long-running services.

Implications. These observations impact the immediate applicability of job scheduling approaches whose efficiency relies on the assumption that the vast majority of jobs' durations are in the order of minutes, and job sizes are insignificant compared to the size of the cluster. For example, Ananthanarayanan et al. [2] propose to mitigate the effect of stragglers by duplicating tasks of smaller jobs. This is an effective approach for Internet service workloads (Microsoft and Facebook are represented in the paper) because the vast majority of jobs can benefit from it, without significantly increasing the overall cluster utilization. For the Google trace, for example, 90% of jobs request less than 0.01% of the cluster each, so duplicating them only slightly increases cluster utilization. At the same time, 25-55% of jobs in the LANL and TwoSigma traces *each* request *more than* 0.1% of the cluster's cores, decreasing the efficiency of the approach and suggesting replication should be used judiciously. This does not consider that LANL tasks are also tightly-coupled and the entire job has to be duplicated.

Another example is the work by Delgado et al. [14], which improves the efficiency of distributed schedulers for short jobs by dedicating them a fraction of the cluster. This partition ranges from 2% for Yahoo and Facebook traces, to 17% for the Google trace where jobs are significantly longer, to avoid increasing job service times. For the TwoSigma and LANL traces we have shown that jobs are even longer than for the Google trace (Figure 2), so larger partitions will likely be necessary to achieve similar efficiency. At the same time, jobs running in the TwoSigma and LANL clusters are also larger (Figure 1), so service times for long jobs are expected to increase unless the partition is shrunk. Other examples of work that is likely affected include task migration of short and small jobs [50] and hybrid scheduling aimed on improving head-of-line blocking for short jobs [13].

4 Workload heterogeneity

Another common assumption about cloud workloads is that they are characterized by heterogeneity in terms of resources available to jobs, and job interarrival times [7, 23, 31, 46, 56]. The private and HPC clusters we study, however, consist of homogeneous hardware (see Table 2) and user activity follows well-defined diurnal patterns, even though the rate of scheduling requests varies significantly across clusters.

Observation 3: *Diurnal patterns are universal. Clusters received more scheduling requests and smaller jobs at daytime, with minor deviations for the Google trace.*

In Figure 3 we show the number of job scheduling requests for every hour of the day. We choose to show metrics for the median day surrounded by the other two quartiles because the high variation across days causes the averages to be unrepresentative of the majority of days (see Section 8). Overall, diurnal patterns are evident in every trace and user activity is concentrated at daytime (7AM to 7PM), similar to prior work [38]. An exception to this is the Google trace, which is most active from midnight to 4AM, presumably due to batch jobs leveraging the available resources.

Sizes of submitted jobs are also correlated with the time of day. We find that longer, larger jobs in the LANL traces are typically scheduled during the night, while shorter, smaller jobs tend to be scheduled during the day. The reverse is true for the Google trace, which prompts our earlier assumption on nightly batch jobs. Long, large jobs are also scheduled at daytime in the TwoSigma clusters, despite having a diurnal pattern similar to LANL

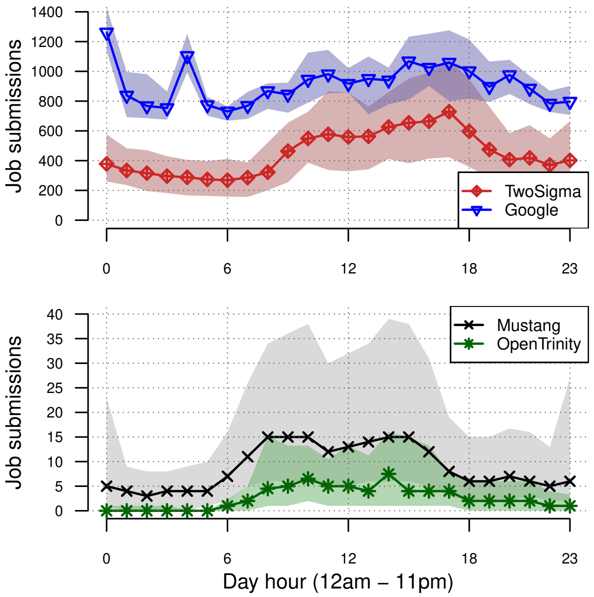

Figure 3: Hourly job submission rates for a given day. The lines represent the median, while the shaded region shows the distance between the 25th and 75th percentiles.

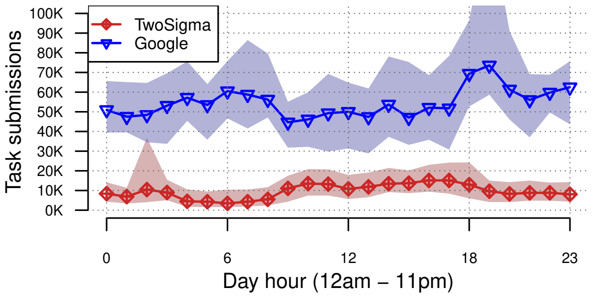

Figure 4: Hourly task placement requests for a given day. The lines represent the median, while the shaded region shows the distance between the 25th and 75th percentiles.

clusters. This is likely due to TwoSigma's workload consisting of financial data analysis, which bears a dependence on stock market hours.

Observation 4: *Scheduling request rates differ by up to 3 orders of magnitude across clusters. Sub-second scheduling decisions seem necessary in order to keep up with the workload.*

One more thing to take away from Figure 3 is that the rate of scheduling requests can differ significantly across clusters. For the Google and TwoSigma traces, hundreds to thousands of jobs are submitted every hour. On the other hand, LANL schedulers never receive more than 40 requests on any given hour. This could be related to the workload or the number of users in the system, as the Google cluster serves 2 times as many user IDs as the Mustang cluster and 9 times as many as OpenTrinity.

Implications: Previous work such as Omega [46] and ClusterFQ [56] propose distributed scheduling designs especially applicable to heterogeneous clusters. This does not seem to be an issue for environments such as LANL and TwoSigma, which intentionally architect homogeneous clusters to lower performance optimization and administration costs.

As cluster sizes increase, so does the rate of scheduling requests, urging us to reexamine prior work. Quincy [31] represents scheduling as a Min-Cost Max-Flow (MCMF) optimization problem over a task-node graph and continuously refines task placement. The complexity of this approach, however, becomes a drawback for large-scale clusters such as the ones we study. Gog et al. [23] find that Quincy requires 66 seconds (on average) to converge to a placement decision in a 10,000-node cluster. The Google and LANL clusters we study already operate on that scale (Table 2). We have shown in Figure 3 that the average frequency of job submissions in the LANL traces is one job every 90 seconds, which implies that this scheduling latency may work, but this will not be the case for long. Trinity is currently operating with 19,000 nodes and, under the DoE's Exascale Computing Project [39], 25 times larger machines are planned within the next 5 years. Note that when discussing scheduling so far we refer to *jobs*, since HPC jobs have a gang scheduling requirement. Placement algorithms such as Quincy, however, focus on *task* placement.

An improvement to Quincy is Firmament [23], a centralized scheduler employing a generalized approach based on a combination of MCMF optimization techniques to achieve sub-second task placement latency on average. As Figure 4 shows, sub-second latency is paramount, since the rate of task placement requests in the Google and TwoSigma traces can be as high as 100K requests per hour, i.e. one task every 36ms. Firmament's placement latency, however, increases to several seconds as cluster utilization increases. For the TwoSigma and Google traces this can be problematic.

5 Resource utilization

A well-known motivation for the cloud has been resource consolidation, with the intention of reducing equipment ownership costs. An equally well-known property of the cloud, however, is that its resources remain underutilized [6, 15, 35, 36, 41]. This is mainly due to a disparity between user resource requests and actual resource usage, which recent research efforts try to alleviate through workload characterization and aggressive consolidation [15, 33, 34]. Our analysis finds that user resource requests in the LANL and TwoSigma traces are characterized by higher variability than in the Google trace. We also look into job inter-arrival times and how they are

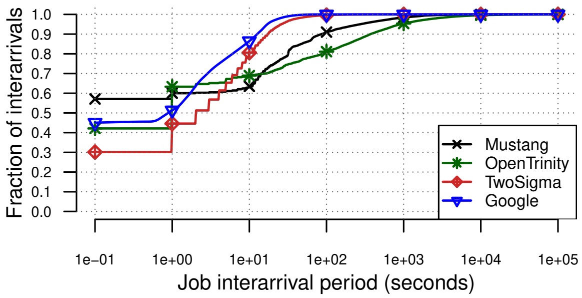

Figure 5: CDF of job interarrival times.

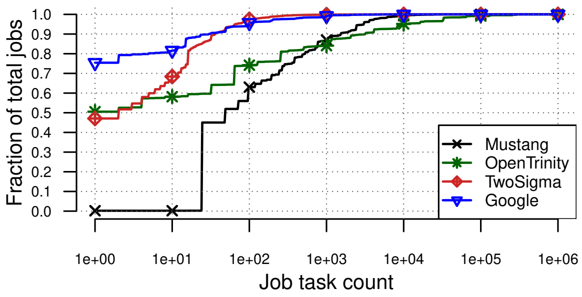

Figure 6: CDF of the number of tasks per job.

approximated when evaluating new research.

Observation 5: *Unlike the Google cluster, none of the other clusters we examine overcommit resources.*

Overall, we find that the fraction of CPU cores allocated to jobs is stable over time across all the clusters we study. For Google, CPU cores are over provisioned by 10%, while for other clusters unallocated cores range between 2-12%, even though resource overprovisioning is supported by their schedulers. Memory allocation numbers follow a similar trend. Unfortunately, the LANL and TwoSigma traces do not contain information on actual resource utilization. As a result, we can neither confirm, nor contradict results from earlier studies on the imbalance between resource allocation and utilization. What differs between organizations is the motivation for keeping resources utilized or available. For Google [41], Facebook [10], and Twitter [15], there is a tension between the financial incentive of maintaining only the necessary hardware to keep operational costs low and the need to provision for peak demand, which leads to low overall utilization. For LANL, clusters are designed to accommodate a predefined set of applications for a predetermined time period and high utilization is planned as part of efficiently utilizing federal funding. For the TwoSigma clusters, provisioning for peak demand is more important, even if it leads to low overall utilization, since business revenue is heavily tied to the response times of their analytics jobs.

Observation 6: *The majority of job interarrivals periods are sub-second in length.*

Interarrival periods are a crucial parameter of an experimental setup, as they dictate the load on the system under test. Two common configurations are second-granularity [15] or Poisson-distributed interarrivals [29], and we find that neither characterizes interarrivals accurately. In Figure 5 we show the CDFs for job interarrival period lengths. We observe that 44-62% of interarrival periods are sub-second, implying that jobs arrive at a faster rate than previously assumed. Furthermore, our attempts to fit a Poisson distribution on this data have been unsuccessful, as Kolmogorov-Smirnov tests [37] reject the null hypothesis with p-values $< 2.2 \times 10^{-16}$. This result does not account for a scenario where there is an underlying Poisson process with a rate parameter changing over time, but it suggests that caution should be used when a Poisson distribution is assumed.

Another common assumption is that jobs are very rarely big, i.e., made up of multiple tasks [29, 56]. In Figure 6 we show the CDFs for the number of tasks per job across organizations. We observer that 77% of Google jobs are single-task jobs, but the rest of the clusters carry many more multi-task jobs. We note that the TwoSigma distribution approaches that of Google only for larger jobs. This suggests that task placement may be a harder problem outside Google, where single-task jobs are common, exacerbating the evaluation issues we outlined in Section 4 for existing task placement algorithms.

Observation 7: *User resource requests are more variable in the LANL and TwoSigma traces than in the Google trace.*

Resource under-utilization can be alleviated through workload consolidation. To ensure minimal interference, applications are typically profiled and classified according to historical data [15, 33]. Our analysis suggests that this approach is likely to be less successful outside the Internet services world. To quantify variability in user behavior we examine the Coefficient of Variation[1] (CoV) across all requests of individual users. For the Google trace we find that the majority of users issue jobs within 2x of their average request in CPU cores. For the LANL and TwoSigma traces, on the other hand, 60-80% of users can deviate by 2-10x of their average request.

Implications: A number of earlier studies of Google [41], Twitter [15], and Facebook [10] data have highlighted the imbalance between resource allocation and utilization. Google tackles this issue by over-committing resources, but this is not the case for LANL and TwoSigma. Another proposed solution is Quasar [15], a system that consolidates workloads while guaranteeing

[1] The Coefficient of Variation is a unit-less measure of spread, derived by dividing a sample's standard deviation by its mean.

a predefined level of QoS. This is achieved by profiling jobs at submission time and classifying them as one of the previously encountered workloads; misclassifications are detected by inserting probes in the running application. For LANL, this approach would be infeasible. First, jobs cannot be scaled down for profiling, as submitted codes are often carefully configured for the requested allocation size. Second, submitted codes are too complex to be accurately profiled in seconds, and probing them at runtime to detect misclassifications can introduce performance jitter that is prohibitive in tightly-coupled HPC applications. Third, in our LANL traces we often find that users tweak jobs before resubmitting them, as they re-calibrate simulation parameters to achieve a successful run, which is likely to affect classification accuracy. Fourth, resources are carefully reserved for workloads and utilization is high, which makes it hard to provision resources for profiling. For the TwoSigma and Google traces Quasar may be a better fit, however, at the rate of 2.7 jobs per second (Figure 3), 15 seconds of profiling [15] at submission time would result in an expected load of 6 jobs being profiled together. Since Quasar requires 4 parallel and isolated runs to collect sufficient profiling data, we would need resources to run at least 360 VMs concurrently, with guaranteed performance isolation between tham to keep up with the average load. This further assumes the profiling time does not need to be increased beyond 15 seconds. Finally, Quasar [15] was evaluated using multi-second inter-arrival periods, so testing would be necessary to ensure that one order of magnitude more load can be handled (Figure 5), and that it will not increase the profiling cost further.

Another related approach to workload consolidation is provided by TSF [56], a scheduling algorithm that attempts to maximize the number of task slots allocated to each job, without favoring bigger jobs. This ensures that the algorithm remains starvation-free, however it results in significant slowdowns in the runtime of jobs with 100+ tasks, which the authors define as big. This would be prohibitive for LANL, where jobs must be scheduled as a whole, and such "big" jobs are much more prevalent and longer in duration. Other approaches for scheduling and placement assume the availability of resources that may be unavailable in the clusters we study here, and their performance is shown to be reduced in highly-utilized clusters [25, 29].

6 Failure analysis

Job scheduler logs are often analyzed to gain an understanding of job failure characteristics in different environments [9, 17, 21, 22, 43]. This knowledge allows for building more robust systems, which is especially important as we transition to exascale computing systems where failures are expected every few minutes [48], and cloud computing environments built on complex software stacks that increase failure rates [9, 44].

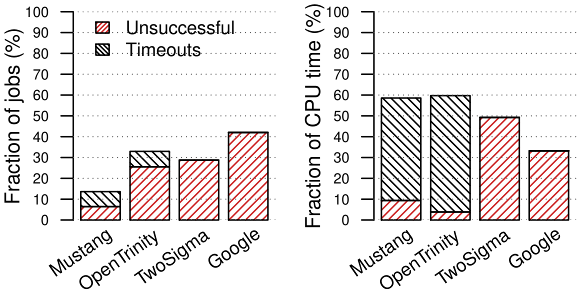

Figure 7: Breakdown of the total number of jobs, as well as CPU time, by job outcome.

Definitions. An important starting point for any failure analysis is defining what constitutes a failure event. Across all traces we consider, we define as *failed jobs* all those that end due to events whose occurrence was not intended by users or system administrators. We do not distinguish failed jobs by their root cause, e.g., software and hardware issues, because this information is not reliably available. There are other job termination states in the traces, in addition to success and failure. For the Google trace, jobs can be killed by users, tasks can be evicted in order to schedule higher-priority ones, or have an unknown exit status. For the LANL traces, jobs can be cancelled intentionally. We group all these job outcomes as *aborted jobs* and collectively refer to failed and aborted jobs as ***unsuccessful jobs***.

There is another job outcome category. At LANL, users are required to specify a runtime estimate for each job. This estimate is treated as a time limit, similar to an SLO, and the scheduler kills the job if the limit is exceeded. We refer to these killings as ***timeout jobs*** and present them separately because they can produce useful work in three cases: (a) when HPC jobs use the time limit as a stopping criterion, (b) when job state is periodically checkpointed to disk, and (c) when a job completes its work before the time limit but fails to terminate cleanly.

Observation 8: *Unsuccessful job terminations in the Google trace are 1.4-6.8x higher than in other traces. Unsuccessful jobs at LANL use 34-80% less CPU time.*

In Figure 7, we break down the total number of jobs (left), as well as the total CPU time consumed by all jobs by job outcome (right). First, we observe that the fraction of unsuccessful jobs is significantly higher (1.4-6.8x) for the Google trace, than for the other traces. This comparison ignores jobs that timeout for Mustang, because as we explained above, it is unlikely they represent wasted resources. We also note that almost all unsuccessful jobs in the Google trace were aborted. According to the trace

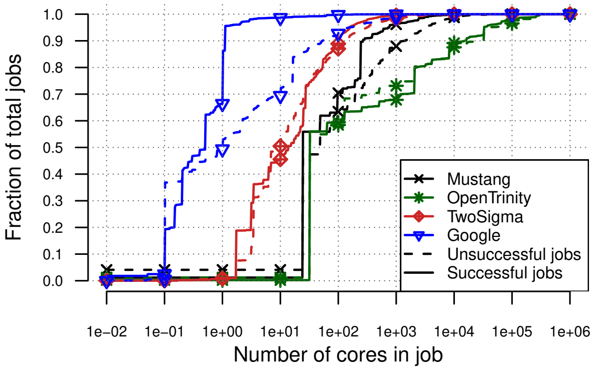

Figure 8: CDFs of job sizes (in CPU cores) for unsuccessful and successful jobs.

documentation [58] these jobs could have been aborted by a user or the scheduler, or by dependent jobs that failed. As a result, we cannot rule out the possibility that these jobs were linked to a failure. For this reason, prior work groups all unsuccessful jobs under the "*failed*" label [17], which we choose to avoid for clarity. Another fact that further highlights how blurred the line between failed and aborted jobs can be, is that all unsuccessful jobs in the TwoSigma trace are assigned a failure status. In short, our classification of jobs as "unsuccesful" may seem broad, but it is consistent with the liberal use of the term "failure" in the literature.

We also find that unsuccessful jobs are not equally detrimental to the overall efficiency of all clusters. While the rate of unsuccessful jobs for the TwoSigma trace is similar to the rate of unsuccessful jobs in the OpenTrinity trace, each unsuccessful job lasts longer. Specifically, unsuccessful jobs in the LANL traces waste 34-80% less CPU time than in the Google and TwoSigma traces. It is worth noting that 49-55% of CPU time at LANL is allocated to jobs that time out, which suggests that at least a small fraction of that time may become available through the use of better checkpoint strategies.

Observation 9: *For the Google trace, unsuccessful jobs tend to request more resources than successful ones. This is untrue for all other traces.*

In Figure 8, we show the CDFs of job sizes (in CPU cores) of individual jobs. For each trace, we show separate CDFs for unsuccessful and successful jobs. By separating jobs based on their outcome we observe that successful jobs in the Google trace request fewer resources, overall, than unsuccessful jobs. This observation has also been made in earlier work [17, 21], but it does not hold for our other traces. CPU requests for successful jobs in the TwoSigma and LANL traces are similar to requests made by unsuccessful jobs. This trend is opposite to what is seen in older HPC job logs [59], and since these traces were also collected through SLURM and MOAB

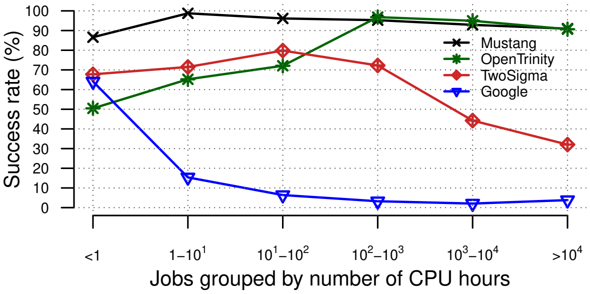

Figure 9: Success rates for jobs grouped by CPU hours.

we do not expect this discrepancy to be due to semantic differences in the way failure is defined across traces.

Observation 10: *For the Google and TwoSigma traces, success rates drop for jobs consuming more CPU hours. The opposite is true for LANL traces.*

For the traces we analyze, the root cause behind unsuccessful outcomes is not reliably recorded. Without this information, it is difficult to interpret and validate the results. For example, we expect that hardware failures are random events whose occurrence roughly approximates some frequency based on the components' Mean Time Between Failure ratings. As a result, jobs that are larger and/or longer, would be more likely to fail. In Figure 9 we have grouped jobs based on the CPU hours they consume (a measure of both size and length), and we show the success rate for each group. The trend that stands out is that success rates decrease for jobs consuming more CPU hours in the Google and TwoSigma traces, but they are increase and remain high for both LANL clusters. This could be attributed to larger, longer jobs at LANL being more carefully planned and tested, but it could also be due to semantic differences in the way success and failure are defined across traces.

Implications. The majority of papers analyzing the characteristics of job failures in the Google trace build failure prediction models that assume the existence of the trends we have shown on success rates and resource consumption of unsuccessful jobs. Chen et al. [9] highlight the difference in resource consumption between unsuccessful and successful jobs, and El-Sayed et al. [17] note that this is the second most influential predictor (next to early task failures) for their failure prediction models. As we have shown in Figure 9, unsuccessful jobs are not linked to resource consumption in other traces. Another predictor highlighted in both studies is job re-submissions, with successful jobs being resubmitted fewer times. We confirm that this trend is consistent across all traces, even though the majority of jobs (83-93%) are submitted exactly once. A final observation that does not hold true for LANL is that CPU time of unsuccessful jobs increases with job runtime [17, 22].

7 A case study on plurality and diversity

Evaluating systems against multiple traces enables researchers to identify practical sensitivities of new research and prove its generality. We demonstrate this through a case study on JVuPredict, the job runtime[2] predictor module of the JamaisVu [51] cluster scheduler. Our evaluation of JVuPredict with all the traces we have introduced revealed the predictive power of logical job names and consistent user behavior in workload traces. Conversely, we found it difficult to obtain accurate runtime predictions in systems that provide insufficient information to identify job re-runs. This section briefly describes the architecture of JVuPredict (Section 7.1) and our evaluation results (Section 7.2).

7.1 JVuPredict background

Recent schedulers [12, 24, 32, 51, 52] use information on job runtimes to make better scheduling decisions. Accurate knowledge of job runtimes allows a scheduler to pack jobs more aggressively in a cluster [12, 18, 54], or to delay a high-priority batch job to schedule a latency-sensitive job without exceeding the deadline of the batch job. In heterogeneous clusters, knowledge of a job's runtime can also be used to decide whether it is better to immediately start a job on hardware that is sub-optimal for it, let it wait until preferred hardware is available, or simply preempt other jobs to let it run [3, 52]. Such schedulers assume most of the provided runtime information is accurate. The accuracy of the provided runtime is important as these schedulers are only robust to a reasonable degree of error [52].

Traditional approaches for obtaining runtime knowledge are often as trivial as expecting the user to provide an estimate, an approach used in HPC environments such as LANL. As we have seen in Section 6, however, users often use these estimates as a stopping criterion (jobs get killed when they exceed them), specify a value that is too high, or simply fix them to a default value. Another option is to detect jobs with a known structure that are easy to profile as a means of ensuring accurate predictions, an approach followed by systems such as Dryad [30], Jockey [20], and ARIA [53]. For periodic jobs, simple history-based predictions can also work well [12, 32]. But these approaches are still inadequate for consolidated clusters without a known structure or history.

JVuPredict, the runtime prediction module of JamaisVu [51], aims to predict a job's runtime when it is submitted, using historical data on past job characteristics and runtimes. It differs from traditional approaches by attempting to detect jobs that repeat, even when successive runs are not declared as repeats. It is more effective, as only part of the history relevant to the newly submitted job is used to generate the estimate. To do this, it uses features of submitted jobs, such as user IDs and job names, to build multiple independent predictors. These predictors are then evaluated based on the accuracy achieved on historic data, and the most accurate one is selected for future predictions. Once a prediction is made, the new job is added to the history and the accuracy scores of each model are recalculated. Based on the updated scores a new predictor is selected and the process is repeated.

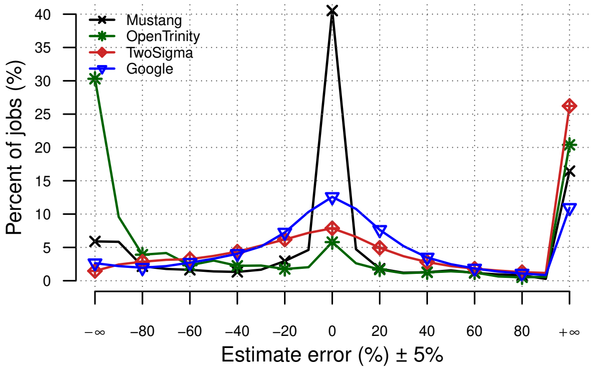

Figure 10: Accuracy of JVuPredict predictions of runtime estimates, for all four traces.

7.2 Evaluation results

JVuPredict had originally been evaluated using only the Google trace. Although predictions are not expected to be perfect, performance under the Google trace was reasonably good, with 86% of predictions falling within a factor of two of the actual runtime. This level of accuracy is sufficient for the JamaisVu scheduler, which further applies techniques to mitigate the effects of such mispredictions. In the end, the performance of JamaisVu with the Google trace is sufficient to closely match that of a hypothetical scheduler with perfect job runtime information and to outperform runtime-unaware scheduling [51]. This section repeats the evaluation of JVuPredict using our new TwoSigma and LANL traces. Our criterion for success is meeting or surpassing the prediction accuracy achieved with the Google trace.

A feature expected to effectively predict job repeats is the job's name. This field is typically anonymized by hashing the program's name and arguments, or simply by hashing the user-defined human-readable job name provided to the scheduler. For the Google trace, predictors using the logical job name field are selected most frequently by JVuPredict due to their high accuracy.

Figure 10 shows our evaluation results. On the x-axis we plot the prediction error for JVuPredict's runtime estimates, as a percentage of the actual runtime of the job. Each data point in the plot is a bucket representing val-

[2] The terms *runtime* and *duration* are used interchangeably here.

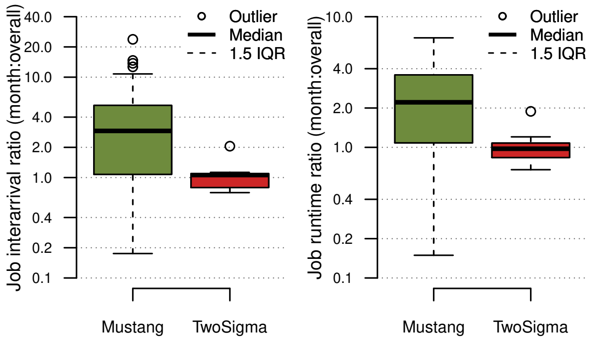

Figure 11: *Is a month representative of the overall workload?* The boxplots show distributions of the average job inter-arrival period (left) and duration (right) per month, normalized by the trace's overall average. Boxplot whiskers are defined at 1.5 times the distribution's Inter-Quartile Range (standard Tukey boxplots).

ues within 5% of the nearest decile. The y-axis shows the percentage of jobs whose predictions fall within each bucket. Overestimations of a job's runtime are easier to tolerate than underestimations, because they cause the scheduler to be more conservative when scheduling the job. Thus, the uptick at the right end of the graph is not alarming. For the Google trace, the total percentage of jobs whose runtimes are under-estimated is 32%, with 11.7% of underestimations being lower than half the actual runtime. We mark these numbers as acceptable, since performance of JVuPredict in the Google trace has been proven exceptional in simulation.

Although the logical job name is a feature that performs well for the Google trace, we find it is either unavailable, or unusable in our other traces. This is because of the difficulty inherent in producing an anonymized version of it, while maintaining enough information to distinguish job repeats. Instead, this field is either assigned a unique value for every job, or entirely omitted from the trace. All traces we introduce in this paper suffer from this limitation. The absence of the field, however, seems to not affect the performance of JVuPredict significantly. The fields selected by JVuPredict as the most effective predictors of job runtime for the Mustang and TwoSigma traces are: the ID of the user who submitted the job, the number of CPU cores requested by the job, or a combination of the two. We find that the TwoSigma workload achieves identical performance to Google: 31% of job runtimes are underestimated and 15% are predicted to be less than 50% of the actual runtime. The Mustang workload is much more predictable, though, with 38% of predictions falling within 5% of the actual runtime. Still, 16% of job runtimes were underestimated by more than half of the actual runtime. The similarity between the TwoSigma and Mustang results suggests that JamaisVu would also perform well under these workloads. Note that these results extend to the Google trace when the job name is omitted.

OpenTrinity performs worse than every other trace. Even though the preferred predictors are, again, the user ID and the number of CPU cores in the job, 55% of predictions have been underestimations. Even worse, 24% of predictions are underestimated by more than 95% of the actual runtime. A likely cause for this result is the variability present in the trace. We are unsure whether this variability is due to the short duration of the trace, or due to the workload being more inconsistent during the OpenScience configuration period.

In conclusion, two insights were obtained by evaluating JVuPredict with multiple traces. First, we find that although logical job names work well for the Google trace, they are hard to produce in anonymized form for other traces, so they may often be unavailable. Second, we find that in the absence of job names, there are other fields that can substitute for them and provide comparable accuracy all but the OpenTrinity trace. Specifically, the user ID and CPU core count for every job seem to perform best for both TwoSigma and the Mustang trace.

8 On the importance of trace length

Working with traces often forces researchers to make key assumptions as they interpret the data, in order to cope with missing information. A common (unwritten) assumption when using or analyzing a trace, is that it sufficiently represents the workload of the environment wherein it was collected. At the same time the Google trace spans only 29 days, while other traces we study in this paper are 3-60 times longer, even covering the entire lifetime of the cluster in the case of Mustang. Being unsure whether 29 days are sufficient to accurately describe a cluster's workload, we decided to examine how representative individual 29-day periods are of the overall workload in our TwoSigma and Mustang traces.

Our experiment consisted of dividing our traces in 29-day periods. For each such month we then compared the distributions of individual metrics against the overall distribution for the full trace. The metrics we considered were: job sizes, durations, and interarrival periods. Overall we found consecutive months' distributions to vary wildly for all these metrics. One distinguishable trend, however, is that during the third year the Mustang cluster is dominated by short jobs arriving in bursts.

Figure 11 summarizes our results by comparing the averages of different metrics for each month against the overall average across the entire trace. The boxplots show the distributions of average job interarrivals (left) and durations (right) per month, when normalized by the overall average for the trace. The boxplots are standard

Tukey boxplots, where the box is framed by the 25^{th} and 75^{th} percentiles, the dark line represents the median, and the whiskers are defined at 1.5 times the distribution's Inter-Quartile Range (IQR), or the furthest data point if no outliers exist (shown in circles here). We see that individual months vary significantly for the Mustang trace, and they differ somewhat less across months in the TwoSigma trace. More specifically, the average job interarrival of a given month can be 0.7-2.0x the value of the overall average in the TwoSigma trace, or 0.2-24x the value of the overall average in the Mustang trace. Average job durations can fluctuate between 0.7-1.9x of the average job duration in the TwoSigma trace, and 0.1-6.9x of the average in the Mustang trace. Overall, our results conclusively show that our cluster workloads display significant differences from month to month.

9 Related Work

The Parallel Workloads Archive (PWA) [19] hosts the largest collection of public HPC traces. At the time of this writing, 38 HPC traces have been collected between 1993 and 2015. Our HPC traces complement this collection. The Mustang trace is unique in a number of ways: it is almost two times longer in duration than the longest publicly available trace, contains four times as many jobs, and covers the entire lifetime of the cluster enabling longitudinal analyses. It is also similar in size to the largest clusters in PWA and its distribution of job duration distribution is shorter than all other HPC traces. The OpenTrinity trace is also complementary to existing traces, as it is collected on a machine almost two times bigger than the largest supercomputer with a publicly available trace (Argonne National Lab's Intrepid) as far as CPU core count is concerned.

Prior studies have looked at private cluster traces, specifically with the aim of characterizing MapReduce workloads. Ren et al. [42] examine three traces from academic Hadoop clusters in an attempt to identify popular application styles and characterize the input/output file sizes, the duration, and the frequency of individual MapReduce stages. These clusters handle significantly less traffic than the Google and TwoSigma clusters we examine. Interestingly, a sizable fraction of interarrival periods for individual jobs are longer than 100 seconds, which resembles our HPC workloads. At the same time, the majority of jobs last less than 8 minutes, which approximates the behavior in the Google trace. Chen et al. [10] look at both private clusters from Cloudera customers and Internet services clusters from Facebook. On the one hand, their private traces cover less than two months, while on the other hand their Facebook traces are much longer than the Google trace. Still, there are similarities in traffic, as measured in job submissions per hour. Specifically, Cloudera customers' private clusters deal with hundreds of job submissions per hour, a traffic pattern similar to the Two Sigma clusters, while Facebook handles upwards of a thousand submissions per hour, which is more related to traffic in the Google cluster. The diversity across these workloads further emphasizes the need for researchers to focus on evaluating new research using a diverse set of traces.

Other studies that look at private clusters focus on Virtual Machine workloads. Shen et al. [47] analyze datasets of monitoring data from individual VMs in two private clusters. They report high variability in resource consumption across VMs, but low overall cluster utilization. Cano et al. [5] examine telemetry data from 2000 clusters of Nutanix customers. The frequency of telemetry collection varies from minutes to days and includes storage, CPU measurements, and maintenance events. The authors report fewer hardware failures in these systems than previously reported in the literature. Cortez et al. [11] characterize the VM workload on Azure, Microsoft's cloud computing platform. They also report low cluster utilization and low variability in tenant job sizes.

Conclusion

We have introduced and analyzed job scheduler traces from two private and two HPC clusters. We publicly release all four traces, which we expect to be of interest to researchers due to their unique characteristics, including: the longest public trace to date spanning the entire 5-year lifetime of a cluster, one representing the largest cluster with a public trace to date, and the two longest private non-academic cluster traces made public to date.

Our analysis showed that the private clusters resemble the HPC workloads studied, rather than the popular Google trace workload, which is surprising. This observation holds across many aspects of the workload: job sizes and duration, resource allocation, user behavior variability, and unsuccessful job characteristics. We also listed prior work that relies too heavily on the Google trace's characteristics and may be affected.

Finally, we demonstrated the importance of dataset plurality and diversity in the evaluation of new research. For job runtime predictions, we show that using multiple traces allowed us to reliably rank data features by predictive power. We hope that by publishing our traces we will enable researchers to better understand the sensitivity of new research to different workload characteristics.

Dataset availability

The LANL Mustang, LANL OpenTrinity, and two Two Sigma scheduler logs can be downloaded from the ATLAS repository, which is publicly accessible through:

`www.pdl.cmu.edu/ATLAS`

Acknowledgments

We would like to thank John Wilkes, Steve Senator, our shepherd Konstantinos Karanasos, and the anonymous reviewers for their invaluable feedback. We also thank the members and companies of the PDL Consortium for their insights, feedback, and support: Alibaba Group, Broadcom, Dell EMC, Facebook, Google, HP Enterprise, Hitachi, IBM Research, Intel, Micron, Microsoft Research, MongoDB, NetApp, Oracle, Salesforce, Samsung, Seagate Technology, Two Sigma, Toshiba, Veritas and Western Digital. A portion of this work was performed at the Ultrascale Systems Research Center (USRC) at Los Alamos National Laboratory, supported by the U.S. Department of Energy contract AC52-06NA25396. The publication has been assigned the LANL identifier LA-UR-18-24488.

SLAOrchestrator: Reducing the Cost of Performance SLAs for Cloud Data Analytics

Jennifer Ortiz[†], Brendan Lee[†], Magdalena Balazinska[†], Johannes Gehrke[*] and Joseph L. Hellerstein[‡]
[†] University of Washington Department of Computer Science & Engineering,[*]Microsoft,[‡]eScience Institute

Abstract

SLAOrchestrator is a new system designed to reduce the price increases necessary to support performance SLAs in cloud analytics systems. SLAOrchestrator is designed for SLAs that guarantee per-query execution times. Its core architecture consists of a double learning loop that improves both SLAs and resource management over time. It further utilizes an efficient combination of elastic query scheduling and multi-tenant resource provisioning algorithms to reduce the costs of performance guarantees.

1 Introduction

A variety of shared-nothing systems for data analytics are available as cloud services today, including Amazon Elastic MapReduce (EMR) [5], Amazon Redshift [4], Azure's HDInsight [8], and Azure Data Lake Analytics [46]. When using those systems, users upload their data to the cloud and issue queries on that data. Queries can include relational operators and various user-defined computations. A key challenge with these services, however, is that users must decide on a desired configuration: how many *service instances* they want to pay for and how powerful these instances should be.

The service configuration dramatically impacts price [2] and performance [53], yet it is known to be very difficult for users to select correctly [24]. Since users do not know what configuration to purchase, one approach is to offer performance-based service level agreements (SLAs), where the system promises to meet a given per-query latency or pay a penalty [41, 42].

Previous research has addressed the challenge of selecting and enforcing SLAs in various ways. One line of work assumes each tenant fits on a single server and the challenge is to pack tenants on a restricted set of servers [17, 34, 47], migrating tenants as needed [16], ordering queries for execution [12, 36], controlling admission [56, 42], and dispatching queries to servers [11, 37]. Other approaches assume the workload is known and require profile runs of queries, possibly restricted to processing samples [53, 25, 18, 23]. Knowledge of the workload and profile runs are reasonable assumptions in a transaction-processing system with a fixed set of stored procedures or in an analytics system that runs predefined reports, but not for ad-hoc analytical workloads.

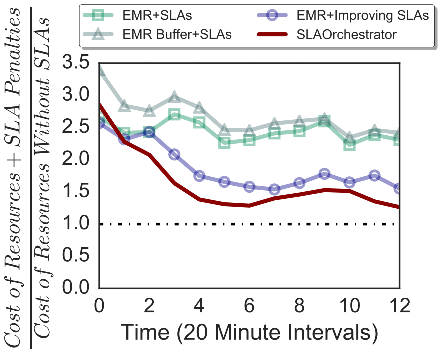

Figure 1: **A time-changing set of tenants executes ad-hoc, analytical queries subject to performance SLAs. Static resource allocation (EMR+SLAs), even with a buffer (EMR+SLA+Buffer) leads to large cost increases. Our improving SLAs (EMR+Improving SLAs), especially with multi-tenancy and other optimizations (SLAOrchestrator), bring costs down.**

Another line of work focuses purely on enforcing SLAs, assuming that SLAs are pre-defined [12, 11, 56]. SLA runtimes are artificially generated by, for example, offering a performance guarantee 10x the true latency [12], or by setting SLAs to be the performance of past executions [29]. Without the right SLAs, the best enforcement does not help: If the cloud provider overprovisions the underlying system, the user has to bear large costs, making the cloud provider less competitive and encouraging the user to take her business elsewhere. If the cloud provider underprovisions the underlying system, the cloud provider has to pay penalties for missed SLAs and thus loses money in the long term or must raise prices to compensate.

In this paper, we address the problem of *selecting* and *enforcing* SLAs for ad-hoc analytical queries over systems with multiple nodes. We develop SLAOrchestrator, a system that enables a cloud provider to offer query-level, performance SLAs for ad-hoc data analytics. Instead of relying on outside-generated SLAs [12, 11, 56], SLAOrchestrator uses our PSLAManager from prior work [41] to show the user what is possible and the price tag associated with various options. SLAOrchestrator generates, updates over time, and enforces SLAs in a way that successfully brings down the cost, close to that of the original service without SLAs.

Figure 1 shows our system in action given a set of random tenants and EC2 prices.[1] The x-axis shows time and the y-axis shows the ratio of the service cost with SLAs to the service cost without SLAs. When we add performance SLAs to Amazon EMR and let the cloud provision the number of Virtual Machines (VMs) purchased under the covers, costs grow dramatically either due to SLA violations (EMR+SLAs) or over-provisioning (EMR+SLAs+Buffer). Since guarantees depend on the quality of the SLAs (measured by how close runtime estimates are to the real runtimes on the purchased resources), a key component of our approach is *to improve SLAs over time* (EMR+Improving SLAs). We complement these improving SLAs with *novel resource scheduling and provisioning algorithms* that minimize costs due to over- or under-provisioning given a per-query SLA (SLAOrchestrator).

SLAOrchestrator achieves its goal through three key techniques that form the core contributions of this work. First, SLAOrchestrator is designed on the core idea of a double nested, learning loop. In the outer loop, every time a tenant arrives, the system generates a performance SLA given its current model of query execution times. That model improves over time as more tenants use the system. The SLA is in effect for the duration of a *query session*, which is the time from the moment a user purchases an SLA and issues their first query until the user stops their data analysis and leaves the system. In the inner loop, SLAOrchestrator continuously learns from user workloads to improve query scheduling and resource provisioning decisions and reduce costs during query sessions. To drive this inner loop, we introduce a new subsystem, that we call *PerfEnforce*. We present the overall system architecture in Section 2.

Second, the PerfEnforce subsystem comprises a new type of query scheduler. Unlike traditional schedulers, which must arbitrate resource access and manage contention, PerfEnforce's scheduler operates in the context of seemingly unbounded, elastic cloud resources. Its goal is *cost-effectiveness*. It schedules queries in a manner that minimizes over- and under-provisioning overheads. We develop and evaluate four variants of the scheduler. The first variant is based on a PI controller. Two variants model the problem as either a contextual or non-contextual multi-armed bandit (MAB) [50]. The last variant models the problem as an online learning problem. We present the query scheduler in Section 3.

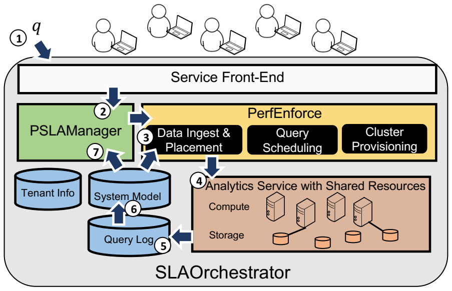

Figure 2: **SLAOrchestrator Architecture.**

Third, PerfEnforce also includes a new resource provisioning component. We evaluate two variants of resource provisioning: The first one strives to maintain a desired resource utilization level. The other one observes tenant query patterns and adjusts, accordingly, both the size of the overall resource pool and the tuning parameters of the query scheduler above. We present the resource provisioning algorithms in Section 4.

We evaluate all techniques in Section 5 and discuss related work in Section 6. As Figure 1 shows, SLAOrchestrator is able to reduce the costs associated with performance guarantees, bringing those costs down close to the basic service costs without guarantees.

2 System Architecture

Figure 2 shows SLAOrchestrator's system architecture. In this section, we present the details of that architecture and SLAOrchestrator's double nested learning loop.

2.1 System Components

SLAOrchestrator runs on top of a distributed, shared-nothing, data management and analytics engine (Analytics Service) such as Spark [7] or Hive [26]. We use our own Myria system [54] in the evaluation. Similar to how tenants use Amazon EMR today, in SLAOrchestrator, tenants upload their data to the service and analyze it by issuing declarative queries. While modern systems support complex queries, in this paper, we focus on relational select-project-join queries as proof-of-concept. However, there is nothing in our approach that precludes more complex queries in principal. On top of the Analytics Service, SLAOrchestrator includes an SLA generator (PSLAManager [41]), which generates performance SLAs for tenants. It also contains a dynamic scaling engine (PerfEnforce), which drives the scheduling and provisioning decisions for the underlying Analytics Service.

Analytics Service The back-end Analytics Service executes on a dynamically resizable pool of virtual

[1] We present the detailed experimental setup in Section 5 and the exact SLA function in Section 3.1.

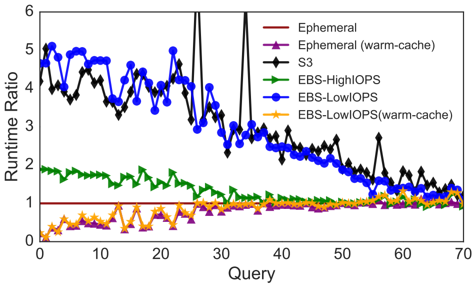

Figure 3: **Runtimes Compared to Local Storage.**

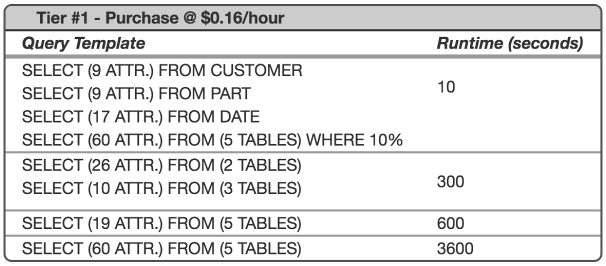

Tier #1 - Purchase @ $0.16/hour	
Query Template	*Runtime (seconds)*

SELECT (9 ATTR.) FROM CUSTOMER
SELECT (9 ATTR.) FROM PART
SELECT (17 ATTR.) FROM DATE
SELECT (60 ATTR.) FROM (5 TABLES) WHERE 10%
	10

SELECT (26 ATTR.) FROM (2 TABLES)
SELECT (10 ATTR.) FROM (3 TABLES)
	300

SELECT (19 ATTR.) FROM (5 TABLES)	600
SELECT (60 ATTR.) FROM (5 TABLES)	3600

Figure 4: **Example performance SLA provided by PSLAManager with one service tier. Additional service tiers would show similar query templates but with different prices and performance thresholds.**

machines (VMs) running a resource manager such as YARN [6]. PerfEnforce uses that engine in a multi-tenant fashion and takes over all query scheduling decisions. When a tenant executes a query, PerfEnforce's query scheduling algorithm determines the number of containers needed to run the query. It then allocates that number of containers from the shared VM pool. Additionally, PerfEnforce's resource provisioning determines when to grow or shrink the pool.

Analytics Service: Tenant Isolation As is common in today's big data systems, each parallel partition of each query is a task that executes in a separate container. Each query submitted by each tenant thus gets allocated its own set of containers across the VMs. Furthermore, our design partitions each tenant's dataset and attaches individual data partitions to containers, allowing for a more isolated environment. In our experiments, we use YARN containers. We schedule one container per VM and thus use the terms interchangeably.

Analytics Service: Storage Once a user purchases an SLA and before they can query their data, PerfEnforce prepares their data by ingesting it into fast networked storage, EBS volumes in our prototype. Figure 3 motivates our choice. The figure shows the median query execution times across three runs for a variety of storage options available on Amazon Web Services (AWS). The y-axis shows the runtime relative to local storage. Queries on the x-axis are sorted by local storage runtimes in ascending order. The 70 queries shown are based on a 100SF TPC-H SSB dataset on Myria [54] running on 32 i2.xlarge instances. As the figure shows, fast networked storage, such as EBS-HighIOPS, provides performance competitive with ephemeral storage, even on a cold cache query, without the need to dynamically migrate (or replicate) data fragments as VMs are added and removed from the shared pool. This type of storage is also affordable at less than 20% of the cost of a VM. Because we seek dynamism and must support data-intensive processing, fast networked storage is appealing.

During query execution, PerfEnforce attaches EBS volumes to different VMs and detaches them as needed. Each EBS volume holds a partition of the data, resulting in a standard shared-nothing configuration. To avoid data shuffling overheads due to scaling, PerfEnforce ingests multiple copies of each table. Each copy is partitioned across a subset of EBS volumes such that, when a query executes over a set of k containers, it uses the version of its data spread across k EBS volumes. Due to space constraints, we refer to our technical report for further details on EBS data placement and its negligible impact on performance [43].

SLA Generation To generate SLAs, we use a system from our prior work, the PSLAManager [41], but our system could work with others. PSLAManager takes as input a database schema and statistics associated with a database instance for a tenant (we use the term user and tenant interchangeably). It generates a performance-based SLA specific to a database instance as shown in Figure 4 for the TPC-H Star Schema Benchmark [40]. Each tier has a fixed hourly price, which maps to a predefined set of storage and compute resources, along with sets of grouped queries where each group contains a time threshold ("Runtime" in the figure). The time threshold represents the performance guarantee for its respective group of queries and corresponds to *query time estimates* made by the SLA generator for the corresponding resource configuration. For each resource configuration, we only consider varying the number of instances, but consistently use a standard network, and EBS-HighIOPS for storage across all configurations.

Each tier represents a performance summary for a specific set of containers the service can use for tenant queries, which we call a *configuration*. Tiers can correspond to different types and numbers of containers, but we use a single type in our experiments. We refer to all possible configurations that the system can use to execute a query as the set $configs$. For example, $config = \{2, 4, \ldots, 64\}$, represents all even numbers of containers up to a maximum of 64. The system shows tiers for a pre-defined subset of these configurations. Later, it can schedule queries using the full set of configurations. The price of each tier is at least the sum of the hourly cost of the containers and network storage.

When a tenant purchases a performance SLA, she unknowingly purchases a configuration. The system starts a *query session* for the tenant and the latter starts paying the corresponding fixed hourly price. During the session, the tenant issues queries. The queries get queued up and execute one after the other, each one running in the entire set of containers in the purchased configuration. As we present in Section 3, PerfEnforce changes these allocations over time based on how fast they execute compared with the initial SLA time.

2.2 Double Nested Learning

To drive the SLA generation, SLAOrchestrator maintains a log of all past queries executed in the system. Initially, it executes queries from a 100GB dataset generated by the Parallel Data Generation Framework(PDGF) [45]. The system runs queries on all configurations that it will sell to populate the query log. With this information, SLAOrchestrator builds a model of query execution times. Each query is represented by a feature vector. Features correspond to query plan properties including the number of tables being joined, their sizes, the query cost estimates from the query optimizer, the number of containers in the configuration, etc. SLAOrchestrator learns a function from that feature vector to a query execution time. In our work, we use a simple linear model as in prior work [41, 53]. More complex models are possible but we find a simple linear model to yield good results for the select-project-join queries that we focus on in this paper. With this model, predictions are made by learning the coefficients (a weight vector, w) [9] given the query features, x_q: $y(x_q, w) = \sum_{d=1}^{D} w_d \cdot x_{q_d}$.

With our previous PSLAManager work [41], we observed that when a new tenant joins the system, estimates for that tenant's queries are likely to be inaccurate because the system has limited information about the tenant data and queries (only statistics on base data). However, as the tenant starts to execute queries, the system can quickly learn the properties of the data and can specialize its model to that data. PerfEnforce uses this information to dynamically adjust query scheduling and resource provisioning decisions in the context of an existing SLA. We call this the **Inner Learning Loop**. The effect of this learning is also that the system updates the SLA that it offers after each query session. This is SLAOrchestrator's **Outer Learning Loop**. The benefit of more precise SLAs to tenants is the overall reduction in the service cost. We use TensorFlow [1] to build this model and train on the PDGF dataset. We generate 4000 queries (500 per configuration) and record the features as well as runtimes into the System Model.

Figure 2 shows in more detail how SLAOrchestrator components interact with one another. Steps 1 through 6 denote the **Inner Learning Loop**: (1) Each tenant query, q is issued through the service front-end. (2) PSLAManager determines q's promised SLA time based on the service tier that the user previously purchased. (3) PerfEnforce uses query scheduling algorithms in conjunction with the System Model to determine the number of containers to schedule for q. (4) PerfEnforce schedules q on the Analytics Service. (5) The Analytics Service sends metadata about the query to the Query Log. (6) The System Model parses the Query Log metadata and stores features for the learning models. Once a tenant completes their session, SLAOrchestrator initiates the **Outer Learning Loop**. In Step 7, the PSLAManager system takes the information from the System Model and generates an improved SLA.

In the next two sections, we focus on the PerfEnforce subsystem and its query scheduling (Section 3) and resource provisioning (Section 4) algorithms, which are part of SLAOrchestrator's inner learning loop.

3 Dynamic Query Scheduling

Every time a new tenant purchases a service tier, PerfEnforce begins a query session for that tenant. The initial state of the query session indicates the configuration (i.e., number of containers) that corresponds to the purchased service tier. Many sessions are active at the same time and PerfEnforce receives streams of queries from these active tenants. Each query is associated with a possibly imperfect SLA. That is, the query may run significantly faster or slower than the SLA time if scheduled on the purchased set of containers. PerfEnforce's goal is to determine how many containers to actually use for each query with the goal to minimize operation costs. In this section, we present PerfEnforce's query scheduling algorithm.

3.1 Optimization Function

Consider a cloud service operation interval $T = [t_{start}, t_{end}]$. The total operating cost to the cloud during that interval is the cost of the resources used for the service and the cost associated with SLA violations for tenants active during that interval. Thus, PerfEnforce's goal is to minimize the following cost function :

$$\text{cost}(T) = \text{cost}_R(T) + \sum_{u \in U(T)} (\text{penalty}(u)) \qquad (1)$$

where $U(T)$ is the set of all tenants active during time interval, T, and $cost_R(T)$, is given by:

$$\text{cost}_R(T) = \sum_{t=t_{start}}^{t_{end}-1} \text{cost}_t(\text{resources}) \qquad (2)$$

where $cost_t(resources)$ represents the cost of resources for time interval $[t, t+1]$, which depends on the size and the price of individual compute instances.

The SLA penalty, $penalty(u)$, is the amount of money to refund to user u in case there are any SLA violations. In this paper, we use the following formulation:

$$\mathcal{S}\left(\frac{1}{|\mathcal{W}_u|} \sum_{q \in \mathcal{W}_u} \max(0, \frac{t_{real}(q) - t_{sla}(q)}{t_{sla}(q)})\right) * \alpha * p_u \qquad (3)$$

where $\mathcal{W}_u$ is the sequence of queries executed by user u, $t_{real}(q)$ is the real query execution time of query q,

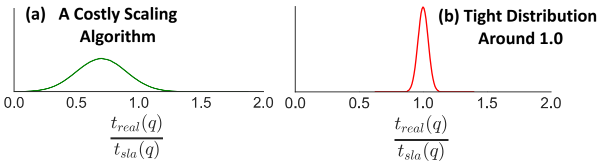

Figure 5: **Examples of Distributions of Query Performance Ratios**

$t_{sla}(q)$ is the SLA time of q, p_u is the session price paid by user u in the absence of SLA violations, and α is a configurable parameter that we vary in our experiments to adjust the cost of SLA penalties compared with container resource costs. $\mathcal{S}$ is a step function that rounds up and truncates values. This step function is inspired by real SLAs in cloud services that incur penalties based on availability outages [8, 49, 51].

3.2 Query Scheduling Algorithms

For each query $q \in \mathcal{W}_u$ and for each user u, PerfEnforce's query scheduling algorithm must determine the number of containers from the shared pool to allocate to the query. PerfEnforce begins with using the number of containers that corresponds to the purchased service tier. It observes the resulting query runtimes and dynamically adjusts the number of containers for subsequent queries by using a *scaling* algorithm. It runs a scaling algorithm separately for each tenant.

To minimize resource costs, the scaling algorithm should schedule queries on the smallest possible number of containers. To avoid SLA penalties, however, it must schedule queries on sufficiently large numbers of containers to ensure that the real query execution time, $t_{real}(q)$, is below the SLA time, $t_{sla}(q)$. We define the *query performance ratio* as $\frac{t_{real}(q)}{t_{sla}(q)}$ and the goal of the query scheduling algorithm is thus to execute each query in the configuration that yields a performance ratio of 1.0. In practice, if the query scheduling algorithm aims for query performance ratios of X, it will yield a query performance ratio distribution around X as illustrated in Figure 5. To illustrate our point, we plot synthetic Gaussians. Real distributions are noisier. Since we can adjust the mean of the distribution (a.k.a. setpoint), X, the quality of the scheduling algorithm is determined by the tightness of the distribution around X. In other words, if the distribution is wide (large standard deviation σ), then the system is either wasting resources for many queries (Figure 5a) or causing a large number of SLA violations. A good query scheduling algorithm should yield a tight distribution as in Figure 5b).

3.2.1 Reactive Scaling Algorithms

A reactive algorithm observes errors between the real and SLA runtimes and adjusts the number of containers accordingly for each subsequent query. We implement a Proportional Integral (PI) controller and a Multi-Armed-Bandit (MAB) as our reactive methods. Both of these techniques have successfully been used in other resource allocation contexts [31, 33, 35, 37].

A limitation of the these techniques is that the configuration size chosen for a new query depends only on the rewards or errors of previous queries ignoring the features of the current query. We use the reactive methods as baseline.

Proportional Integral Control (PI). Feedback control [28] in general, and PI controllers in particular, are commonly used to regulate a system in order to ensure that it operates at a given reference point. With a PI controller, at each time step, t, the controller produces an actuator value $u(t)$. In our scenario, this is the number of containers to use for the current query. The actuator value, causes the system to produce an output $y(t+1)$ at the next time step. We compute $y(t)$ as the average query performance ratio over some time window of queries w: $y(t) = \frac{1}{|w|}\sum_{q\in w}\frac{t_{real}(q_j)}{t_{sla}(q_j)}$ where $|w|$ is the number of queries in w. The goal is for the output, $y(t)$, to be equal to some desired reference output $r(t)$, 1.0 in our setting.

The error $e(t) = y(t) - r(t)$ captures a percent error between the current and desired average runtime ratios. Since the number of containers to spin up and remove given such a percent error depends on the configuration size, we add that size to the error computation as follows: $e(t) = (y(t) - r(t))u(t)$.

The PI controller, chooses the next number of containers as a combination of the initial configuration size $u(0)$, the most recently observed error, $e(t)$, and the sum of all accumulated errors $\sum_{x=0}^{t} e(x)$. k_p and k_i are tunable controller parameters, which determine how strongly the controller reacts to recent errors and how much it weighs history: $u(t+1) = u(0) + \sum_{x=0}^{t} k_i e(x) + k_p e(t)$

Multi-Armed Bandits (MAB). In a MAB problem, the system must repeatedly choose among k different options, or *arms*. At each timestep t, the system makes a decision by selecting one of k arms, a_t, and receives a reward, r_t [50]. In our setting, each arm is a configuration from the set $configs$. The arm choice is the decision to schedule the next query using a given configuration size.

The goal is to maximize the total reward across many timesteps. In the bandit setting, the algorithm must learn the reward distributions for different arms through a process of trial and error [9]. At each timestep, the system must thus choose to either select the arm with the highest estimated reward (*exploitation*) or try another arm (*exploration*) in order to acquire more information and maximizing the reward across all timesteps [50].

To help balance between exploration and exploitation, we use a heuristic known as *Thompson Sampling* [10]. During initialization, we define priors describing the expected reward of each arm. In our setting, we do not make assumptions for each configuration. Instead, we initialize the model for each arm using a uniform distribution, a noninformative prior. At timestep t, the system constructs a posterior distribution for each arm based on observed rewards, $P(\theta|a, r_0, ..., r_{t-1})$, where θ represents the model parameters. For each query submitted, the system samples from a candidate posterior distribution, defined as $\hat{\theta}$. Given that our prior is based on a uniform distribution, we use a t-distribution to represent our posterior. This t-distribution takes the reward mean, variance, and count as input. As the system samples from this posterior, we select the arm with the highest expected reward, $arg\,max_a \mathbb{E}[P(r_t|\hat{\theta}_\alpha)]$.

3.2.2 Proactive Scaling Algorithms

To address the limitations of the reactive techniques, we consider two other scaling algorithms that both include additional context, x_q, for each incoming query, where x_q is a $D-$dimensional vector of features describing the query, $x_q = (x_{q_1}, ..., x_{q_D})^T$. To generate the feature vector, we use the query optimizer of the back-end query execution engine and include information from the query plans (e.g. number of columns, estimated costs, estimated rows, estimated width, and the number of workers scheduled to run the query).

Contextual Multi-Arm Bandit (CMAB). This approach is a variant of the multi-armed bandit problem that includes contextual information. In a CMAB problem, at each timestep t, the algorithm receives a feature vector, x_q, as input, and uses it to determine the best arm, a_t. CMAB does this by building a model *for each configuration* that predicts the reward in that configuration given a query feature vector. The expected value of the reward for each arm and feature vector thus becomes: $q_\star(a) = \mathbb{E}[r_t|a_t, x_q, \theta]$.

Where θ represents the parameters of the generated model [10]. As with MAB, PerfEnforce uses the Thomson sampling heuristic to balance exploration and exploitation. At each timestep t, PerfEnforce builds a predictive model for each state by computing a bootstrap sample over all previous observations. PerfEnforce selects the action that corresponds to the state with the best predicted reward (i.e., reward closest to 1.0). In our prototype implementation, we use the REPTree model from Weka [22] as used in BanditDB [37]. For the first N queries in a tenant's session, we begin with a "warm-up" phase where we execute queries a small number of times in each configuration to initialize the observations for that configuration. PerfEnforce runs the "warm-up" session at the start of the query session, which could impact performance for some queries.

Online Learning The CMAB technique described above presents two practical challenges. First, it is difficult to determine the number of queries that should be used to initialize the distributions for each state. At least one query must be executed in each state, which can be either unnecessarily expensive or undesirably slow. The overhead especially penalizes short query sessions as early queries undergo larger amounts of exploration. Second, the observations collected are independent for each state. If one configuration suddenly results in slower or faster runtimes, this knowledge does not propagate to other states.

Because of the above limitations, we propose a different algorithm for our setting. We build a single model of query execution times with the configuration size as a feature. As a user executes queries, we always schedule those queries in configuration sizes expected to yield the best performance ratio and use the resulting query execution times to update our global model.

As described in the previous section, SLAOrchestrator maintains a model of query execution time that it uses for SLA generation. The idea here is for PerfEnforce to *continuously update* that model, during a tenant's query session, based on the measured query execution times. To update the model, PerfEnforce uses stochastic gradient descent. For each data point, it slowly updates the weight vector based on the gradient of a loss function, E: $w^{(\tau+1)} = w^{(\tau)} - \eta\nabla E$ [9]. Where τ represents the nth data point and η represents the learning rate. Importantly, PerfEnforce maintains a separate model of query execution time for each dataset so as to specialize its model to the properties of that dataset. If the underlying data significantly changes, the model could take time to adjust to changes, depending on the learning rate. Since we primarily focus on analytic sessions, we do not evaluate how this model adapts to updates. Training this model is relatively cheap, taking approximately 2.38s for a single epoch. Each prediction takes ∼10ms.

Setpoint Adjustment With all algorithms above, PerfEnforce strives to schedule queries such that their performance ratios form a tight distribution around a desired setpoint. An important question is how to tune the value of that setpoint. If the setpoint is 1.0 and the mean of the distribution falls on that setpoint, 50% of all queries will miss their SLA times. The setpoint can be lowered such that more, perhaps 90% of all queries, meet their SLA time. Lowering the setpoint, however, will increase the number of containers used for those queries and will thus raise resource costs. In SLAOrchestrator, we adjust the setpoint dynamically. We do so at the same time as we make cluster provisioning decisions as described next.

4 Dynamic Provisioning

With the above query scheduler, the total number of containers needed to service the active set of tenants varies over time. To reduce operation costs, PerfEnforce includes a resource provisioning component that determines when to grow and shrink the *shared* pool of compute resources. Provisioning is particularly challenging as it can take time to spin up new virtual machines. We observe that it takes approximately 12 seconds to spin up a virtual machine with a pre-loaded image on Amazon. We consider this start up time throughout our evaluation.

Utilization Provisioning: The most common approach to resource provisioning is to maintain a desired resource utilization level. Typically, this means adding (or removing) resources when CPU, I/O, network and memory usage move beyond (or below) set thresholds [3, 8, 21, 48].

We posit, however, that measuring resource utilization levels directly is not the right approach for PerfEnforce because tenants are allocated resource containers. As such, some tenants might execute I/O intensive workloads while others may run CPU intensive workloads, leading to very different resource utilization levels for various containers. In general, high resource utilization does not imply a higher demand for resources [14].

Instead of aiming for a given CPU or I/O utilization goal, we aim for an average *VM utilization* target, Z. The utilization of each machine is measured by the percentage of time it is actively running queries (wall clock time). For our target Z, we aim for an average utilization across all shared VMs, $AvgUtilization$.To determine the number of machines the system should provision to meet Z, we implement a PI controller where the set point is Z. Besides wall clock time, we note that other metrics for system state could be used as well. For example, the system could target a desired percentage of idle machines or a desired tenant query queue length.

Simulation-based Provisioning: For a more proactive approach to provisioning, we propose to explicitly consider tenant recent workloads rather than only measure resource utilization. Specifically, we propose to build models of tenant workloads and estimate the smallest number of shared resources to support these modeled workloads. This approach should be more effective than simply looking at utilization, since the latter is tightly coupled with the specific set of executed queries and the query scheduler's resource allocation decisions, which are themselves constrained by the amount of shared resources. To estimate the best number of shared resources to support tenant modeled workloads, we use simulations. This approach is not new and has been recently used in the "What-If" engine from Tempo [52], where the goal is to simulate the performance of many configurations of the MapReduce Resource Manager. We aim to understand how such a provisioning algorithm in combination with a learning query scheduler can help make profitable decisions in a multi-tenant service.

In this provisioning approach, we model each tenant, u, with a tuple (Q_u, λ_u), where Q_u is a set of queries that the tenant may issue and λ_u is the tenant's average think time between consecutive queries. PerfEnforce learns both values from a recent window of each tenant's query session. Based on these models, PerfEnforce then generates random sessions for each active tenant. To generate a random session, PerfEnforce samples queries from the recent query workload and also samples the think time based on a Poisson distribution. During these simulations, we also evaluate the costs of dynamically shifting the setpoint. In general, these simulations help PerfEnforce discover whether setpoint adjustments are necessary for active tenants or whether nodes should be added or removed to further save on costs.

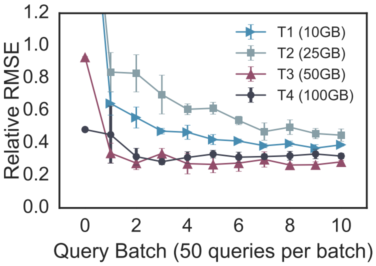

Figure 6: **SLA improvements across query sessions**

5 Evaluation

We run SLAOrchestrator and execute all queries on Amazon EC2 using i2.xlarge (4 ECU, 30 GB Memory) instance types priced at $0.12/hr. We consider eight types of query scheduling configurations, each with a different number of compute instances: `configs` $= \{4, 8, 12, 16, 20, 24, 28, 32\}$. For multi-tenant experiments, we run simulations with up to thousands of servers and use the query times measured on EC2. For our underlying shared-nothing, database management system, we use Myria [54]. Myria uses PostgreSQL as its storage subsystem.

To generate each tenant's query sequence, $\mathcal{W}_u$, we alternate between different patterns of queries. For example, one tenant might run small, lightweight queries for a majority of the session before switching to queries with larger joins and higher latencies. Thus, for some random number of queries, k, we define the following three discrete distributions: (1) number of joins, (2) number of projected attributes, and (3) selectivity factor. For the next k queries, we sample from each of these distributions and generate a query that meets all the sampled characteristics. Once k queries are generated, we define new distributions for the next random interval of queries. We use both uniform and skewed (zipfian) distributions. Unless stated otherwise, all the query workloads throughout the evaluation are generated in this fashion.

5.1 Evaluation of SLA Predictions

A key tenet of SLAOrchestrator is the idea that the system should update SLAs because they rapidly improve as a tenant queries a database. We validate this hypothesis in this section. Figure 6 shows the error of the SLA predictions for four tenants, each with a different, random star schema [45] and database instance: T1 = 10GB, T2 = 25GB, T3 = 50GB, T4= 100GB. We generate a set of SPJ queries with random selection predicates for each tenant. As tenants execute queries, SLAOrchestrator updates the query time model separately for each database. After each query batch, PSLAManager re-generates an updated SLA. As the figure shows, in all cases, the RRMSEs (relative root mean squared errors) between the real runtimes and the predicted SLA runtimes decreases rapidly after the first batch and then improves more slowly. We compute the error on a sample of queries generated by the PSLAManager for the tenant SLA. We measure the RRMSE as: $\sqrt{\frac{1}{|\mathcal{W}|}\sum_{q\in\mathcal{W}}(\frac{(t_{real}(q)-t_{sla}(q))}{t_{sla}(q)})^2}$. The prediction errors observed before running an initial batch of queries (Query Batch 0), are highly dependent on the similarity between the tenant's database and the synthetic database used to train our offline base model. In our experiments, while databases differ in their schemas and table sizes, we find that table sizes have the greatest impact on prediction errors. Our offline model is trained on a generated 100GB PDGF dataset. We observe a higher initial RRMSE error (approx. 2.4-2.5) for tenants T1 and T2 with the smaller databases.

5.2 Evaluation of Query Schedulers

The goal of each query scheduler is to ensure a tight distribution (small σ) of query performance ratios around a μ close to 1.0 (later in Section 5.4, we consider dynamic setpoint tuning). In this section, we evaluate how the different scheduling algorithms perform in the face of different tenant workloads. All tenant workloads are based on the 100GB TPC-H SSB benchmark [40]. We evaluate the algorithms using different-quality SLAs as shown in Table 1, which could correspond, for example, to different model qualities as shown in Section 5.1.

We first evaluate the PI-Control scheduling algorithm on four different SLA types and, in each case, on 10 different, randomly generated, tenant query sessions. We execute the PI controller on each tenant's query session independently and measure the resulting query performance distribution for that tenant. We then compute the average μ and σ across these 10 distributions and plot them in the first row of Figure 7. The y-axis represents the distance between μ and 1.0, while the x-axis displays the standard deviation of the query performance distributions. Because the PI controller has three tunable parameters (k_p, k_i and w), each point in the figure corresponds to one such parameter combination. For each graph, we also plot the average distribution of an Oracle, which always selects the best configuration size for each query. The best parameter combinations are those closest to the Oracle. If any technique's parameters result in a distribution with a higher σ or a μ farther from 1.0, this error impacts cost, which ultimately depends on the cost function. As the figure shows, for all SLAs, the PI-Control algorithm results in average distributions that are far from the average distribution of the Oracle. There are no best set of parameters that work across all workloads.

In the second row of Figure 7, we show the average distributions for MAB, CMAB, and online learning across the same set of SLA types and tenant query sessions. Note, the ranges for the axes are much smaller for these graphs compared to the PI-Controller, which shows that these techniques result in average distributions much closer to the Oracle. For both bandit techniques, we execute each tenant's query session 20 times due to their variance when sampling. For online learning, we vary the learning parameter, η. In the first 4 columns of the figure, we omit the performance ratios for the first 20 queries for all scaling techniques, since the bandits require an initial "warm-up" phase, where they need to try each configuration at least two times.

For the SG SLA, the bandit techniques result in average distributions nearly identical to the Oracle. Since both techniques rely on learning a distribution of query performance ratios per configuration, they quickly find the optimal configuration during the warm-up phase and select this configuration for a majority of the queries. Since the online learning technique is directly predicting the runtimes for each query, the prediction errors result in average distributions that are slightly farther away from the Oracle. For the PLJ SLA, all techniques perform similarly as most of the runtimes are meet at configurations that are close to the purchased tier. In contrast, online learning outperforms both bandit-based methods for the NLJ and Initial SLAs. The NLJ SLA underestimates runtimes, which requires the schedulers to accurately choose across a wider set of configuration options. For these more difficult cases, context is critical as the scheduling algorithm must make different decisions for different queries. There is no single best configuration. As a result, CMAB and the online learning approach both outperform the simpler MAB scheduler. Online learning further outperforms CMAB because this technique is able to quickly learn the performance correlations between configurations, which is crucial for the initial SLA as it requires scaling for each query.

The final column shows the average performance ratio distributions when using the initial SLA and including the queries in the warm-up period. As the figure shows, the online learning technique significantly outperform the bandit-based methods because it has the extra benefit of starting to learn from the offline model and learning more quickly because it learns a single model for all configurations. These results show that the PI controller is ill-suited to our problem and we do not consider

SLA	Description
Small Gaussian Error (SG SLA)	SLA assumes a good prediction model and tests sensitivity to small errors (or variance) in query times. Generated by taking the real query execution times at the purchased tier and adding a small Gaussian error: $\mathcal{N} = (\sigma = 0.1 * t_{real}(q), \mu = 0)$.
Positive/Negative Gaussian Errors for Large Joins (PLJ/NLJ SLA)	We skew SLA runtimes for some query types. We introduce large positive/negative errors to the real runtimes on queries with a large number of joins (>3 joins) and with a runtime $>$100 seconds. We update the runtime to $t_{real}(q) + \|e\|$ (or $-\|e\|$), where e is sampled from a Gaussian distribution, $\mathcal{N} = (\sigma = 0.3 * t_{real}(q), \mu = 0)$. For other queries, we still inject small errors as in SG SLA.
Initial SLA	This is the least accurate SLA, where runtimes are generated by an initial offline-trained model.

Table 1: **SLAs used in experiments.**

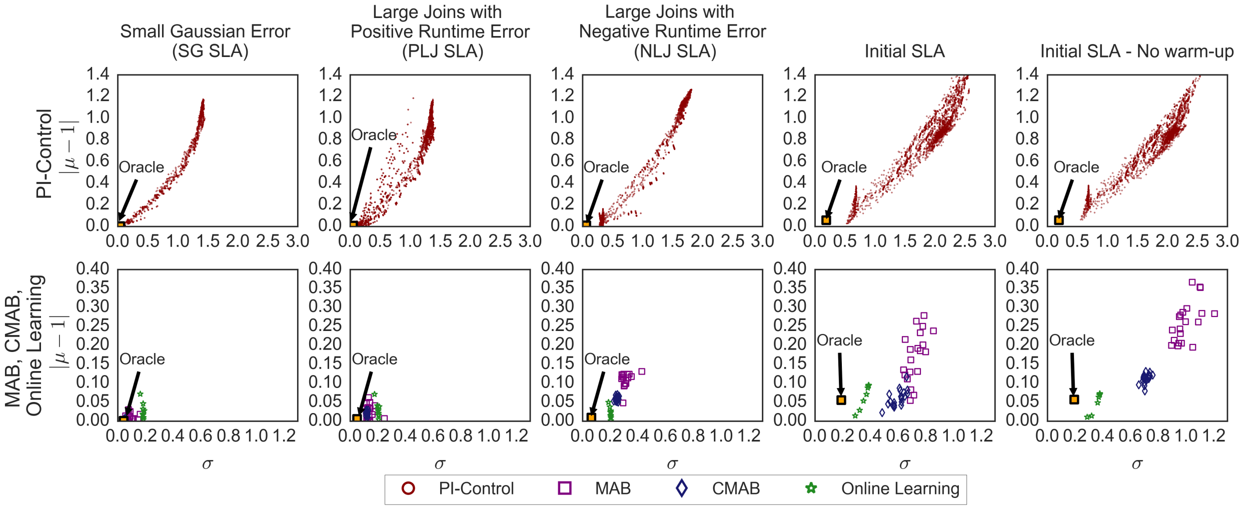

Figure 7: **Evaluation of PI-Controller, MAB, CMAB and online learning scheduling algorithms**

	MAB	CMAB	Online Learning	Oracle
μ	1.1368	1.1244	1.0161	1.0015
σ	0.1680	0.0871	0.0522	0.0008

Table 2: **Ratio distributions during slow down**

it further.

We now evaluate how query scheduling algorithms can adapt to changing conditions. Recall, the goal of these query schedulers is to ensure a query performance ratio distribution close to 1.0. We generate a query sequence by selecting one query and running it repeatedly several times. Each time we run this query, we record the query performance ratio. Once we reach the 250th iteration, we increase the query's runtime by 25% (essentially slowing down the system) for the rest of the session, running up to 1000 iterations. Table 2 shows that the online learning technique reacts the fastest to this change in conditions, leading to an overall mean performance ratio closest to 1.0. We omit additional experiments with different changing workloads due to space constraints.

5.3 Evaluation of Provisioning Algorithms

We first evaluate each provisioning algorithm in combination with the Oracle query scheduler to ensure that query runtime penalties are not a side-effect of the query scheduler's mispredictions. We launch each multi-tenant tenant session based on session parameters summarized in Table 3.

We introduce up to 100 tenants in a session and simulate a shared cluster with thousands of containers/VMs. We sample arrival times, think times, and session durations from Poisson distributions defined by their corresponding parameters $\lambda_{arrival}$, $\lambda_{thinktime}$ and $\lambda_{terminate}$. PerfEnforce always keeps at least a minimum of 4 machines launched at all times, to ensure that there are enough machines available to execute queries. Each provisioning algorithm monitors the shared resources and tenants for $\mathcal{M}$ minutes before adding or removing VMs from the pool. Our step function $\mathcal{S}$ provides no service credit if the system misses the runtime by 10%. For each additional 20% increment and given a threshold from x% to y%, we increase the credit to y%.

Notation	Description
U_{init}	Initial number of tenants in the session
V_{init}	Initial number of virtual machines
$\lambda_{arrival}$	Average time between new tenants
$\lambda_{thinktime}$	Average tenant think time
$\lambda_{terminate}$	Average tenant session duration
$\mathcal{M}$	Provisioning monitoring time interval

Table 3: **Parameters of multi-tenant experiments**

As described in Section 2, each submitted query gets allocated a set of containers. We schedule one container (running a Myria process) per VM. For each query, the system assigns the tenant's EBS volumes to a set of VMs in the pool. After the query completes, the volumes are detached from the VMs, making them available to other tenants. We find it takes 4 seconds to mount a volume to

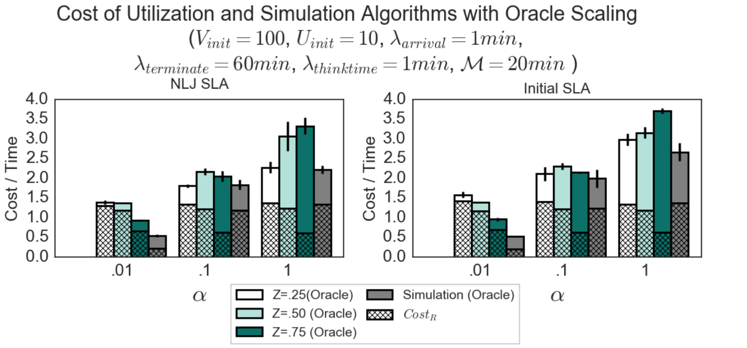

Figure 8: **Comparing utilization-based and simulation-based provisioning in conjunction with an Oracle query scheduler. The hash pattern represents the proportion of the cost due to $Cost_R$**

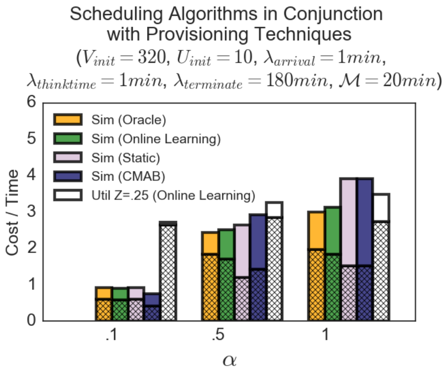

Figure 9: **Costs of query scheduling in conjunction with provisioning**

a VM. Detaching takes approximately 11 seconds. We include these delays in the experiments.

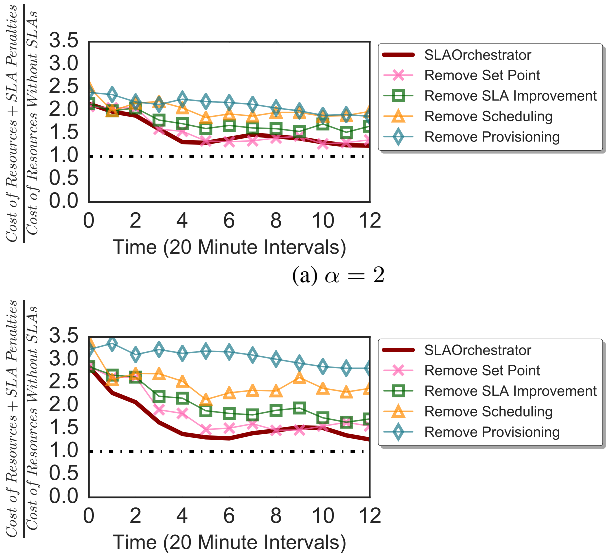
Utilization and Simulation-based Provisioning We compare the multi-tenant session costs when provisioning VMs using either the utilization-based or simulation-based approaches. We launch 100 VMs with 10 initial tenants and set the provisioning monitoring time to $20min$. Figure 8 shows the results and the other experimental parameters. For different average utilizations, Z, we show the results for the best parameter values V_{k_p} and V_{k_i}. The y-axis shows the cost per time unit, while the x-axis shows the value of the α parameter. Recall from Equation 3 that we define α as a tunable parameter that amplifies the weight of the SLA penalty compared to the resource cost. The hash pattern in each bar represents the proportion of the cost due to $Cost_R$, the cost of resources. Other costs come from SLA violations. Error bars show variance across 10 runs. As expected, the utilization-based method requires tuning depending on the α value. Simulation-based provisioning has the double-benefit of avoiding any tuning and more cost effectively provisioning shared resources compared to the utilization-based approach.

Combining Scheduling and Provisioning We now evaluate the performance of simulation-based provisioning in conjunction with various query scheduling algorithms on the initial SLA. In Figure 9, we vary alpha (x-axis) and measure the total cost compared with an Oracle query scheduler (y-axis). As a baseline, we also include a naive query scheduler, *static*, which simply schedules each query on the configuration initially purchased by the user. We also include utilization-based provisioning at $Z = .25$ (using online learning as the query scheduler). We still initialize the session with 10 tenants, but we start with a larger pool of 320 VMs, allowing enough room to have each initial tenant schedule queries on up to 32 containers. In this experiment, since we also include CMAB, we extend the session times to 180 to ensure the algorithm has more time to operate in steady state (beyond the warm-up phase).

Overall, simulation-based provisioning continues to outperform the utilization-based approach even with a less perfect scheduler. Even when penalties are high, simulation-based provisioning reduces costs by 11% and more for lower penalties. Additionally, the online learning-based scheduler yields similar costs to the Oracle scheduler (a 4% overhead). As expected, it significantly outperforms the static scheduler and CMAB when SLA penalties are expensive, with 20% cost savings. CMAB does worse because it causes more SLA violations. For small α, the CMAB approaches result in costs lower than even the Oracle scheduler. This is because the CMAB's warm-up phase initially schedules queries on all available configurations (even small configurations), which then causes the simulation approach to provision less resources. Throughout the session, resources are not added back in due to the low α value.

5.4 Dynamic Setpoint Tuning

Finally, we evaluate the benefits of dynamic setpoints together with the relative benefits of the other optimizations. Figure 10a shows the results. In the figure, we start with SLAOrchestrator as initially shown in Figure 1. We then remove optimizations one at a time in order. First, we remove the ability to use dynamic setpoints, followed by removing SLA improvements, scheduling and provisioning. We remove these optimizations to run SLAOrchestrator as a simpler multi-tenant system. To emphasize the differences between optimizations, we use $\alpha = 2$ and $\alpha = 3$. In this experiment, we start the session with 5 tenants and 80 VMs (ensuring 16 nodes per tenant, the amount they have purchased). New tenants arrive approximately every 5 minutes, and tenants finish their session after 180 minutes. As seen in the figures, removing each optimization increases the cost. This is



(a) $\alpha = 2$

(b) $\alpha = 3$

Figure 10: **Performance when disabling different SLAOrchestrator optimizations**

especially apparent for $\alpha = 3$, where SLAOrchestrator decreases the cost by up to 59% compared to the case with no optimizations.

5.5 Evaluation Discussion

The SPJ query workloads we use throughout the evaluation allow us to demonstrate a proof of concept for SLAOrchestrator. Incorporating more complex query workloads (e.g., considering aggregates and subqueries), would impact the online learning and CMAB techniques as they would require more advanced models and more extensive feature engineering than those considered in this work. Second, for a more thorough provisioning evaluation, running SLAOrchestrator against real tenant traces would help to better understand how the system would behave under more bursty workloads.

6 Related Work

Elastic Scaling for Performance Guarantees Performance guarantees have been the focus of real-time database systems [30], where the goal is to schedule queries in a fixed-size cluster and minimize deadlines. Provisioning and admission control methods have enabled OLAP and OLTP systems to make profitable choices with respect to performance guarantees [12, 11, 56], possibly postponing or even simply rejecting queries. Work by Das et. al [14], uses telemetry to determine whether to scale up containers within a single node, whereas our goal is to scale the number of containers per query. Ernest [53], CherryPick [2], Morpheus [29] and CloudScale [48] find good configurations for analytical workloads, but require representative workloads or repeated tenant usage patterns. Several systems have studied performance SLAs through dynamic resource allocation, including feedback control [33], and TIRAMOLA [31] which use reinforcement learning techniques. Others leverage decisions based on resource utilization goals [13, 15, 19, 39, 51, 57]. Tempo [52] simulates the performance of many MapReduce Resource Manager configurations to meet a global system objective, but jobs can be preempted to allow high priority tenants to finish first.

Multi-Tenant Workload Consolidation Related work addresses bad tenant packings by either finding a good initial placement strategy or dynamically migrating tenants [15, 17, 32, 34, 51, 55]. Finding a good tenant placement strategy is not the focus of our work. Instead, we focus on algorithms that help determine when to launch or turn off machines.

Query Runtime Prediction Previous work has relied on techniques to find whether a query will miss a deadline [56], build gray-box performance models [20], use historical traces of workloads [18], use benchmarks to profile resources [58], or run smaller samples of the workload [53]. Herodotou et. al. [24], assumes a previously profiled workload to predict the runtime throughout different sized clusters. Jalaparti et. al. [27] generates resource combinations given performance goals. Instead of building an analytical model, we use a model that does not require an extensive understanding of a single system. We also focus on ad-hoc queries with no prior profiles.

Provisioning In terms of provisioning, some rely on machine learning techniques such as the hill-climbing approach seen in Marcus et. al. [37], which allows machines to learn an optimal time to wait before they shut down. Neural networks for dynamic allocation [38] or dynamic provisioning [44] have also been used, but have distinct goals. One focuses on allocating resources with minimal use of electrical power while the other assumes predictable workloads.

7 Conclusion

We presented SLAOrchestrator, a new system designed to minimize the price of performance SLAs in cloud analytics systems. SLAOrchestrator uses a double learning loop that improves SLAs and resource management over time. To support the latter, the system also includes an efficient combination of elastic query scheduling and multi-tenant resource provisioning algorithms that work toward minimizing service costs. Experiments demonstrate that SLAOrchestrator dramatically reduces service costs for a common type of per-query latency SLAs.

Spindle: Informed Memory Access Monitoring

Haojie Wang[*†], Jidong Zhai[*], Xiongchao Tang[*†], Bowen Yu[*], Xiaosong Ma[†], Wenguang Chen[*]

Abstract

Memory monitoring is of critical use in understanding applications and evaluating systems. Due to the dynamic nature in programs' memory accesses, common practice today leaves large amounts of address examination and data recording at runtime, at the cost of substantial performance overhead (and large storage time/space consumption if memory traces are collected).

Recognizing the memory access patterns available at compile time and redundancy in runtime checks, we propose a novel memory access monitoring and analysis framework, Spindle. Unlike methods delaying all checks to runtime or performing task-specific optimization at compile time, Spindle performs *common static analysis* to identify predictable memory access patterns into a compact program structure summary. Custom memory monitoring tools can then be developed on top of Spindle, leveraging the structural information extracted to dramatically reduce the amount of instrumentation that incurs heavy runtime memory address examination or recording. We implement Spindle in the popular LLVM compiler, supporting both single-thread and multi-threaded programs. Our evaluation demonstrated the effectiveness of two Spindle-based tools, performing memory bug detection and trace collection respectively, with a variety of programs. Results show that these tools are able to aggressively prune online memory monitoring processing, fulfilling desired tasks with performance overhead significantly reduced (2.54× on average for memory bug detection and over 200× on average for access tracing, over state-of-the-art solutions).

1 Introduction

Memory access behavior is crucial to understand applications and evaluate systems. They are widely monitored in system and architecture research, for memory bug or race condition detection [21, 27, 31], information flow tracking [16, 30], large-scale system optimization [35, 36, 42], and memory system design [14, 17, 20].

Memory access monitoring and tracing need to obtain and check/record memory addresses visited by a program and this process is quite expensive. Even given complete source-level information, much of the relevant information regarding locations to be accessed at runtime is not available at compile time. For example, it is common that during static analysis, we see a heap object accessed repeately in a loop, but does not have any of the parameters needed to perform our desired examination or tracing: where the object is allocated, how large it is, or how many iterations there are in a particular execution of the loop. As a result, existing memory checking tools mostly delay the checking/transcribing of such memory addresses to execution time, with associated instructions instrumented to perform task-specific processing. Such runtime processing brings substantial performance overhead (typically bringing 2× or more application slowdown [5, 33] for online memory access checking and much higher for memory trace collection [6, 22, 26]).

However, there are important information not well utilized at compile time. Even with actual locations, sizes, branch taken decisions, or loop iteration counts unknown, we still see patterns in memory accesses. In particular, accesses to large objects are not isolated events that have to be verified or recorded individually at runtime. Instead, they form groups with highly similar (often identical) behaviors and *relative* displacement in locations visited given plainly in the code. The processing tasks that are delayed to execution time often perform the same checking or recording on individual members of such large groups of highly homogeneous accesses. In addition, the memory access patterns recognizable during static analysis summarize *common structural information* useful to many memory checking/tracing tasks.

Based on these observations, we propose Spindle,

[*]Department of Computer Science and Technology, Tsinghua University {wanghaoj15, txc13, yubw15}@mails.tsinghua.edu.cn, {zhaijidong, cwg}@mail.tsinghua.edu.cn

[†]Qatar Computing Research Institute, HBKU {whaojie, txiongchao, xma}@qf.org.qa

a new platform that facilitates hybrid static+dynamic analysis for efficient memory monitoring. It leverages common static analysis to identify from the target program the source of redundancy in runtime memory address examination. By summarizing groups of memory accesses with statically identified program structures, such compact intermediate analysis results can be passed to Spindle-based tools, to further perform task-specific analysis and code instrumentation. The regular/predictable patterns contained in Spindle-distilled structural information allow diverse types of memory access checking more efficiently: by ***computing*** rather than ***collecting*** memory accesses whenever possible, even when certain examination has to be conducted at runtime, it can be elevated from instruction to object granularity, with the amount of instrumentation dramatically pruned.

We implement Spindle on top of the open-source LLVM compiler infrastructure [10]. On top of it, we implement two proof-of-concept custom tools, a memory bug detector (S-Detector) and a memory trace collector (S-Tracer), that leverage the common structural information extracted by Spindle to optimize their specific memory access monitoring tasks.

We evaluated Spindle and the aforementioned custom tools with popular benchmarks (NPB, SPEC CPU2006, Graph500, and PARSEC) and open-source applications covering areas such as machine learning, key-value store, and text processing. Results show that S-Detector can reduce the amount of instrumentation by 64% on average using Spindle static analysis results, allowing runtime overhead reduction of up to 30.25× (2.54× on average) over the Google AddressSanitizer [33]. S-Tracer, meanwhile, reduces the trace collection time overhead by up to over 500× (228× on average) over the polular PIN tool [22], and cuts the trace storage space overhead by up to over 10000× (248× on average).

Spindle is publicly available at `https://github.com/thu-pacman/Spindle`.

2 Overview

2.1 Spindle Framework

Spindle is designed as a hybrid memory monitoring framework. Its main module performs static analysis to extract program structures relevant to memory accesses. Such structural information allows Spindle to obtain regular or predictable patterns in memory accesses. Different Spindle-based tools utilize these patterns in different ways, with the common goal of reducing the amount of instrumentation that leads to costly runtime check or information collection.

Figure 1 gives the overall structure of Spindle, along with sample memory monitoring tools implemented on top of it. To use Spindle-based tools, end-users only have to compile their application source code with the Spindle-enhanced LLVM modules, whose output then goes through tool-specific analysis and instrumentation. More specifically, the common static analysis performed by Spindle will generate a highly compact *Memory Access Skeleton (MAS)*, describing the structured, predictable memory access components.

Figure 1: Spindle overview

Spindle tool developers write their own analyzer, which uses MAS to optimize their code instrumentation, aggressively pruning unnecessary or redundant runtime checks or monitoring data collection. In general, such task-specific tools enable *computing* groups of memory addresses visited before or after program executions, to avoid *examining* individual memory accesses at runtime. As illustrated in Figure 1, each of such Spindle-based tools (the memory bug detector S-Detector and memory trace collector S-Tracer in this case) will generate its own instrumented application code. As our results will show, for typical applications, the majority of memory accesses are computable given a small amount of runtime information, leading to dramatic reduction of instrumentation and runtime collection.

End-users then execute their tool-instrumented applications, with again task-specific runtime libraries linked. The instrumented code conducts runtime processing to perform the desired form of memory access monitoring, such as bug or race condition detection, security check, or memory trace collection. The runtime libraries capture dynamic information to fill in parameters (such as the starting address of an array or the actual iteration count of a loop) to instantiate the Spindle MAS and complete the memory monitoring tasks. In addition, all the "unpredictable" memory access components, identified by Spindle at compile time as input-dependent, are monitored/recorded in the traditional manner.

Spindle's static analysis workflow to produce MAS is further divided into multiple stages, performing intra-procedural analysis, inter-procedural analysis, as well as tool specific analysis and instrumentation. During the intra-procedural stage, Spindle analyzes the program control flow graph and finds out the dependence among memory access instructions. The dependence checking is then expanded across functions in inter-procedural analysis.

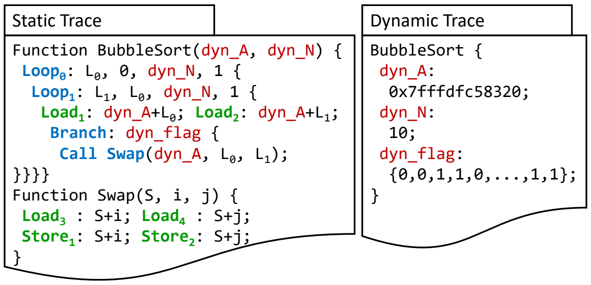
One limitation of the current Spindle framework is that it requires source level information of target programs. As this work is a proof-of-concept study, also considering the current trend of open-source software adoption [9, 41], our evaluation uses applications with source code available. Spindle can potentially work without source code though: it starts with LLVM IR and can therefore employ open-source tools such as Fcd [7] or McSema [37] to translate binary codes into IR. In our future work we are however more interested in direct static analysis, performing tasks such as loop and dependency detection on binaries.

2.2 Sample Input/Output: Memory Trace Collector

```
void BubbleSort(int *A, int N){
    for (int i = 0; i < N; ++i){
        for (int j = i+1; j < N; ++j){
            bool flag = (A[i] > A[j]);
            if (flag) {
                Swap(A, i, j);
}}}}

void Swap(int *S, int i, int j) {
    int tmp = S[i];
    S[i] = S[j];
    S[j] = tmp;
}
```

Figure 2: Sample bubble sort program



Static Trace

```
Function BubbleSort(dyn_A, dyn_N) {
 Loop_0: L_0, 0, dyn_N, 1 {
  Loop_1: L_1, L_0, dyn_N, 1 {
   Load_1: dyn_A+L_0; Load_2: dyn_A+L_1;
    Branch: dyn_flag {
     Call Swap(dyn_A, L_0, L_1);
}}}}
Function Swap(S, i, j) {
 Load_3 : S+i; Load_4 : S+j;
 Store_1: S+i; Store_2: S+j;
}
```

Dynamic Trace

```
BubbleSort {
 dyn_A:
  0x7fffdfc58320;
 dyn_N:
  10;
 dyn_flag:
  {0,0,1,1,0,...,1,1};
}
```

Figure 3: Memory traces of the bubble sort program

We take S-Tracer, our Spindle-based trace collector, as an example to give a more concrete picture of Spindle's working. Suppose the application to be monitored is the bubble sort program listed in Figure 2. S-Tracer's output, given in Figure 3, is a complete yet compressed memory access trace, consisting of its MAS (coupled with corresponding dynamic parameters) and dynamic traces collected in the conventional manner.

In the static trace, we list out the structure of the program, including the control flow, the memory accesses pattern and the call graph. There are information items that cannot be determined during static analysis, such as the base address of array A and its size N, which is also the final value of loop induction variables i and j , as well as the value of flag, which is data-dependent and determines the control flow of this program. The "Instrumented code 1" shown in Figure 1 records these missing values at executing time, which compose the dynamic trace shown on the right.

This new trace format, though slightly more complex than traditionally traces, is often orders of magnitude smaller. A straightforward post-processor can easily take S-Tracer traces and restore the traditional full traces. More practically, an S-Tracer trace driver performing similar decompression can be prepended to typical memory trace consumers, to enable fast replay without involving large trace files or slow I/O.

3 Static Analysis

3.1 Intra-procedural Analysis

During this first step, Spindle extracts a program's per-function control structure to identify memory accesses whose traces can be computed and hence can be (mostly) skipped in dynamic instrumentation.

3.1.1 Extracting Program Control Structure

A program's memory access patterns (or the lack thereof) are closely associated to its control flows. It is not surprising that it shares a similar structure with the program's control flow graph (CFG). Therefore we call this graph M-CFG. Unlike traditional control flow graphs, M-CFG records only instructions containing memory references (rather than the entire basic block), program control structures (loops and branches), and function calls. For loops and branches, we need to record related variables, such as loop boundaries and branch conditions.

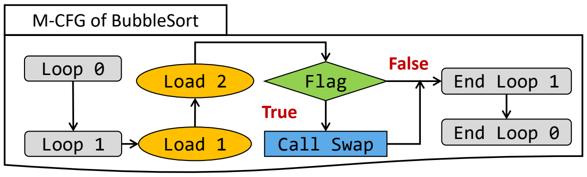


Figure 4: The M-CFG for the function BubbleSort

With M-CFG, memory access instructions are embedded within program basic control structures, as illustrated in Figure 4 for the aforementioned BubbleSort function (Figure 2). Here the M-CFG records a nested loop containing two memory accesses and a branch with a function call. Subsection 3.1.2 discusses dependence analysis regarding memory access instructions and identification of computable memory accesses, while Section 3.2 discusses as handling of function calls.

3.1.2 Building Memory Dependence Trees

In Spindle, we classify all memory accesses into either *computable* or *non-computable* types. The computable accesses can have traces computed based on the static trace, with the help of little or no dynamic information; the non-computable ones, on the other hand, need to fall back to traditional instrumentation and runtime tracing.

For such classification, we build a *memory dependence tree* for each memory access instruction. It records data dependence between a specific memory access instruction and its related variables. The tree is rooted at the memory address accessed, with non-leaf nodes denoting operators between variables such as addition or multiplication and leaf nodes denoting variables in the program. Edges hence intuitively denote dependence.

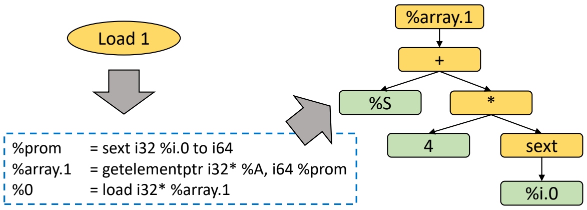
Below we list the types of leaf nodes in memory dependence trees:

- *Constant value*: value determined at compile time
- *Base memory address*: start address for continuously allocated memory region (such as an array), with value acquired at compile time for global or static variables, and at runtime for dynamically allocated variables.
- *Function parameter*: value determined at either compile time or runtime (see Section 3.2)
- *Data-dependent variable*: value dependent on data not predictable at compile time – to be collected at runtime
- *Function return value*: value collected at runtime
- *Loop induction variable*: variable regularly updated at each loop iteration, value determined at compile time or runtime

Algorithm 1 Algorithm of building memory dependence tree

```
input: A worklist $WL[A]$. Predefined Leaf types: $Type$
output: memory dependence tree: $T(A)$
Insert a root note $r$ to $T(A)$
while $WL[A] \neq \phi$ do
    Remove an item $v_1$ from $WL[A]$
    if $v_1 \notin Type$ then
        for $v_2 \in UD(v_1)$ do
            if $v_2 \in Type$ then
                Insert a leaf node $v_2$
                Insert an edge from $v_1$ to $v_2$
            else
                Insert an operator node in $v_2$ to $T(A)$
                Add all variables used in $v_2$ to $WL[A]$
    else
        Insert a leaf node $v_1$ to $v_1$ to $T(A)$
        Insert an edge from $r$ to $v_1$ to $T(A)$
return $T(A)$
```

The memory dependence tree is built by performing a backward data flow analysis at compile time. Specifically, for each memory access, we start from the variable storing this memory address and traverse its use-define data structure, which describes the relation between the definition and use of each variable, to identify all the variables and operators affecting it. This traversal is an iterative process that stops when all the leaf nodes are categorized into one of the types listed above. We give the worklist algorithm (Algorithm 1) that performs such backward data flow analysis with, where we repeatedly variables storing memory addresses into the worklist $WL(A)$ and iteratively find all the related variables through the use-define structure $UD(v)$, till the worklist becomes empty.



```
%prom      = sext i32 %i.0 to i64
%array.1   = getelementptr i32* %A, i64 %prom
%0         = load i32* %array.1
```

Figure 5: Sample memory dependence tree

Figure 5 shows a group of instructions (generated from the source code in Figure 2) and the memory dependence tree corresponding to the variable `%array.1` in the last line. Here `getelementptr` is an instruction that calculates the address of an aggregate data structure (where an addition operation is implied) and does not access memory. We omit certain arguments for this instruction for simplicity. `sext` performs type casting. As to the leaf nodes, `%A` is an array base address, `4` is a constant value, and `%i.0` is a loop induction variable.

Such a dependence tree allows us to approach the central task of Spindle: ***computable memory access identification***. This is done by analyzing the types of the leaf nodes in the memory dependence tree. Intuitively, a memory access is computable if the leaf nodes of its dependence tree are either constants (trivial) or loop induction variables (computable by replicating computation performed in the original program using initial plus final values, collected at compile time or runtime). The M-CFG and the memory access dependence trees, preserving control flows, data dependencies, and operations to facilitate such replication, can be viewed as a form of *program pruning* that only retains computation relevant to memory address calculation. By replacing each memory instruction of the M-CFG with its dependence tree, we obtain a single graph representing main memory access patterns for a single function. Note that such dependence analysis naturally handles aliases.

3.2 Inter-procedural Analysis

At the end of the intra-procedural analysis, we have a memory dependence tree for every memory access within each function. Below we describe how Spindle analyzes memory address dependence across functions.

The core idea here is to propagate function arguments *plus their dependence* from the caller to the callee, and replace all the function parameters of the dependence trees in the callee with actual parameters. For this, we first build a program call graph (PCG), on which we subsequently perform top-down inter-procedural analysis. Algorithm 2 gives the detailed process.

Algorithm 2 The algorithm of inter-procedural analysis

```
input: The dependence trees for each procedure p
input: The program call graph (PCG)
Change ← True
/* Top-Down inter-procedural analysis */
while (Change == True) do
    Change ← False
    for all procedure p in Pre-Order over PCG do
        for all dependence trees d in p do
            if A leaf node l of d is a function's parameter then
                Replace l with its actual parameter
                Change ← True
```

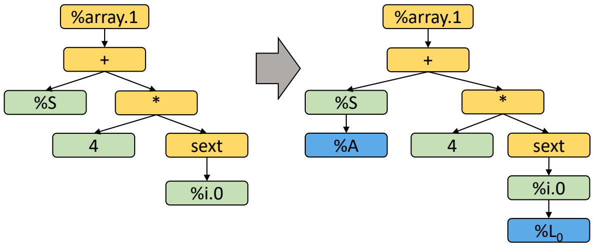


Figure 6: Transformation of dependence tree

Figure 6 illustrates the transformation a dependence tree in function `Swap` (Figure 2) undergoes during inter-procedural analysis. After intra-procedural analysis, the dependence tree for the load instruction `Load`$_3$ of function `Swap` has two leaf nodes that are function parameters, which cannot be analyzed then as the variables `%S` and `%i.0` are undetermined. Within inter-procedural analysis, these two nodes are replaced with their actual parameters, a base address `%A` and a loop induction variable `%i.0` Now the dependence tree rooted at `%array.1` is computable.

For function calls forming a loop in PCG, such as recursive calls, currently we do not perform parameter replacement for any function in this loop during our inter-procedural analysis, as when these functions terminate is typically data-dependent.

3.3 Special Cases and Complications

Index arrays If a memory dependence tree has data-dependent variables as its leaf nodes, normally we consider it non-computable. However, we still have chance to extract regular patterns. Index array is an important case of such data-dependent variables, storing "links" to other data structures, as explained below.

```
for (j=0; j<i; j++){
    for (k=0; k<m; k++)
        sum += delta * z[colidx[k]]
        //colidx is index array to z
    r[k] = d
}
```

Figure 7: NPB CG code with index array `colidx`

Figure 7 gives a simplified version of a code snippet from NPB CG [2], where the array `z` is repeatedly accessed via the index array `colidx`, which cannot be determined at compile time. However, we find that in many programs (including here) the index array itself is not modified across multiple iterations of accesses. Therefore, there is still significant room for finding repeated access patterns and removing redundancy.

To this end, Spindle performs the following extra evaluation during its static analysis. First, it compares the size of index array and its total access count. If the latter is larger, we only need to record the content of the index array and *compute* the memory accesses accordingly rather than instrumenting them at runtime. Such evaluation needs to be repeated if the content of this index array is changed, of course. This is the case with the example given in Figure 7, where the total memory access count for the index array `colidx` is `i*m` and greater than the size of `colidx`. Thus at runtime we only need to record its content at the beginning of this nested loop and the base address of array `z`. Combining such information and memory dependence tree, we can compute all the memory access locations.

Multi-threaded programs The discussion so far has been focused on analyzing single-thread programs. However, Spindle's methodology can also be easily applied to multi-threaded applications. Spindle is thread-safe and we perform the same static analysis as for single-thread programs, except that we also mark the point where a new thread is created and record relevant parameter values. With parallel executions, during dynamic memory monitoring (discussed in the next section), the current thread ID would be easily fetched along with information such as loop iteration count and branch taken, which allows us to distinguish runtime information collected by different threads. Note that certain techniques need to be augmented to handle multi-threaded executions. E.g., the array index technique (Section 3.3) needs to be protected by additional check, as an array could be modified by another thread.

Again, with addresses or values that cannot be determined at compile time, such as shared objects or branches affected by other threads, we fall back to runtime instrumentation. So typical SPMD codes will share the same static MAS, to be supplemented by per-thread or even per-process runtime information, making Spindle even more appealing in efficiency and scalability. If significant amount of output is generated, such as with memory trace collection, Spindle allows users to have the option to look at a single-thread's memory accesses or correlating accesses from all threads (though trace interleaving is a separate topic that requires further study.)

For example, with *pthread*, Spindle instruments `pthread_create` to record where a new thread is created. During multi-threaded execution, the appropriate thread ID is recorded for each function. Thus we know which thread the dynamic information collected by Spindle belongs to, therefore can apply per-thread static analysis, similar to that in single-thread executions.

4 Spindle-based Runtime Monitoring

This section illustrates how Spindle's static analysis results can be used to reduce runtime instrumentation. We first describe common runtime information to be obtained through instrumentation, then present two samples of Spindle-based tool design, for memory bug detection and memory trace collection, respectively.

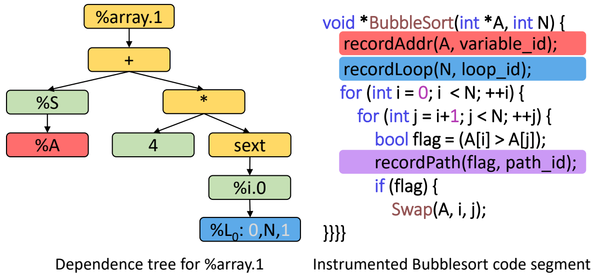
4.1 Runtime information collection

During program runs, Spindle's static memory access skeleton is supplemented by information not available at compile time. Generally, three cases require instrumentation: control structures, input-dependent variables, and non-computable memory accesses:

Control structures Spindle needs to record the initial values of all the loop induction variables and the loop iteration count if they are unknown at compilation time. Moreover, for a loop with multiple exit points, we need to instrument each exit point to track where the loop exits. Similarly, for conditional branches in MAS, we need to record their taken statuses to track taken paths.

Input dependent variables For input dependent variables, runtime information is necessary but certain static analysis can indeed reduce runtime overhead. For instance, the address of a dynamically allocated memory region can be obtained at runtime by collecting actual values. An optimization in Spindle is that we do not instrument every instruction that references input dependent variables, but only where they are defined, initialized, or updated. E.g., for a global variable needed by the analysis, it leverages static analysis to only record its initial value at the beginning of the program, and then again upon its updates.

Non-computable memory accesses For non-computable memory accesses (as mentioned in Subsection 3.1.2), we fall back to conventional dynamic monitoring/instrumentation.



```
void *BubbleSort(int *A, int N) {
  recordAddr(A, variable_id);
  recordLoop(N, loop_id);
  for (int i = 0; i  < N; ++i) {
    for (int j = i+1; j < N; ++j) {
      bool flag = (A[i] > A[j]);
      recordPath(flag, path_id);
      if (flag) {
        Swap(A, i, j);
}}}}
```

Dependence tree for %array.1 Instrumented Bubblesort code segment

Figure 8: Sample runtime information collection

Figure 8 shows an example of runtime information collection for the BubbleSort routine discussed earlier in Section 2.2. The left side gives the dependence tree of the variable %array.1 in function Swap, where undetermined address %A and loop L$_0$'s induction variable %N need to be collected at runtime. Note that L$_0$'s initial index value (0) and increment (1) can be determined at compile time. The right side lists the instrumented BubbleSort code. Here Spindle automatically instruments three memory accesses by inserting the highlighted statements (for A, N, and the branch related flag, which falls out of the dependence tree shown). variable_id, loop_id, and path_id are also automatically generated by Spindle for its runtime library to find the appropriate static structures.

4.2 Spindle-based tool developing

Spindle's performs automatic code instrumentation for runtime information collection, based on its static analysis. To build a memory monitoring tool on top of Spindle, users only need to supply additional codes using its API to perform custom analysis, as to be illustrated below. Our two sample tools, S-Detector and S-Tracer, each takes under 500 lines of code to implement both compile-time analysis and runtime library.

4.2.1 Memory Bug Detector (S-Detector)

Memory bugs, such as buffer overflow, use after free, and use before initialization, may cause severe runtime errors or failures, especially with programming languages like C and C++. There have been a series of tools, software- or hardware-based, developed to detect memory bugs at compile-time or runtime. Among them, Memchecker [39] uses hardware support for memory access monitoring and debugging and is therefore fast (only 2.7% performance overhead for SPECCPU 2000). Such special-purpose hardware is nevertheless not yet adopted by general processors. ARCHER [43] relies on static analysis only, so is faced with the difficult trade-off between accuracy (false positives) and soundness (false negatives), like other static tools. A recent, state-of-the-art tool is AddressSanitizer (ASan) [33], an industrial-strength memory bug detection tool developed by Google and now built into the LLVM compiler. ASan inserts memory checking instructions (such as out-of-bound array accesses) into programs at compile time, then uses shadow memory [25] for fast runtime checking. Despite well implemented and highly tuned, ASan still introduces 2–3× slowdown to SPEC programs.

In this work, we present S-Detector, a memory bug detector that leverages Spindle-gathered static information to eliminate unnecessary instrumentation to facilitate efficient online memory checking. Our proof-of-concept implementation of S-Detector can currently detect invalid accesses (e.g., out-of-bound array access and use after free) and memory leaks (dynamically allocated objects remaining unfreed upon program termination).

With Spindle's MAS, S-Detector is aware of a program's groups of memory accesses and therefore able to perform checking at a coarser granule. E.g., with dynamically allocated arrays, even when neither the starting address (*base*) or size (*bound*) is known at compile time, its accesses are given as relative to these two values and can therefore be checked for out-of-bound bugs at compile time. With existing tools like ASan, however, such checks are delayed till runtime and repeated at every memory acesses.

Therefore, S-Detector performs aggressive *memory check pruning* by proactively conducting compile-time access analysis and replacing instruction-level checks by object-level ones. Only for accesses labeled "non-computable" by Spindle, S-Detector falls back to traditional instrumentation. Below, we illustrate S-Detector's memory check pruning with two sample scenarios, both contained in the same code snippet from SPEC CPU2006 `mcf` (Figure 9).

```
1  while (pos - 1 && red_cost >
2              (cost_t)new[pos/2-1].flow){
3      new[pos-1].tail = new[pos/2-1].tail;
4      new[pos-1].head = new[pos/2-1].head;
5      // Three more accesses to struct members
6      // of new[pos-1] and new[pos/2-1].
7      pos = pos/2;
8      new[pos-1].tail = tail;
9      // Four more accesses to struct members
10     // of new[pos-1].
11 }
```

Figure 9: Sample code from SPEC CPU 2006 `mcf`

In-structure accesses This sample code references an array of structures (`new`), issuing multiple accesses to members of its elements. In this case, assisted with Spindle-extracted MAS, all access targets can be represented as `addr = struct_base + constant_offset`. Once S-Detector finds that the constant `offset` is valid for this struct, i.e., `offset<struct_size`, it only needs to determine if this structure element itself is valid at runtime, i.e., the memory range `[struct_base, struct_base + struct_size)` is a valid range. This groups the per-member access checks to per-element checks (validating structure elements like `new[pos-1]` and `new[pox/2-1]`) and significantly reduces the amount of instrumentation.

In-loop accesses Given the `while` loop in the same sample code, Spindle records the following information for its loop induction variable `pos`: its initial and final values (denoted here as `pos_init` and `pos_final`), as well as the operation used to update it across iterations (divided by 2 at Line 7). Based on the MAS, S-Detector can easily infer the offset range of array `new`'s access to be within [`pos_end/2-1`, `pos_init-1`]. In addition, it records array `new`'s size in bytes (`new_size`) and the size of `new`'s elements (`struct_size`). Aside from quick checks to ensure that the object has been allocated and not freed yet, S-Detector verifies that

$$(\texttt{pos\_init} - 1) * \texttt{struct\_size} < \texttt{new\_size} \quad (1)$$

and

$$\texttt{pos\_end}/2 - 1 \geq 0 \quad (2)$$

Actually inequality (2) is guaranteed by the loop's exit condition, so S-Detector only needs to check (1). Even when none of these four parameter values is available at compile time, S-Detector only needs to perform a *one-time*, *object-level* check at runtime, for array object accesses within this `while` loop.

Combining the structure- and loop-level pruning described above, S-Detector can eliminate all per-instruction memory checks on accesses of the `new` object in the sample code, performing at most one single run-time check instead.

4.2.2 Memory Trace Collector (S-Tracer)

Complete, detailed memory access traces allow diverse analysis and faithful benchmarking or simulation tests. However, their colletion is expensive, both in time and space. Existing tools like PIN [22], Valgrind [26], and DynamoRIO [6] produce memory trace output of daunting sizes, due to the high frequency of memory accesses in typical program executions. It is common for several seconds' execution to generate hundreds of GBs, sometimes even over one TB, of memory traces using any of the existing tools. Large memory trace size not only introduces large overhead for underlying trace storage and various trace-based analysis tools, but also affects the performance of the original programs. For example, PIN introduces an average slowdown of 38× for SPEC INT programs to perform memory analysis [38]. In addition, large traces bring back the I/O bottleneck during replay time, slowing down trace-driven simulations. Such limitations make it less and less practical for existing memory tracing tools to measure significant portions of modern data-intensive applications.

We present S-Tracer, a memory trace collection tool based on Spindle. With the static information that provided by Spindle, S-Tracer can generate highly compressed memory access traces with much lower runtime overhead than traditional tracing tools using dynamic instrumentation. At runtime, S-Tracer couples the Spindle-extracted MAS with dynamically collected information mentioned earlier in this section. The result would be a pair of static and dynamic traces, as illustrated in Figure 2 and Figure 3.

Our discussion below focuses on specific challenges due to the limitation of using LLVM IR, where we propose several techniques to generate approximate but fairly accurate traces.

Register spilling Since Spindle performs its static analysis in the LLVM IR level, where local scalar variables are usually represented as register variables, it is difficult for our approach to capture the stack memory accesses caused by register spilling in the final binary code. Considering the small footprint of register variables even with spilling, we implement typical register allocators used in the compiler backend for Spindle at the IR level, to calculate register spilling. Based on our experiments, our approach is able to achieve the similar statistical behavior of stack accesses as by traditional tracing tools.

Implicit memory accesses with function calls Function calls can also generate stack memory operations, not explicitly described in IR and hence not captured by our intra- and inter-procedural analysis. There are two categories of such accesses. For the caller, it has to write into stack the return address, the contents of registers to be used, and function parameters (with x86_64, the first 6 parameters are put in registers while the others in stack). For the callee, upon returning it has to read from stack the return address of the caller, the content of register `EBP` (for 32-bit systems) or `RBP` (for 64-bit systems), and the content of saved registers. To handle this, we again write a simple simulator to generate these memory accesses.

Dynamically linked libraries Since Spindle performs source code analysis, for calls to functions in dynamically linked libraries, we cannot capture their memory accesses in the IR level and have to fall back again to traditional dynamic instrumentation. As an optimization, we adopt a hybrid approach, by using dynamic instrumentation to collect the relative memory traces within such functions, along with their base stack addresses within the dynamic library. When a program calls such a function, we can then calculate new memory accesses based on the new base stack address.

5 Evaluation

In this section, we demonstrate the effectiveness of Spindle with the aforementioned two sample tools built on top of its static analysis framework: S-Detector for online memory bug detection and S-Tracer for full memory access trace collection.

We compare S-Detector with the state-of-the-art memory bug detector, ASan [33] by Google. In our experiments, S-Detector and ASan do the same checks: use after free, heap buffer overflow, stack buffer overflow, global buffer overflow, and memory leaks. Note that ASan does support additional checks (use after return, use after scope, and initialization order bugs), which need to be explicitly enabled by certain compiler options. Our tests used the default compiler options and we performed extra verification to confirm that these additional checks were disabled in all of our ASan experiments.

For S-Tracer, we show that it produces orders of magnitude smaller trace output, and thus lower overhead, by omitting redundant information. To validate its correctness, we also compare its decompressed trace with trace generated by PIN, a widely used dynamic tool.

5.1 Experiment Setup

Test platform We evaluate Spindle on a server with Intel Xeon E7-8890 v3 processors (running CentOS 7.1), 128GB of DDR3 memory, and 1TB SATA-2 hard disk. For memory bug detection, the tests use mandatory options to enable ASan and DrMem. For memory trace collection, we record each memory access in a 16-byte entry, 8 bytes for memory address and another 8 bytes for access type (read/write) and access size.

Test programs Currently, Spindle fully supports C and partially supports C++ and Fortran. For memory bug detection, we follow the practice of previously published tools and use 11 C programs from SPEC CPU 2006 [1]: `400.perlbench`, `401.bzip2`, `403.gcc`, `429.mcf`, `433.milc`, `445.gobmk`, `456.hmmer`, `458.sjeng`, `464.h264ref`, `470.lbm`, and `482.sphinx3`. The program `998.specrand` is omitted as it has too few memory accesses. Using these common test programs, we not only can compare the tools' runtime overhead, but also their effectiveness of capturing known bugs.

For memory trace collection, we use the popular NPB parallel benchmark suite [2] as codes with mostly regular memory accesses, plus SPEC `429.mcf` as a memory-intensive, non-numerical program. We also sample from modern data-intensive and irregular datacenter applications: (1) the Breadth First Search (`BFS`) component of the Graph500 Benchmark [11], a representative graph application with input-dependent memory accesses, (2) a convolutional neural network for digit recognition (`MNIST`) [29], (3) `kissdb`, a key-value store [18], and (4) `Fido`, a lightweight, modular machine learning library [8]. Finally, for multi-threaded applications, we test 3 programs from the PARSEC suite [4] covering different application domains: `streamcluster` (stream processing), `freqmine` (data mining), and `blackscholes` (PDE solving), plus one MapReduce [23]-style program performing `word count`, denoted as `SC`, `FM`, `BS` and `WC` respectively.

5.2 Spindle Compilation Overhead

Before we get to the tool use cases, we first assess the extra overhead brought by Spindle's static analysis. Table 1 summarizes this compilation overhead for evaluated programs, as well as their original compilation time and code size. In general, the Spindle compilation overhead only composes a small fraction of the original LLVM compilation cost (2% to 35%, average at 10%). We consider such one-time static analysis overhead negligible, considering the significant savings in the much larger runtime checking/tracing cost.

Table 1: Spindle compilation overhead

Program	Extra	Original	Code size	Program	Extra	Original	Code size
BT	0.260s	4.170s	232KB	perlbench	4.662s	23.036s	4418KB

5.3 S-Detector for Memory bug detection

S-Detector runtime overhead We compare S-Detector with two popular memory bug detection tools: Google's AddressSanitizer (ASan) [33] and DynamoRIO [6]-based Dr. Memory (DrMem) [5]. To examine the benefits of instrumentation pruning based on Spindle's static analysis, we test two versions of S-Detector: *SD-All*, a baseline version that instruments all memory accesses, and *SD-Opt*, after check pruning.

On bug detection results, S-Detector captures most of the common SPEC bugs reported by DrMem and ASan, plus additional memory leaks (dynamically allocated objects not freed by program termination) that are verified by our manual code examination.

Figure 10 shows the runtime overhead of ASan, SD-All and SD-Opt, in percentage of the original program execution time. As DrMem is much heavier than others (for most programs over 10× slowdown), we omit its results from the figure for clarity. ASan is an industrial-strength tool, whose streamlined implementation delivers lower overhead than SD-All (geometric mean of overhead at 66% by the former vs. 184% by the latter), both with similar amount of instrumentation. SD-Opt, however, overcomes its slower checking implementation and brings down runtime overhead to geometric mean of 26%. Except for two out of 11 cases (`bzip2` and `h264ref`), SD-Opt reduces overhead from ASan, by up to 30.25× (`sphinx3`). We give more detailed discussion of these special cases later.

Spindle-enabled instrumentation pruning To take a closer look, we examine the amount of checks avoided by Spindle's static analysis. Figure 11 gives the percentage of eliminated memory checks, from SD-All to SD-Opt. On average, Spindle enables S-Detector to cut runtime memory checks by 64%, lowering its performance overhead consequently. The check and overhead reduction level depends on several factors, such as the amount of irregular/unpredictable memory accesses (Amdahl's Law), the overall intensiveness of memory accesses, and control flow behavior. Below we give more detailed results and analysis via several case studies.

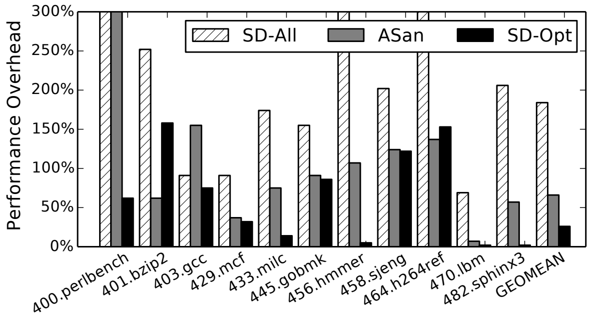

Figure 10: Overhead comparison (bars over 300% truncated)

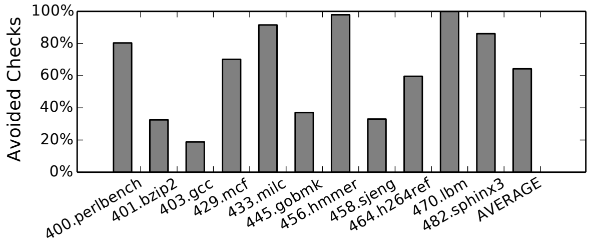

Figure 11: Reduction in runtime memory checks

`lbm`, `hmmer`, `milc`: These are the best cases among tested. Function-level profiling shows that the vast majority of their execution time and most of their memory accesses are spent within loops, where Spindle analysis allows S-Detector to apply the loop-level check presented in Section 4.2.1, replacing the per-access checks performed by ASan and DrMem. As a result, these three programs have 99%, 97%, and 91% of memory checks removed by S-Detector, respectively. Such instrumentation pruning then lowers S-Detector's runtime overhead, e.g., to 5% for `hmmer`, vs. ASan's 107%.

`gcc`: this compiler program is inherently input-dependent and as a result, has the lowest reduction by S-Detector in memory checks (19%). Interestingly, though its execution does spend most time within Spindle-identified loop structures, most of its loops are found to run only a few iterations, limiting the benefit of S-Detector's loop-level static checks. However, in this case even SD-All is faster than ASan. Follow-up measurements reveal that S-Detector's shadow memory implementation, though less efficient in general, offers better spatial locality than ASan's. With `gcc` accessed memory areas being particularly spread out, ASan's runtime check harms its locality, bringing the LLC miss rate from the original 1.3% to 5.9%, while S-Detector retains the original caching performance.

`bzip2`: this compression/decompression program is also input-dependent. Profiling reveals a performance hot-spot in sorting, with many branches whose taken status relies on input data. Even with 32% of runtime memory checks pruned, the less efficient instrumentation of

S-Detector brought overall higher overhead than ASan, 158% vs. 62%.

Despite such worst cases, the overall strong performance of S-Detector indicates that its Spindle-based static analysis, if adopted by highly-tuned, mature tools like ASan, may lead to even lower runtime overhead.

5.4 S-Tracer for Memory Trace Collection

Result Trace Verification Next, we evaluate S-Tracer, comparing it with the widely used PIN tool [22] for memory tracing. We first validate the correctness of its memory trace generation. Note that Spindle is based on compile-time instrumentation while traditional tools like PIN use runtime instrumentation. The two systems run application programs within different frameworks, each with different components (such as dynamic libraries), which may in turn alter the absolute locations of memory objects. Therefore, one would not expect them to generate identical trace sequences.

Recognizing such limitations, we first check the output trace size. We compare the size of PIN's trace with full traces recovered from Spindle's output, in the same format. The Spindle recovered trace has the similar volume to PIN's, with relative difference between 0.5% and 6% (median at 3.2%). Additional examination reveals that such discrepancies stem from the aforementioned inaccuracy caused by Spindle's approximation of stack accesses and register spilling. Though amounting for up to a few percent of the overall trace entries, affected accesses are typically localized to a very small footprint and hardly impact the overall memory access behavior.

We then validate the Spindle-generated heap memory access sequence. We examine trace fidelity by performing more detailed trace alignment and checking difference in heap access sequences. For each access on heap, we break it into a pair: (`object`, `offset`), since for each execution the dynamically allocated `object`'s `base` is different but the `offset` remains constant. We use `Linux diff` tool to compare S-Detector's heap trace and PIN's and find that overall, S-Tracer generates heap traces close to PIN's (relative difference ratio between 0.0% and 4.7%, median at 1.5%).

In the worst case, S-Tracer could generate an overall 5.9% difference in total trace size and 4.7% difference ratio on heap accesses, mostly attributed to stack accesses (more influenced by register allocation) and register spilling. Below we test this worst case, `BFS`, using a cache simulator, to (1) demonstrate a use case of our fast and large-capacity memory tracing and (2) provide a validation for trace fidelity. The test uses a simple trace-driven tool that simulates an 8-way set-associative cache with 64-byte cache line, and two replacement algorithms (LRU and FIFO). We validate simulation results using S-Tracer traces against that using PIN's, at varied cache sizes (including typical L2 and LLC sizes). Figure 12 shows that S-Tracer output achieves almost identical outcome as the PIN trace in miss ratio, across different combinations of cache size and replacement strategies.

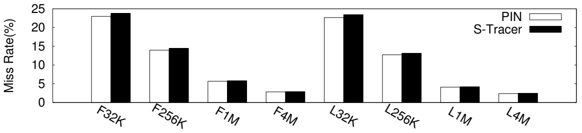

Figure 12: The cache miss rate of `BFS` in a trace-driven simulator. F means FIFO algorithm, L means LRU algorithm. The size means the cache size we simulate.

Trace Size Reduction Next we assess S-Tracer's gain in tracing time/space efficiency. Figure 13 shows a comparison of the trace size generated by S-Tracer and PIN, *in log scale*, for 13 single-thread and 4 multi-threaded programs. Truncated bars are from programs whose PIN traces exceed our 1TB storage capacity (`BT`, `EP`, `LU`, `SP` of Class A). For S-Tracer, the trace size includes both the static and dynamic components.

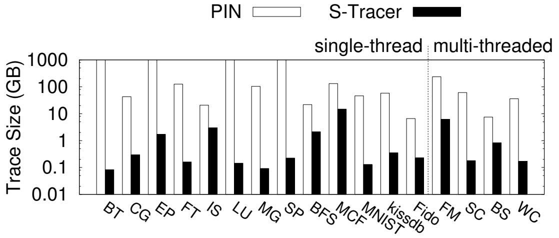

Figure 13: Trace size comparison

As expected, S-Tracer achieves orders of magnitude reduction in trace size from the PIN baseline. For programs dominated by regular memory accesses, like most of the programs in NPB benchmark, `MNIST`, `kissdb`, `streamcluster`, and `wordcount`, it reduces trace size by more than 100×. For the four NPB benchmarks where PIN exceeds the 1TB storage space, S-Tracer generates traces sized at 85MB-1.71GB. Even for the less regular programs, such as `BFS` and `freqmine`, Spindle brings considerable trace size reduction. In the worst case (`IS`, integer sorting), a 6.93× reduction is achieved.

We also evaluated compressing PIN's trace with a naive alternative, `gzip`, which ended up producing orders of magnitude larger traces than S-Tracer does. Besides, generating then compressing traces is much more expensive than Spindle-based approach, online or offline.

Runtime Tracing Overhead Reduction To evaluate the runtime overhead of trace collection, Figure 14 shows the slowdown factor (left axis, in *log scale*), calculated by dividing the execution time with tracing by the original time, for S-Tracer and PIN.

As expected, the online overhead difference is dramatic. In the 13 programs that PIN can complete tracing (full trace size under 1TB disk space), the average slowdown is 502× (and up to over 2000×), while S-

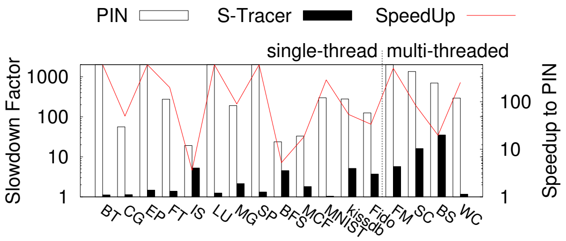

Figure 14: Application slowdown by S-Tracer and PIN with I/O (left) and S-Tracer speedup over PIN (right)

Tracer brings that of 6.5× on average (and up to 35.2×), making full trace collection/storage much more affordable. Across the applications, S-Tracer reduces slowdown from PIN by a factor of 61× on average.

Though we do not have space to show the no-I/O results, the savings there are still significant. For the 17 test programs, PIN introduces an average slowdown of 70.1× (and up to 384×), while S-Tracer brings that of 4.5× on average (and up to 33×). Across the applications, S-Tracer reduces slowdown from PIN by a factor of 17.9× on average. The reason is that Spindle allows S-Tracer to perform far less dynamic instrumentation, and an application's relative time overhead is highly correlated to its dynamic trace generation rate.

6 Related Work

Using Static Analysis to Assist Runtime Checking This group of work is closest to Spindle in approach. In particular, GreenArray [24] is an LLVM-based tool that analyzes the value range of index variables as well as the boundary of memory regions at compile time, to eliminate unnecessary runtime memory check. Spindle is different in that (1) its static analysis performs much more than inferring variables' value range, allowing complete computation of their value by iteration and full trace collection, and (2) the static skeleton it produces enables more types of and much more aggressive pruning in runtime checking, judging by reported GreenArray performance relative to AddressSanitizer.

Abstract Execution (AE) [19] produces a target-event-specific program slice, to be coupled by a "schema compiler" with runtime collected information and executed again for analysis or trace collection. Spindle, instead, records static trace at compile time, which is directly utilized during the target programs (production) execution.

On utilizing static information to assist trace collection, Cypress [44] uses hybrid static-dynamic analysis for parallel programs' communication trace compression. There are also techniques that perform static binary rewriting/instrumentation [32] or regular-expression-based memory access pattern construction for memory layout transformation [15]. However, none of these approaches is able to gather enough static structural information to enable versatile runtime monitoring/tracing as Spindle does.

Also, logical connectives proposed for relational analyses between input and output memory states [13] may be used by Spindle to further reduce instrumentation.

Monitoring/Tracing overhead reduction Prior work has explored reducing monitoring or tracing overhead in other ways. MemTrace [28] performs lightweight memory tracing of unmodified binary applications by translating 32-bit codes to 64-bit codes, which is fast but limits its application to running 32-bit programs on 64-bit machines. Among sampling-based methods, Vetter [40] evaluates techniques for analyzing communication activity in large-scale distributed applications. RACEZ [34] uses hardware performance monitoring units to sample memory accesses at runtime, and then uses the collected memory access trace for offline data-race detection. However, such low-overhead methods lose important information, such as temporal order of operations, or miss detection targets.

Finally, Bao et al. [3, 12] adopt a DIMM-snooping hardware mechanism to collect virtual memory reference traces. This hardware solution indeed minimizes collection overhead, but is rather costly and only catches memory accesses missed by on-chip caches.

7 Conclusion and Future Work

This paper presents Spindle, a versatile memory monitoring framework that performs detailed static analysis to extract program structures, allowing different types of static and dynamic techniques to *compute* rather than *collect* memory accesses whenever possible. Our development and experiments confirm that there are abundant redundancy and regularity in memory accesses, even for applications perceived as more irregular and data-dependent. By identifying predictable memory access behaviors at compile time and supplementing statically obtained memory access skeletons with runtime information, we can dramatically reduce the amount of online checking (for purposes like bug or race detection) or data collection (for purposes like memory access pattern analysis or memory tracing).

Abstract

Query-aware synthetic data generation is an essential and highly challenging task, important for database management system (DBMS) testing, database application testing and application-driven benchmarking. Prior studies on query-aware data generation suffer common problems of limited parallelization, poor scalability, and excessive memory consumption, making these systems unsatisfactory to terabyte scale data generation. In order to fill the gap between the existing data generation techniques and the emerging demands of enormous query-aware test databases, we design and implement our new data generator, called *Touchstone*. *Touchstone* adopts the random sampling algorithm instantiating the query parameters and the new data generation schema generating the test database, to achieve fully parallel data generation, linear scalability and austere memory consumption. Our experimental results show that *Touchstone* consistently outperforms the state-of-the-art solution on TPC-H workload by a 1000× speedup without sacrificing accuracy.

1 Introduction

The applications of query-aware data generators include DBMS testing, database application testing and application-driven benchmarking [5, 15]. For example, during the database selection and performance optimization, the internal databases in production are hard to be shared for performance testing due to the privacy considerations, so we need to generate synthetic databases with the similar workload characteristics of the target queries. A bulk of existing data generators, e.g., [12, 11, 4, 20], generate test databases independent of the test queries, which only consider the data distribution of inter- and intra-attribute. They fail to guarantee the similar workload characteristics of the test queries, therefore it's difficult to match the overheads of the query execution engine for real world workloads. A number of other studies, e.g., [6, 14, 5, 15], attempt to build query-aware data generators. But the performance of the state-of-the-art solution MyBenchmark [15] still remains far from satisfactory, due to the lack of parallelization, scalability and memory usage control, as well as the narrow support of non-equi-join workload. In order to generate the enormous query-aware test databases, we design and implement *Touchstone*, a new query-aware data generator, based on the following design principles:

Full Parallelization: With the explosive growth of data volume in the industrial applications, the database system is expected to support storage and access services for terabyte or even petabyte scale data. So the synthetic data generator must be fully parallel for generating such extremely large test databases.
Linear Scalability: The single machine has been far from meeting the requirements of generating large test databases, and the data scales may be unbelievably big for the future applications, therefore the data generator needs to be well scalable to multiple nodes and data size.
Austere Memory Consumption: When generating the synthetic database for multiple queries, memory could easily be the bottleneck, because massive information is maintained by the data generator in order to guarantee the dependencies among columns. The memory usage needs to be carefully controlled and minimized.

Since [6, 14, 5, 15] are closest to the target of this work, we list the following key insufficiencies of these studies for elaborating the necessity of proposing *Touchstone*. In particular, all of these approaches do not support fully parallel data generation in a distributed environment due to the primitive data generation algorithms over the huge shared intermediate state, limiting the efficiency of data generation over target size at terabytes. Moreover, their memory consumptions, e.g., symbolic databases of QAGen [6], constrained bipartite graphs of WAGen [14] and MyBenchmark [15], caching referenced tables for generating foreign keys of DCGen [5], strongly depend on the size of generation outputs. Once the memory is insufficient to host the complete intermediate state, vast computational resources are wasted on disk I/O operations. In addition, one key advantage of our work is the support of non-equi-join workload, which is important for real world applications but not supported by any of the existing approaches.

In query-aware data generation, we need to handle the extremely complicated dependencies among columns which are caused by the complex workload characteristics specified on the target test queries, as well as the data characteristics specified on the columns. *Touchstone* achieves fully parallel data generation, linear scalability and austere memory consumption for supporting the generation of enormous query-aware test databases. There are two core techniques employed by *Touchstone* beneath the accomplishments of all above enticing features. Firstly, *Touchstone* employs a completely new

*Rong Zhang is the corresponding author.

query instantiation scheme adopting the random sampling algorithm, which supports a large and useful class of queries. Secondly, *Touchstone* is equipped with a new data generation scheme using the constraint chain data structure, which easily enables thread-level parallelization on multiple nodes. In summary, *Touchstone* is a scalable query-aware data generator with a wide support to complex queries of analytical applications, and achieves a 1000× performance improvement against the state-of-the-art work MyBenchmark [15].

2 Preliminaries

2.1 Problem Formulation

The input of *Touchstone* includes database schema H, data characteristics D and workload characteristics W, as illustrated in Figure 1. H defines data types of columns, primary key and foreign key constraints. In Figure 1, there are three tables R, S, and T. For example, table S has 20 tuples and three columns. Data characteristics D of columns are defined in a meta table, in which the user defines the percentage of *Null* values, the domain of the column, the cardinality of unique values and the average length and maximum length for varchar typed columns. In our example, the user expects to see 5 unique values on column $R.r_2$ in the domain [0, 10], and 8 different strings with an average length of 20 and a maximum length of 100 for column $T.t_3$ with 20% *Null* values. Workload characteristics W are represented by a set of parameterized queries which are annotated with several cardinality constraints. In Figure 1, our sample input consists of four parameterized queries, i.e., $Q = \{Q_1, Q_2, Q_3, Q_4\}$. These four queries contain 11 variable parameters, i.e., $P = \{P_1, P_2, ..., P_{11}\}$. Each filter/join operator in the queries is associated with a size constraint, defining the expected cardinality of the processing outcomes. Therefore, there are 14 filter/join operators and corresponding 14 cardinality constraints in our example, i.e., $C = \{c_1, c_2, ..., c_{14}\}$. Our target is to generate the three tables and instantiate all the variable query parameters. In the following, we formulate the definition of cardinality constraints.

Definition 1 ***Cardinality Constraint:*** *Given a filter (σ) or join ($\bowtie$) operator, a cardinality constraint c is denoted as a triplet c = [Q, p, s], where Q indicates the involving query, p gives the predicate on the incoming tuples, and s is the expected cardinality of operator outcomes.*

The cardinality constraint c_1 in Figure 1, for example, is written as [Q_1, $R.r_2 < P_1$, 4], indicating that the operator with predicate $R.r_2 < P_1$ in query Q_1 is expected to output 4 tuples. For conjunctive and disjunctive operators, their cardinality constraints can be split to multiple cardinality constraints for each basic predicate using standard probability theory. These cardinality constraints generally characterize the computational workload of query processing engines, because the computational overhead mainly depends on the size of the data in processing. This hypothesis is verified in our experimental evaluations.

While the focus of cardinality constraints is on filter and join operators, *Touchstone* also supports complex queries with other operators, including aggregation, groupby and orderby. For example, the query Q_2 in Figure 1 applies groupby operator on $T.t_3$ and summation operator on $S.s_3$ over the grouped tuples. The cardinality of the output tuples from these operators, however, is mostly determined, if it does not contain a having clause. And such operators are usually engaged on the top of query execution tree, hence the output result cardinalities generally do not affect the total computational cost of query processing. Based on these observations, it is unnecessary to pose explicit cardinality constraints over these operators [14, 5] in *Touchstone*.

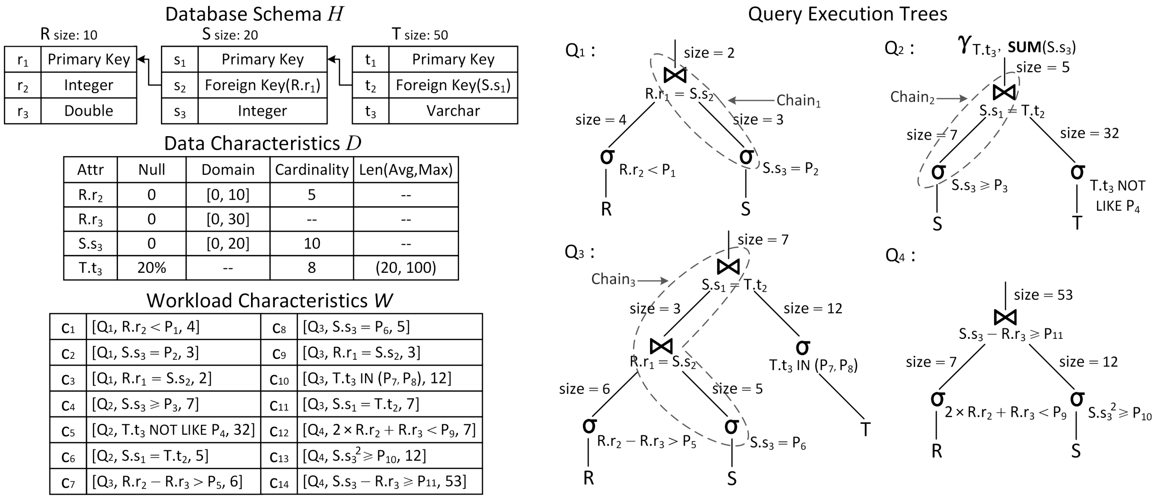
Based on the target operators (filter or join) and the predicates with equality or non-equality conditional expressions, we divide the cardinality constraints into four types, i.e., $C = C^{\sigma}_{=} \cup C^{\sigma}_{\neq} \cup C^{\bowtie}_{=} \cup C^{\bowtie}_{\neq}$. Accordingly, we classify the example constraints in Figure 1 as $C^{\sigma}_{=} = \{c_2, c_5, c_8, c_{10}\}$[1], $C^{\sigma}_{\neq} = \{c_1, c_4, c_7, c_{12}, c_{13}\}$, $C^{\bowtie}_{=} = \{c_3, c_6, c_9, c_{11}\}$ and $C^{\bowtie}_{\neq} = \{c_{14}\}$. Following the common practice in [5, 24, 25], the equi-join operator is *always* applied on the pair of primary and foreign keys.

Then we formulate the problem of query-aware data generation as follows.

Definition 2 ***Query-Aware Data Generation Problem:*** *Given the input database schema H, data characteristic D and workload characteristics W, the objective of data generation is to generate a database instance (DBI) and instantiated queries, such that 1) the data in the tables strictly follows the specified data characteristics D; 2) the variable parameters in the queries are appropriately instantiated; and 3) the executions of the instantiated queries on the generated DBI produce exactly the expected output cardinality specified by workload characteristics W on each operator.*

While the general solution to query-aware data generation problem is NP-hard [21], we aim to design a data generator, by relaxing the third target in the definition above. Specifically, the output DBI is expected to perform as closely as the cardinality constraints in C. Given the actual/expected cardinalities of processing outputs, i.e., $\{\hat{s}_1, \hat{s}_2, \ldots, \hat{s}_n\}$, corresponding to constraints on the queries in $C = \{c_1, c_2, \ldots, c_n\}$, we aim to minimize the global relative error $\frac{\sum_{c_i \in C} |c_i.s - \hat{s}_i|}{\sum_{c_i \in C} c_i.s}$. Even if the user specified workload in W contains conflicted constraints,

[1] If the relational operator in a selection predicate belongs to {=, *!=*, *in*, *not in*, *like*, *not like*}, then the corresponding cardinality constraint is classified to $C^{\sigma}_{=}$.



Database Schema H

R size: 10

Touchstone still attempts to generate a DBI with the best effort.

2.2 Overview of Touchstone

The infrastructure of *Touchstone* is divided into two components, which are responsible for query instantiation and data generation respectively, as shown in Figure 2.

Query Instantiation: Given the inputs including database schema H, data characteristics D, *Touchstone* builds a group of random column generators for non-key columns, denoted by G, each G_i in which corresponds to a column of the target tables. Given the input workload characteristics W, *Touchstone* instantiates the parameterized queries by adjusting the related column generators if necessary and choosing appropriate values for the variable parameters in the predicates of $c \in C^{\sigma}_{=} \cup C^{\sigma}_{\neq} \cup C^{\bowtie}_{\neq}$. The instantiated queries $\bar{Q}$ are output to the users for reference, while the queries $\bar{Q}$ and the adjusted column generators $\bar{G}$ are fed into the data generation component. The technical details are available in Section 3.

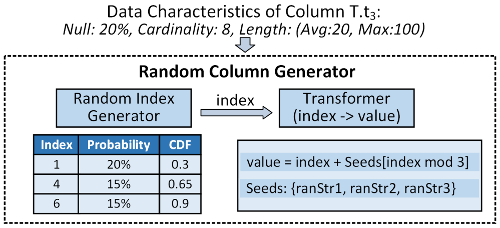
Data Generation: Given the inputs including instantiated queries $\bar{Q}$ and constraints over the equi-join operators $C^{\bowtie}_{=}$ specified in W, *Touchstone* decomposes the query trees annotated with constraints into constraint chains, in order to decouple the dependencies among columns, especially for primary-foreign-key pairs. Data generation component generally deploys the data generators over a distributed platform. The random column generators and constraint chains are distributed to all data generators for independent and parallel tuple generation. The technical details are available in Section 4.

2.3 Random Column Generator

The basic elements of *Touchstone* system are a group of random column generators $G = \{G_1, G_2, \ldots, G_n\}$, which determine the data distributions of all non-key columns to be generated. A random column generator G_i in G is capable of generating values for the specified column, while meeting the required data characteristics *in expectation*. In the following, we give the detailed description of the random column generator.

A random column generator G_i contains two parts, a random index generator and a value transformer as shown in Figure 3. In the random index generator, the output index domain is the integers from 0 to $n-1$ while n is the specified cardinality of unique values in corresponding column. Given an index, the transformer deterministically maps it to a value in the specified domain of the column. We adopt different transformers based on the type of the column. For numeric types, e.g., *Integer*, we simply pick up a linear function which uniformly maps the index to the value domain. For string types, e.g., *Varchar*, there are some seed strings pregenerated randomly, which satisfy the specified length requirements. We first select a seed string based on the input index as shown in Figure 3, and then concatenate the index and the selected seed string as the output value. This approach allows us to easily control the cardinality of string typed columns with tiny memory consumption.

To manipulate the distribution of the column values, there is a probability table in the random index generator.



Data Characteristics of Column T.t3:
Null: 20%, Cardinality: 8, Length: (Avg:20, Max:100)
Random Column Generator
Random Index Generator
index
Transformer (index -> value)

Index	Probability	CDF
1	20%	0.3
4	15%	0.65
6	15%	0.9

value = index + Seeds[index mod 3]

Seeds: {ranStr1, ranStr2, ranStr3}

Figure 3: An example generator for column $T.t_3$

The probability table consists of a number of entries and each entry corresponds to an index. Specifically, each entry in the table (k_i, p_i, c_i) specifies an index k_i, the probability p_i of occurrence, and the cumulative probability c_i for all indexes no larger than k_i. In order to save the memory space, we compress the table by keeping only the entries with non-uniform probabilities. If an index does not appear in the probability table, its probability is automatically set by the uniform probability. The entries in the table are ordered by k_i. In Figure 3, we present an example of random column generator designed for column $T.t_3$ from example inputs in Figure 1. The specified data characteristics request this column to contain 8 unique strings with average length 20 and maximum length 100. In the result generator, based on the indexes in $[0,7]$ generated by random index generator, the transformer outputs random strings with the desired lengths, at probabilities $\{p_{0,2,3,5,7} = 0.1, p_1 = 0.2, p_{4,6} = 0.15\}$. The details of probability assignment will be discussed in Section 3.

Value Generation: Given the random column generator, firstly, a *Null* value is output with the probability of the specified percentage. If *Null* value is not chosen, the index generator picks up an index based on the probabilities by running binary search over CDF (c_i) in the probability table with a random real number in $(0,1]$, and the transformer outputs the corresponding column value.

3 Query Instantiation

There are two general objectives in query instantiation, targeting to 1) construct the random column generators for each non-key column in the tables; and 2) find concrete values for the variable parameters in the queries.

Generally speaking, the query instantiation component is responsible for handling three types of constraints, i.e., $C^{\sigma}_{=}$, $C^{\sigma}_{\neq}$ and $C^{\bowtie}_{\neq}$. Note that the fourth type of constraints $C^{\bowtie}_{=}$ involves matching between primary and foreign keys, which is taken care of by the data generation process at runtime. In Algorithm 1, we list the general workflow of query instantiation. The algorithm iteratively adjusts the data distribution adopted by the random column generators and the concrete values of the variable parameters, in order to meet the constraints as much as possible. The distribution adjustment on the column generator is accomplished by inserting entries in its probability table. In each iteration, the algorithm reinitializes the column generators (line 3) such that there is no entry in the probability table, namely the probabilities of candidate values are uniform. The algorithm then attempts to adjust the column generators in $\bar{G}$ and the concrete values of the variable parameters in queries $\bar{Q}$ (lines 4-11). Specifically, it firstly adjusts the column generators and instantiates the variable parameters based on the equality constraints over filters (lines 4-6). It then follows to revise the variable parameters in the queries in order to meet the non-equality constraints on filter and join operators (lines 7-11). The details of the adjustment on column generators and the parameter instantiation are presented in the following subsections. The algorithm outputs the new (adjusted) generators $\bar{G}$ and the instantiated queries $\bar{Q}$, when the global relative error for all constraints is within the specified threshold θ or the number of iterations reaches its maximum I.

Algorithm 1 Query instantiation

```
Input: Initial generators $G$, input queries $Q$, error threshold $\theta$ and maximum number of iterations $I$
Output: New generators $\bar{G}$ and instantiated queries $\bar{Q}$
 1: Initialize $\bar{Q} \leftarrow Q$
 2: for all iteration $i = 1$ to $I$ do
 3:     Initialize $\bar{G} \leftarrow G$
 4:     for all constraint $c \in C^{\sigma}_{=}$ do
 5:         Adjust the generator in $\bar{G}$ for the column within $c$
 6:         Instantiate the corresponding parameter in $\bar{Q}$
 7:     for all $c \in C^{\sigma}_{\neq}$ do
 8:         Instantiate the corresponding parameter in $\bar{Q}$
 9:     for all $c \in C^{\bowtie}_{\neq}$ do
10:         Obtain constraints from all descendant nodes
11:         Instantiate the corresponding parameter in $\bar{Q}$
12:     Calculate the global relative error $e$
13:     if $e \leq \theta$ then return $\bar{G}$ and $\bar{Q}$
14: return $\bar{G}$ and $\bar{Q}$ (historical best solution with minimum $e$)
```

In the rest of the section, we discuss the processing strategies for these three types of constraints respectively.

Filters with Equality Constraint always involve a single non-key column at a time like the workloads of standard benchmarks. Given all these equality constraints on the filter operators, i.e., $C^{\sigma}_{=}$, the system groups the constraints according to the involved column. In our running example in Figure 1, there are four such constraints $C^{\sigma}_{=} = \{c_2, c_5, c_8, c_{10}\}$, among which, c_2 and c_8 target column $S.s_3$, and c_5 and c_{10} target column $T.t_3$. Note that all relational operators in equality constraints are handled by treating them as '='. For example, $c_5 = [Q_2, T.t_3 \text{ NOT LIKE } P_4, 32] \Rightarrow [Q_2, T.t_3 \text{ LIKE } P_4, 8] \Rightarrow [Q_2, T.t_3 = P_4, 8]$.

The processing strategy for equality constraints on filters runs in three steps. Firstly, the algorithm randomly selects an index and obtains the corresponding value from the transformer of the column generator, for instantiating each variable parameter in the equality con-

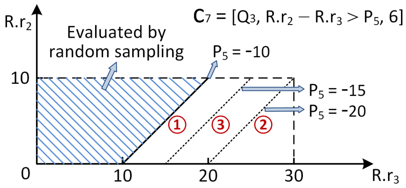


Figure 4: An example of parameter searching procedure for constraint c_7. Given the predicate in c_7, our algorithm attempts to cut the space by revising the parameter P_5. For a concrete P_5, the expected number of tuples meeting the predicate is evaluated by the random sampling algorithm. The best value for P_5 is returned, after the binary search identifies the optimal value at desired precision or reaches the maximum iterations.

straints. Secondly, the algorithm updates the occurrence probability of the selected index in the column generator by inserting an entry in the probability table, in order to meet the required intermediate result cardinality. Whether the filter is the leaf node of the query execution tree or not, the probability of the inserted entry is calculated as $\frac{s_{out}}{s_{in}}$, where s_{in} is the size of input tuples and s_{out} is the expected size of output tuples. After the above two steps for all equality constraints, the algorithm calculates the cumulative probabilities in the probability table of adjusted column generators. In Figure 3, there are three entries in the probability table for generating data with the distribution that satisfies the constraints c_5 and c_{10}. For example, the entry with index 1 is inserted for instantiating parameter P_4 in the predicate of c_5, while the two entries with indexes 4 and 6 are inserted for instantiating parameters P_7 and P_8 in the predicate of c_{10}.

Suppose there are k variable parameters in the equality constraints over filters. The total complexity of the processing strategy is $O(k \log k)$, because the algorithm only needs to instantiate the parameters one by one, and accordingly it inserts an entry into the probability table in order of selected index for each parameter instantiation.

Filters with Non-Equality Constraint could involve multiple non-key columns. In Figure 1, some constraints, e.g., $c_1 = [Q_1, R.r_2 < P_1, 4]$ and $c_4 = [Q_2, S.s_3 \geq P_3, 7]$, apply on one column only, while other constraints, e.g., $c_7 = [Q_3, R.r_2 - R.r_3 > P_5, 6]$ and $c_{12} = [Q_4, 2 \times R.r_2 + R.r_3 < P_9, 7]$, involve more than one column with more complex mathematical operators. Our underlying strategy handling these non-equality constraints is to find the concrete parameters generating the best matching output cardinalities against the constraints, based on the data distributions adopted by the random column generators.

Since the cardinality of tuples satisfying the constraints is monotonic with the growth of the variable parameter, it suffices to run a binary search over the parameter domain to find the optimal concrete value for the variable parameter. In Figure 4, we present an example to illustrate the parameter searching procedure. The cutting line in the figure represents the parameter in the constraint, which decides the ratio of tuples in the shadow area, i.e., satisfying the constraint. By increasing or decreasing the parameter, the likelihood of tuples in the shadow area changes correspondingly. The technical challenge behind the search is the hardness of likelihood evaluation over the satisfying tuples, or equivalently the probability of tuples falling in the shadow area in our example. To tackle the problem, we adopt the random sampling algorithm, which is also suited for the non-uniform distribution of the involved columns. Note that the binary search may not be able to find a parameter with the desired precision, based on the determined data distribution of columns after processing equality constraints over filters. Therefore, in Algorithm 1, we try to instantiate the parameters for non-equality constraints upon different data distributions by iteration.

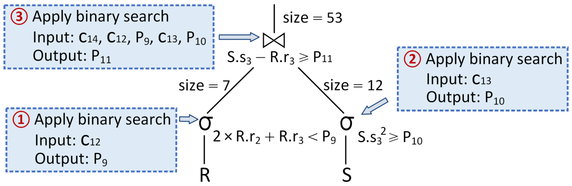

Figure 5: An example of parameter instantiation for non-equality constraints on join operator

The complexity of the approach is the product of two components, the number of iterations in parameter value search and the computational cost of probability evaluation using random sampling algorithm in each iteration. The number of iterations for the binary search is logarithmic to the domain size of the parameter, decided by the minimal and maximal value that the expression with multiple columns could reach. The cost of random sampling depends on the complexity of the predicate, which usually only involves a few columns.

Joins with Non-Equality Constraint are slightly different from the filters with non-equality constraints, because the columns involved in their predicates may overlap with the columns in the predicates of their child nodes as query Q_4 in Figure 1, which usually does not happen to filters in the query execution tree. Therefore, we must process the constraints in a bottom-up manner without the premise of probability independence, such that the precedent operators are settled before the join operator with non-equality constraint is handled. In Figure 5, we present the processing flow on query Q_4. After *Touchstone* concretizes the parameters P_9 and P_{10} in constraints c_{12} and c_{13}, the input data to the join operator with constraint c_{14} is determined. Based on the characteristics of the inputs, we apply the same binary search strategy designed for filter operator to construct the optimal parameter, e.g., P_{11} in Figure 5, for the desired result cardinality. Since the algorithm is identical to that for filter operator, we hereby skip detailed algorithm descriptions as well as the complexity analysis.

4 Data Generation

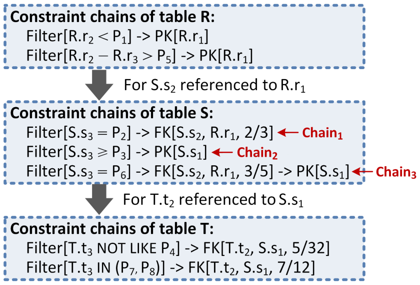
Given the generators of all non-key columns and the instantiated queries, the data generation component is responsible for assembling tuples based on the outputs of the column generators. The key technical challenge here is to meet the equality constraints over the join operators, i.e., $C^{\bowtie}_{=}$, which involve the dependencies among primary and foreign keys from multiple tables. To tackle the problem, we design a new tuple generation schema, which focuses on the manipulation of foreign keys only.

The tuple generation consists of two steps. In the first *compilation* step, *Touchstone* orders the tables as a generation sequence and decomposes the query trees into constraint chains for each target table. In the second *assembling* step, the working threads in *Touchstone* independently generate tuples for the tables based on the result order from compilation step. For each tuple, the working thread fills values in the columns by calling the random column generators independently and incrementally assigns a primary key, while leaving the foreign keys blank. By iterating the constraint chains associated with the table, the algorithm identifies the appropriate candidate keys for each foreign key based on the maintained join information of the referenced primary key, and randomly assigns one of the candidate keys to the tuple.

Compilation Step: The generation order of the tables is supposed to be consistent with the dependencies between primary keys and foreign keys, because the primary key must be generated before the adoption of its join information for generating corresponding foreign keys of other tables. Since such primary-foreign-key dependencies form a directed acyclic graph (DAG), *Touchstone* easily constructs a topological order over the tables. In Figure 6, we illustrate the result order over three tables, $R \to S \to T$, based on the database schema H in Figure 1.

In order to decouple the dependencies among columns and facilitate parallelizing, *Touchstone* decomposes the query trees annotated with constraints into *constraint chains*. A constraint chain consists of a number of constraints corresponding to the cardinality constraints over the operators in query trees. There are three types of constraints included in the constraint chains, namely FILTER, PK and FK, which are associated with the types of related operators. The constraint chains with respect to a table are defined as the sequences of constraints with descendant relationship in the query trees. In Figure 6, we present all the constraint chains for tables R, S and T. For example, table R has two constraint chains extracted from queries Q_1 and Q_3. And the constraint chains of table S are marked in Figure 1 for easily understanding.

Each FILTER constraint keeps the predicate with the instantiated parameters. Each PK constraint in the chain records the column name of the primary key. Each FK constraint maintains a triplet, covering two column names of the foreign key and the referenced primary key, and the expected *ratio* of tuples satisfying the predicate on the join operator. The second constraint in the first chain for table S in Figure 6, for example, is $\mathrm{FK}[S.s_2, R.r_1, \frac{2}{3}]$, indicating the foreign key is $S.s_2$, the referenced primary key is $R.r_1$ and two out of three tuples in table S are expected to meet the predicate $S.s_2 = R.r_1$ of join operator in the case of satisfying the predicate $S.s_3 = P_2$ of previous filter. The expected ratios in FK constraints are calculated based on the cardinality requirements of the specified cardinality constraints.



Constraint chains of table R:
Filter[R.r$_2$ < P$_1$] -> PK[R.r$_1$]
Filter[R.r$_2$ – R.r$_3$ > P$_5$] -> PK[R.r$_1$]
For S.s$_2$ referenced to R.r$_1$
Constraint chains of table S:
Filter[S.s$_3$ = P$_2$] -> FK[S.s$_2$, R.r$_1$, 2/3]
Chain$_1$
Filter[S.s$_3$ ⩾ P$_3$] -> PK[S.s$_1$]
Chain$_2$
Filter[S.s$_3$ = P$_6$] -> FK[S.s$_2$, R.r$_1$, 3/5] -> PK[S.s$_1$]
Chain$_3$
For T.t$_2$ referenced to S.s$_1$
Constraint chains of table T:
Filter[T.t$_3$ NOT LIKE P$_4$] -> FK[T.t$_2$, S.s$_1$, 5/32]
Filter[T.t$_3$ IN (P$_7$, P$_8$)] -> FK[T.t$_2$, S.s$_1$, 7/12]

Figure 6: Results of constraint chain decomposition

Assembling Step: For simplicity, we assume that there is a single-column primary key and one foreign key in the table. Note that our algorithm can be naturally extended to handle tables with composite primary key and multiple foreign keys. The result constraint chains are distributed to all working threads on multiple nodes for parallel tuple generation. When generating tuples for a specified table, each working thread maintains two bitmap data structures at runtime, i.e., ϕ_{fk} and ϕ_{pk}. They are used to keep track of the status of joinability, e.g., whether the generating tuple satisfies individual predicates over join operators, for primary key and foreign key, respectively. The length of the bitmap ϕ_{fk} (resp. ϕ_{pk}) is equivalent to the number of FK (resp. PK) constraints in all chains of the target table. Each bit in the bitmap corresponds to a FK/PK constraint. It has three possible values, T, F and N, indicating if the join status is successful, unsuccessful or null. In Figure 6, for example, table S has two FK constraints and two PK constraints, resulting in 2-bit representations for both ϕ_{fk} and ϕ_{pk}.

Touchstone also maintains the join information table to track the status of joinability of primary keys based on the bitmap representation ϕ_{pk}. In Figure 7, we show two join information tables of primary keys $R.r_1$ and $S.s_1$ respectively. The join information table of $R.r_1$ is maintained in the generation of table R, which is ready for generating the foreign key $S.s_2$ of table S. During the generation of table S, the join information table of $S.s_1$ is maintained for generating the foreign key $T.t_2$ of table T. There are two attributes in the entry of join information table, i.e., bitmap and keys, indicating the status of joinability and the corresponding satisfying primary key values. Note that the keys in the entry may be empty (such entries will not be stored in practice), which means there is no primary key with the desired joinability status.

Algorithm 2 Tuple generation

```
Input: Column generators $\bar{G}$, constraint chains of the target table $\Omega$, join information tables of referenced primary key and current primary key $t_{rpk}$ and $t_{pk}$
Output: Tuple $r$ and join information table $t_{pk}$
1:  $r.pk \leftarrow$ a value assigned incrementally
2:  $r.columns \leftarrow$ values output by column generators $\bar{G}$
3:  $\phi_{fk} \leftarrow N...N$, $\phi_{pk} \leftarrow N...N$
4:  for all constraint chain $\omega \in \Omega$ do
5:      $flag \leftarrow True$
6:      for all constraint $c \in \omega$ do
7:          if ($c$ is FILTER) && ($c.predicate$ is $False$) then
8:              $flag \leftarrow False$
9:          else if $c$ is PK then
10:             $\phi_{pk}[i] \leftarrow flag$  // $i$ is the bit index for $c$
11:         else if ($c$ is FK) && $flag$ then
12:             if $random[0,1) \geq c.ratio$ then $flag \leftarrow False$
13:             $\phi_{fk}[i] \leftarrow flag$  // $i$ is the bit index for $c$
14: $r.fk \leftarrow$ a value selected from $t_{rpk}$ satisfying $\phi_{fk}$
15: Add $r.pk$ in the entry of $t_{pk}$ with bitmap $\phi_{pk}$
16: return $r$ and $t_{pk}$
```

The tuple generation algorithm is listed in Algorithm 2. We present a running example of tuple generation in Figure 7. A new tuple for table S is initialized as $(S.s_1 = 7, S.s_2 = ?, S.s_3 = 16)$, $\phi_{fk} = NN$ and $\phi_{pk} = NN$ (lines 1-3). The $flag$ is set to True before traversing each constraint chain (line 5), which is used to track if the predicates from the precedent constraints of current chain are fully met. On the first constraint chain, since the predicate in the first FILTER constraint is $S.s_3 = 4$, $flag$ is then set to False (line 8), and algorithm does not need to handle the next FK constraint (line 11). On the second chain, the tuple satisfies the predicate $S.s_3 \geq 15$, resulting in the update of bitmap representation as $\phi_{pk} = NT$ (line 10). On the third chain, after passing the first FILTER constraint, the corresponding bit of next FK constraint in ϕ_{fk} is randomly flipped to F at the probability of $\frac{2}{5}$ (lines 12-13), because the expected $ratio$ of satisfying tuples is $\frac{3}{5}$. The $flag$ is set to False (line 12) to reflect the failure of full matching of precedent constraints for later PK constraint. Then, the bit corresponding to next PK constraint in ϕ_{pk} is set as F according to the value of $flag$ (line 10). Therefore, the two bitmaps are finalized as $\phi_{fk} = FN$ and $\phi_{pk} = FT$. Then the algorithm identifies (line 14) two entries matching $\phi_{fk} = FN$, namely satisfying the T/F requirements on the corresponding bits of ϕ_{fk}, with bitmaps FT and FF respectively, in the join information table of $R.r_1$. Given these two entries, it randomly selects (line 14) a foreign key, e.g., 6, from four candidate referenced primary keys $\{2,7,6,8\}$, which are all appropriate as the foreign key $S.s_2$. That there is no entry in t_{rpk} satisfying the T/F requirements of ϕ_{fk}, which is called *mismatch case*, is dealt in the rest of the section. Finally, the algorithm updates (line 15) the join information table of $S.s_1$ by adding the primary key $S.s_1 = 7$ into the entry with bitmap FT.

FT	0, **7**
FF	1, 2, 4, 6

Figure 7: Running example of tuple generation for table S

For a table, suppose there are k non-key columns, m constraints in the related constraint chains and n entries in the join information table of referenced primary key. The complexity of tuple generation mainly consists of three parts, k times of calling random column generators for filling the values of non-key columns, the traversing over m constraints within chains for determining the joinability statuses of foreign key and primary key, and the comparing with n bitmaps in the join information table for searching the appropriate foreign key candidates. For practical workloads, k, m and n are all small numbers, e.g., $k \leq 12$, $m \leq 20$ and $n \leq 40$ for TPC-H [3] workload, so our tuple generation is highly efficient.

Handling Mismatch Cases: For the data generation of big tables, if a joinability status of the primary key may occur, its occurrence can be considered as inevitable based on the probability theory. However, there are still some joinability statuses of the primary key that never occur. For example, in Figure 7, the bitmap ϕ_{pk} for primary key $S.s_1$ can not be TF due to the constraints, i.e., Filter[$S.s_3 = 16$] and Filter[$S.s_3 \geq 15$]. Therefore, in the tuple generation, it should be avoided to generate the bitmap ϕ_{fk} that does not have any matching entry in the join information table of the referenced primary key. In order to achieve this objective, the main idea is to add rules to manipulate relevant FK constraints.

Figure 8 gives an example of adjustments to FK constraints for handling the mismatch case. There are three FK constraints with the serial numbers of 1, 2 and 3 in the three constraint chains, respectively. Since there are four bitmaps, i.e., FTT, TTT, TFT, FTF, that are not presented in the join information table of the referenced primary key rpk corresponding to the foreign key fk of the target table, three rules are added in two FK constraints to avoid

Figure 8: An example of adjustments to FK constraints

producing any ϕ_{fk} triggering the mismatch case. For example, there is a rule $[FT \leftarrow T]$ added in the second FK constraint, which indicates that the status of the second FK constraint must be F if the status of the first FK constraint is T in the tuple generation. Since there are extra F statuses forcibly generated by the added rule for the second FK constraint, the actual ratio of tuples satisfying the corresponding predicate could be lower than the expected ratio 0.6. Consequently, it is necessary to adjust the ratio in the second FK constraint for eliminating the impact of the added rule. In this example, we adjust the ratio as $0.65 = \frac{0.6 \times 0.4}{0.4 - 0.1 \times 0.3}$, in which 0.4 is the ratio of tuples satisfying the predicate in the second FILTER constraint, 0.6×0.4 is the cumulative probability of the status T for the second FK constraint, 0.1 is the ratio of tuples satisfying the two predicates in the first two FILTER constraints, 0.3 is the ratio in the first FK constraint and 0.1×0.3 is the cumulative probability of the extra F status generated by the rule. The general algorithm of adjustments to FK constraints and the corresponding analyses are presented in our online technical report [2].

To reflect the adjustments to FK constraints in the tuple generation, minor modification is applied on the original tuple generation algorithm on lines 12-13 in Algorithm 2. Specifically, the updated algorithm first checks all existing rules in current FK constraint. If there is a rule which can be applied to the statuses of previous constraints, ϕ_{fk} and $flag$ are updated according to the rule. Otherwise, the algorithm updates ϕ_{fk} and $flag$ by the probability based on the adjusted ratio.

Management of Join Information: For generation of a table, it can be completely parallel on multiple nodes with multiple working threads on each node. Each working thread maintains its own join information table of the primary key to avoid contention. But the join information table of referenced primary key can be shared among multiple working threads on each node. After the generation of the table, we merge the join information tables maintained by the multiple working threads in distributed controller as in Figure 2. But there are serious memory and network problems for the space complexity of the join information table is $O(s)$ with s as the table size.

Since the relationship of foreign key and primary key can be many to one and the intermediate result cardinality is the main factor that affects the query performance, we design a compression method by storing less primary key values in the join information table but still promise the randomness of remaining values. Assuming the size of keys in an entry of join information table is N, which is hard to know in advance and may be very large. We aim to store only L ($L << N$) values in the keys and promise the approximately uniform distribution of these L ones among all N values. The compression method is implemented as follows: we store the first L arriving values in the keys, if any; and for the i-th ($i > L$) arriving value, we randomly replace a value stored previously in the keys with the probability of L/i. By such a method, the space complexity of the join information table is reduced to $O(n * L)$, where n is the number of entries in the join information table and L is the maximum allowed size of keys in each entry. Since n is generally small, e.g., $n \leq 40$ for TPC-H workload, and L usually can be set to thousands, the memory consumption and network transmission of the join information table are acceptable.

5 Experiments

Environment. Our experiments are conducted on a cluster with 8 nodes. Each node is equipped with 2 Intel Xeon E5-2620 @ 2.0 GHz CPUs, 64GB memory and 3 TB HDD disk configured in RAID-5. The cluster is connected using 1 Gigabit Ethernet.

Workloads. The TPC-H [3] is a decision support benchmark which contains the most representative queries of analytical applications, while the transactional benchmarks, e.g., TPC-C and TPC-W, do not contain queries for analytical processing. So we take the TPC-H workload for our experiments. We compare *Touchstone* with the state-of-the-art work MyBenchmark [15] with source codes from the authors.[2] The workloads for comparison consist of 6 queries from TPC-H, including $Q_{2,3,6,10,14,16}$. Note that these queries are selected based on the performance of MyBenchmark, which drops significantly when other queries are included in the workloads. *Touchstone*, on the other hand, can easily handle all of the first 16 queries, i.e., Q_1 to Q_{16}, in TPC-H with excellent performance. To the best of our knowledge, *Touchstone* provides the widest support to TPC-H workload, among all the existing studies [6, 14, 5, 15].

Input Generation. To build valid inputs for experiments, we generate the DBI and queries of TPC-H using its tools *dbgen* and *qgen*, respectively. And the DBI of TPC-H is imported into the MySQL database. The database schema of TPC-H is used as the input H. We can easily obtain the input data characteristics D for all columns from the DBI in MySQL. Given the TPC-H queries, their physical query plans are obtained from MySQL query parser and optimizer over the DBI. The

[2] We would like to thank Eric Lo for providing us the source code of MyBenchmark.

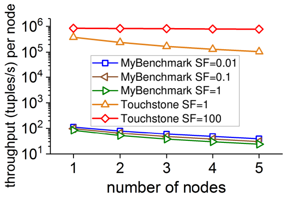

Figure 9: Comparison of data generation throughput

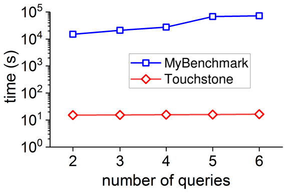

Figure 11: Comparison of data generation time

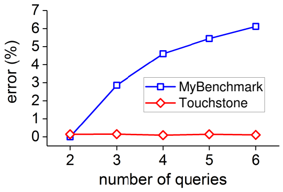

Figure 12: Comparison of global relative error

cardinality constraints corresponding to the operators in query plans are then identified by running the queries on the DBI in MySQL. The input workload characteristics W are constructed by the parameterized TPC-H queries and above cardinality constraints. Note that we can generate databases with different scale factors using the same input W by employing selectivities instead of the absolute cardinalities in our input constraints.

Settings. As data is randomly generated according to the column generators in *Touchstone*, the distribution of generated data may be difficult to satisfy the expectation for small tables such as *Region* and *Nation*. We therefore revise the sizes of *Region* and *Nation* from 5 to 500, and from 25 to 2500 respectively. The cardinality constraints involving these two tables are updated proportionally. In addition, the small tables can also be pre-generated manually. The error threshold (desired precision) and maximal iterations in query instantiation are set to 10^{-4} and 20 respectively. The default maximum allowed size L of keys in join information table is set to 10^4.

5.1 Comparison with MyBenchmark

We compare *Touchstone* with MyBenchmark from four aspects, including data generation throughput, scalability to multiple nodes, memory consumption and capability of complex workloads.

Figure 9 shows the data generation throughputs per node of *Touchstone* and MyBenchmark as we vary the number of nodes under different scale factors. Due to the unacceptably long processing time of MyBenchmark, we adopt smaller scale factors for it and large scale factors for *Touchstone*. Overall, the data generation throughput of *Touchstone* is at least 3 orders of magnitude higher than that of MyBenchmark. This is because MyBenchmark does not have a good parallelization or an efficient data generation schema. Furthermore, as the number of nodes increases from 1 to 5, the data generation throughput per node of MyBenchmark decreases dramatically for all three scale factors. Although the decline of data generation throughput per node of *Touchstone* is obvious too when $SF = 1$, *Touchstone* is linearly scalable (the throughput per node is stable) when $SF = 100$. This is because for small target database, e.g., $SF = 1$, the distributed maintenance rather than data generation dominates the computational cost in *Touchstone*, while its overhead comparatively diminishes by increasing the target database size.

Figure 10 reports the peak memory consumptions of *Touchstone* and MyBenchmark under different data scales. The experiment is conducted on 5 nodes with no restriction on memory usage. The memory usage of MyBenchmark mainly consists of two parts, namely, memory consumed by MyBenchmark Tool and memory consumed by PostgreSQL for managing intermediate states. The memory usage of *Touchstone* mainly includes memory for JVM itself and memory for maintaining join information. As shown in Figure 10, the memory consumption of *Touchstone* is much lower than that of MyBenchmark under the same scale factors. It is worth noting that the memory consumption of *Touchstone* remains almost constant when $SF > 10$. This is because for *Touchstone*, the JVM itself occupies most of the memory, while the join information maintenance only spends a tiny piece of memory.

Figure 11 and Figure 12 present the data generation time (total running time) and global relative error separately of *Touchstone* and MyBenchmark as we vary the number of input queries with $SF = 1$. The input queries are loaded in order of their serial numbers. The experiment is carried out on 5 nodes. In Figure 11, it is obvious that the data generation time of MyBenchmark increases significantly as the number of queries increases. At the same time, the generation time of *Touchstone* grows very little when more queries are included, significantly outperforming MyBenchmark. In Figure 12, the error of *Touchstone* is much smaller than that of MyBenchmark. Moreover, as there are more input queries, the global relative error of *Touchstone* remains small with little change, while the error of MyBenchmark has an obvious rise. In summary, *Touchstone* is more capable of supporting complex workloads than MyBenchmark.

It can be seen from previous experiments that MyBenchmark can not be easily applied to generate the terabyte scale database for complex workloads due to its poor performance. In the following, we further demonstrate the advantages of *Touchstone* by a series of experiments using the workload of 16 queries, i.e., Q_1 to Q_{16}.

5.2 Performance Evaluation

In this section, we evaluate the impact of workload complexity on query instantiation time and total running time

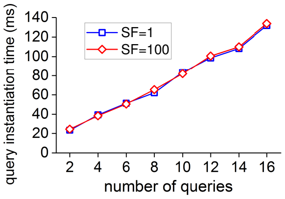

Figure 13: Query instantiation time

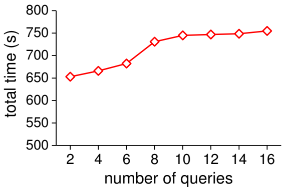

Figure 14: Total running time

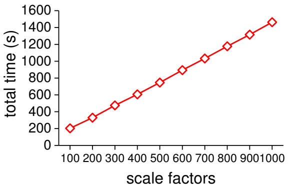

Figure 15: Scalability to data scale

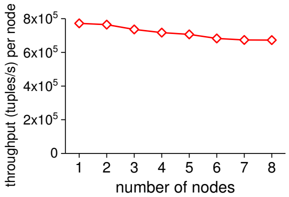

Figure 16: Scalability to multiple nodes

in *Touchstone*, as well as the scalability to data scale and multiple nodes of *Touchstone*.

Figure 13 shows the query instantiation time of *Touchstone* as we vary the number of queries with $SF = 1$ and $SF = 100$, respectively. The input queries are loaded in order of their serial numbers. The query instantiator is deployed on a single node. As shown in Figure 13, even when all 16 queries are used for input, query instantiation is finished within 0.2s. And there is a minimal difference in query instantiation time for $SF = 1$ and $SF = 100$, as the complexity of query instantiation is independent of data scale. Overall, the query instantiation time is only correlated to the complexity of input workloads.

Figure 14 shows the total running time of *Touchstone* as we vary the number of queries with $SF = 500$. *Touchstone* is deployed on 8 nodes. From the result, it can be seen that the running time increases slowly as the number of queries increases. For Q_7 and Q_8, there are relatively more cardinality constraints over equi-join operators, so the time increment is larger when we change from 6 queries to 8 queries. But when the number of queries changed from 10 to 16, the time increment is almost indiscernible, for Q_{11} to Q_{16} are simple, among which Q_{12} to Q_{15} have no cardinality constraints on equi-join operators[3]. Overall, the total running time increased by only 16% from 2 queries to 16 queries for 500GB data generation task, so *Touchstone* is insensitive to the workload complexity.

Figure 15 presents the total running time of *Touchstone* under different scale factors with the input of 16 queries. *Touchstone* is deployed on 8 nodes. As shown in Figure 15, *Touchstone* is linearly scalable to data size. Because the generation of each tuple is independent and the generated tuples need not be stored in memory, the data generation throughput is stable for different data scales. Moreover, the total runtime of *Touchstone* is less than 25 minutes for $SF = 1000$ (1TB), so it is capable of supporting industrial scale database generation.

Figure 16 presents the data generation throughputs per node of *Touchstone* as we vary the number of nodes with $SF = 500$. The input workload includes 16 queries. The result shows that the data generation throughput per node is approximatively unchanged as the number of nodes increases, validating the linear scalability of *Touchstone*. To the best of our knowledge, *Touchstone* is the first query-aware data generator which can support full parallel data generation on multiple nodes.

5.3 Data Fidelity Evaluation

The data fidelity of synthetic database is evaluated by relative error on cardinality constraints and performance deviation on query latencies. We calculate the relative error for each query in the similar way with global relative error, which only involves its own cardinality constraints. We compare the latency of query processing on base database generated by *dbgen* against that on synthetic database generated by *Touchstone* to show the performance deviation.

Figure 17 shows the relative errors for Q_1 to Q_{16} with different scale factors from 1 to 5. The maximum error among all 16 queries is less than 4%, and there are 14 queries with errors less than 1%. Figure 18 shows the global relative error of all 16 queries as we vary the scale factor, which is less than 0.2% for all scale factors. And with the increase of scale factor, the global relative error has a sharp decrease. Since data is randomly generated by column generators, as expected by the probability theory, the larger the data size, the smaller the relative error.

Figure 19 presents the performance deviations of all 16 queries with $SF = 1$. We vary the maximum allowed size L of keys in the join information table from 10^3 to 10^5. We can see that the performance deviation is inconspicuous for all 16 queries, and the size of L has no significant influence on query latencies. The result strongly illustrates the correctness and usefulness of our work. We are the first work to give such an experiment to verify the fidelity of the generated DBI.

More experimental results are available in our online technical report [2], which demonstrate the effectiveness for data generation of non-equi-join workloads, handling mismatch cases, the compression method on join information table, and other benchmark workloads.

6 Related Work

There are many data generators [7, 12, 11, 4, 20, 23, 1, 9] which only consider the data characteristics of the target database. For example, Alexander et al. [4] proposes pseudo-random number generators to realize the parallel

[3] Depending on the physical query plans of Q_{12} to Q_{15}, the primary keys in their equi-join operators are from the original tables, so all foreign keys must be joined and the sizes of output tuples are determined.

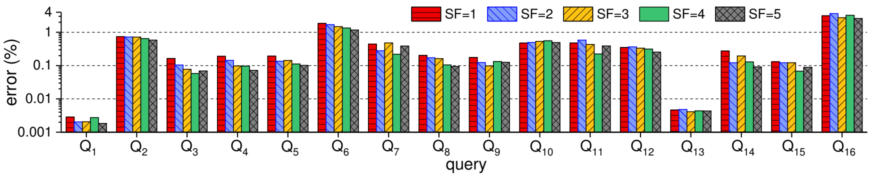

Figure 17: Relative error for each query

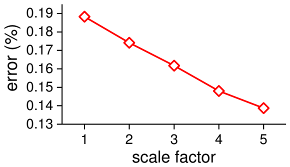

Figure 18: Global relative error vs. scale factor

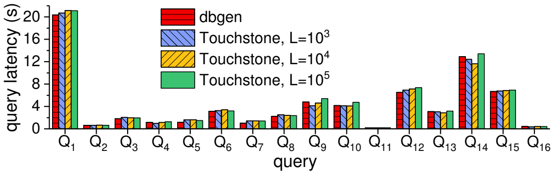

Figure 19: Performance deviation for each query

data generation. Torlak [23] supports the scalable generation of test data from a rich class of multidimensional models. However, all these data generators can not generate test databases with the specified workload characteristics on target queries.

There are query-aware data generators [6, 14, 5, 15], among which [6, 14, 15] are a series of work. QAGen [6] is the first query-aware data generator, but for each query it generates an individual DBI and its CSP (constraint satisfaction program) has the usability limitations as declared in experimental results. WAGen [14] makes a great improvement that it generates m ($\leq n$) DBIs with n input queries, but WAGen can't guarantee that only one DBI is generated and still has CSP performance problem. Though MyBenchmark [15] has done a lot of performance optimization, generating one DBI can not be promised for multiple queries and the performance is still unacceptable for the generation of terabyte scale database. DCGen [5] uses a novel method to represent data distribution with ideas from the probabilistic graphical model. But DCGen is weak in support of foreign key constraint, and it cannot easily support parallel data generation in a distributed environment.

There are some interesting non-relational data generators [18, 8, 13, 19, 10]. For example, Olston et al. [18] introduces how to generate example data for dataflow programs. Sara [8] generates structural XML documents. [13, 19] are synthetic graph generators. Chronos [10] can generate stream data for real time applications. In addition, there are query generation works [17, 16] which are partly similar to us, but they generate queries satisfying the specified cardinality constraints over an existing DBI. Moreover, the dataset scaling works [22, 25] can serve part of our targets, which scale up/down a given DBI with similar column correlations.

7 Discussion and Conclusion

Limitations. *Touchstone* aims to support the most common workloads in real world applications. Below we list the scenarios that we cannot support currently. (1) *Touchstone* does not support filters on key columns. Primary and foreign keys are identifiers of tuples and generally have no physical meaning, so the filters which are representations of business logics usually do not involve key columns. (2) Equality constraints over filters involving multiple columns are not supported in *Touchstone*. The equality predicate with multiple columns for filter is a very strict constraint, and has not been found in workloads of standard benchmarks. (3) Equi-joins on columns with no reference constraint are not supported in our work. This is because the equi-join is usually applied on the pair of primary and foreign keys in practical workloads, which is also the assumption of many works [5, 24, 25]. (4) *Touchstone* does not support the database schema with cyclic reference relationship. In our data generation process, generating foreign keys requires the join information tables of corresponding referenced primary keys, so the primary-foreign-key dependencies must form a direct acyclic graph (DAG), which is also the precondition of DCGen [5].

Privacy issue. Our work can help to protect privacy to some extend by removing query parameter values or using approximate query intermediate cardinalities. However, if the database statistics and workload characteristics are strictly related to privacy issues in some cases, it will not be a good way to use this kind of workload-aware data generators for performance testing.

In this paper we introduce *Touchstone* [2], a query-aware data generator with characteristics of completely parallelizable and bounded usage to memory. And *Touchstone* is linearly scalable to computing resource and data scale. Our future work is to support more operators, e.g., intersect and having, for covering the complex queries of TPC-DS, which has not be well supported by any existing query-aware data generation work.

DSAC: Effective Static Analysis of Sleep-in-Atomic-Context Bugs in Kernel Modules

Jia-Ju Bai[1], Yu-Ping Wang[1], Julia Lawall[2], Shi-Min Hu[1]
[1]Tsinghua University, [2]Sorbonne Université/Inria/LIP6

Abstract

In a modern OS, kernel modules often use spinlocks and interrupt handlers to monopolize a CPU core to execute concurrent code in atomic context. In this situation, if the kernel module performs an operation that can sleep at runtime, a system hang may occur. We refer to this kind of concurrency bug as a sleep-in-atomic-context (SAC) bug. In practice, SAC bugs have received insufficient attention and are hard to find, as they do not always cause problems in real executions.

In this paper, we propose a practical static approach named DSAC, to effectively detect SAC bugs and automatically recommend patches to help fix them. DSAC uses four key techniques: (1) a hybrid of flow-sensitive and -insensitive analysis to perform accurate and efficient code analysis; (2) a heuristics-based method to accurately extract kernel interfaces that can sleep at runtime; (3) a path-check method to effectively filter out repeated reports and false bugs; (4) a pattern-based method to automatically generate recommended patches to help fix the bugs.

We evaluate DSAC on kernel modules (drivers, file systems, and network modules) of the Linux kernel, and on the FreeBSD and NetBSD kernels, and in total find 401 new real bugs. 272 of these bugs have been confirmed by the relevant kernel maintainers, and 43 patches generated by DSAC have been applied by kernel maintainers.

1. Introduction

Concurrency bugs are known to be difficult to debug. Many tools have been proposed to detect common concurrency bugs such as atomicity violations and data races. However, as a kind of concurrency bug, sleep-in-atomic-context (SAC) bugs have received less attention. SAC bugs occur at the kernel level when a sleeping operation is performed in atomic context [10], such as when holding a spinlock or executing an interrupt handler. Code executing in atomic context monopolizes a CPU core, and the progress of other threads that need to concurrently access the same resources is delayed. Thus the code execution in atomic context should complete as quickly as possible. Sleeping in atomic context is forbidden, as it can block a CPU core for a long period and may lead to a system hang.

Even though sleeping in atomic context is forbidden, many SAC bugs still exist, especially in kernel modules, such as device drivers and file systems. The main reasons why SAC bugs continue to occur include: (1) Determining whether an operation can sleep often requires system-specific experience; (2) Testing kernel modules can be difficult, for example, running a device driver requires its associated device; (3) SAC bugs do not always cause problems in real execution, and they are often hard to reproduce at runtime. Recent studies [12, 48] have shown that SAC bugs have caused serious system hangs at runtime. Thus, it is necessary to detect and fix SAC bugs in kernel modules.

Many existing approaches [7, 19, 28, 42] can detect concurrency bugs, but most of them are designed for user-level applications. Some approaches [13, 17, 18, 41, 44] can detect some common kinds of kernel-level concurrency bugs, such as atomicity violations and data races, but they have not addressed SAC bugs. Several approaches [2, 9, 16, 34, 53] can detect common kinds of OS kernel faults, including SAC bugs. But they are not specific to SAC bugs, and most of them [9, 16, 34] are designed to collect statistics rather than report specific bugs to the user, making issues such as detection time and false positive rate less important.

In this paper, we propose a static approach named DSAC[1] that targets accurately and efficiently detecting SAC (sleep-in-atomic-context) bugs in kernel modules, and can automatically recommend patches to help fix the detected bugs. DSAC consists of four phases. Firstly, DSAC uses a *hybrid of flow-sensitive and -insensitive analysis* (subsequently referred to as a *hybrid flow analysis*) to analyze the source code, in order to collect the set of functions that are possibly called in atomic context. Secondly, from the collected functions, DSAC exploits a *heuristics-based* method, which uses some heuristics based on the analysis of the call graphs and comments of the kernel code, to extract kernel interfaces that can sleep at runtime. Thirdly, with the extracted

[1] DSAC website: *http://oslab.cs.tsinghua.edu.cn/DSAC/index.html*

sleep-able kernel interfaces, DSAC first reuses the hybrid flow analysis to detect possible bugs, and then uses a *path-check* method to filter out repeated reports and false bugs by validating the code path of each detected bug. Finally, DSAC exploits a *pattern-based* method to automatically generate patches to help fix the bugs. This method analyzes the bug reports generated in the previous phase, and uses common fixing patterns to correct the buggy code.

We have implemented DSAC using LLVM [51]. To validate its effectiveness, we first evaluate DSAC on Linux drivers, which are typical of modules in the Linux kernel. To validate the generality and portability, we then use DSAC to check file systems and network modules in the Linux kernel, and finally use DSAC in FreeBSD and NetBSD to check their kernel source code. The results show that DSAC can indeed accurately and efficiently find real SAC bugs and recommend a number of correct patches to help fix the bugs.

DSAC has four main advantages in practical use:

1) Efficient and accurate code analysis. DSAC uses an efficient inter-procedural and context-sensitive analysis to maintain a lock stack across function calls, which can accurately identify the code in atomic context. All source files of the kernel module are analyzed at once to perform accurate analysis across function calls.

2) Precise and detailed bug reports. To achieve precise bug detection, DSAC uses a heuristics-based method to extract sleep-able kernel interfaces, and uses a path-check method to filter out repeated reports and false bugs. It also produces detailed reports of the found bugs, including code paths and source file names, for the user to locate and check.

3) Recommended patch generation. With the generated bug reports, DSAC uses a pattern-based method to automatically generate patches to help fix the detected bugs, which can reduce the manual work of bug fixing.

4) High automation, generality and portability. Once the user offers the names of spin-lock and -unlock functions, interrupt-handler-register functions and basic sleep-able kernel interfaces, the remaining phases of DSAC are fully automated. DSAC can effectively check kernel modules, including drivers, file systems and network modules. And it can also be easily ported in another OS to check the kernel code.

In this paper, we make three main contributions:

- We first analyze the challenges in detecting SAC bugs in kernel modules, and then propose four key techniques to address these challenges: (1) a hybrid flow analysis to perform accurate and efficient code analysis; (2) a heuristics-based method to accurately extract sleep-able kernel interfaces in the analyzed kernel modules; (3) a path-check method to effectively filter out repeated reports and false bugs; (4) a pattern-based method to automatically generate recommended patches to help fix the bugs.
- Based on the four techniques, we propose a practical approach named DSAC, to accurately and efficiently detect SAC bugs in kernel modules and automatically recommend patches to help fix the bugs.
- We evaluate DSAC on drivers in Linux 3.17.2 and 4.11.1. We select these kernel versions as they are near the beginning of stable series, and thus the simplest bugs should have been fixed in them. We find 200 and 320 real bugs respectively in these versions. 50 real bugs in 3.17.2 have been fixed in 4.11.1, and 209 real bugs in 4.11.1 have been confirmed by kernel maintainers. To validate the generality and portability, we use DSAC to check file systems and network modules in the Linux kernel, and then run it in FreeBSD 11.0 and NetBSD 7.1 to check their kernel code, and find 81 new real bugs. 43 generated patches for the three OS kernels have been applied by kernel maintainers.

The remainder of the paper is organized as follows. Section 2 presents the background. Section 3 presents the challenges and our techniques. Section 4 introduces DSAC in detail. Section 5 presents the evaluation. Section 6 compares DSAC to previous approaches. Section 7 presents limitations and future work. Section 8 gives the related work. Section 9 concludes this paper.

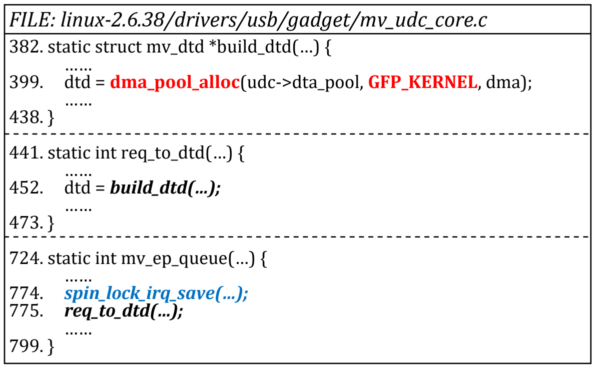
2. Background

In this section, we first introduce atomic context, and then motivate our work by an example of a real SAC bug in a Linux driver.

2.1 Atomic Context

Atomic context is an OS kernel state that a CPU core is monopolized to execute the code, and the progress of other threads that need to concurrently access the same resources is delayed. This context can protect resources from concurrent access, in which the code execution should complete as quickly as possible without able to be rescheduled. Due to this special situation, sleeping in atomic context is forbidden, as it can block CPU cores for long periods and may lead to a system hang.

There are two common examples of atomic context in the kernel, namely *holding a spinlock* and *executing an interrupt handler*. If a thread sleeps when holding a spinlock, another thread that requests the same spinlock will spin on a CPU core to wait until the former thread releases the spinlock. If threads spin on all CPU cores like this, no CPU core will be available for the former thread to release the spinlock, causing a deadlock [11]. If an interrupt handler sleeps, the kernel scheduler cannot reschedule it and a system hang may occur, as the interrupt handler is not backed by a process [29].



```

-----------------------------------------------------------
724. static int mv_ep_queue(...) {
         ......
774.     spin_lock_irq_save(...);
775.     req_to_dtd(...);
         ......
799. }
```

Figure 1: Part of the *usb_gadget* driver code in Linux 2.6.38.

Note that atomic context only occurs at the kernel level, as user-level applications are regularly interrupted by the OS scheduler when their time slices end. Though kernel developers often know that sleeping is not allowed in atomic context, many SAC bugs still exist [16, 34], especially in kernel modules.

2.2 Motivating Example

We motivate our work by a real bug in the *usb_gadget* that persisted over 8 releases (1.5 years) from Linux 2.6.38 to Linux 3.7. Figure 1 presents part of the source code for the driver. The function *mv_ep_queue* calls *spin_lock_irqsave* to take a spinlock (line 774) and then calls *req_to_dtd* (line 775). The function *req_to_dtd* calls *build_dtd* (line 452), which calls *dma_pool_alloc* with *GFP_KERNEL* to request a DMA memory pool (line 399). According to the kernel documentation [50], *dma_pool_alloc* called with *GFP_KERNEL* can sleep, thus a SAC bug exists. This bug was first fixed in Linux 3.7, by replacing *GFP_KERNEL* with *GFP_ATOMIC*, which indicates to *dma_pool_alloc* that it cannot sleep.

This example illustrates three main reasons why SAC bugs occur in kernel modules. (1) Determining whether an operation can sleep requires OS-specific knowledge. In this example, without experience in Linux kernel development, it may be hard to know that the function *dma_pool_alloc* called with *GFP_KERNEL* can sleep at runtime. (2) SAC bugs do not always cause problems in real execution and are hard to reproduce at runtime. In this example, the function *dma_pool_alloc* called with *GFP_KERNEL* only sleeps when memory is insufficient. Even in a low-memory situation, this SAC bug is not always triggered at runtime in a multi-core system, because of the non-determinism of concurrent execution. (3) Multiple layers of function calls need to be considered when finding SAC bugs. In this example, the function *dma_pool_alloc* is called across two function levels after *spin_lock_irqsave* is called.

The bug in Figure 1 has been fixed, but many SAC bugs still remain in current kernel modules. Some recent studies [12, 48] have shown that SAC bugs have caused serious system hangs, and these bugs were often hard to locate and reproduce. Thus, to improve the reliability of the operating system, it is necessary to design an approach to detect SAC bugs in kernel modules.

3. Challenges and Techniques

In this section, we first discuss the main challenges in detecting SAC bugs and then propose our techniques to address these challenges.

3.1 Challenges and Overview of Our Solutions

There are four main challenges in detecting SAC bugs in kernel modules:

C1: *Code analysis coverage, accuracy and time.* A key goal in bug detection is to efficiently cover more code and generate accurate results. Running kernel modules can be difficult (for example, running a driver needs the associated device), and thus we use static analysis to achieve high code coverage without the need to execute the code. Static analysis can be either flow-sensitive or flow-insensitive. Flow-sensitive analysis searches each code path of a branch and can cover all code paths. For this reason, it can produce accurate results, but it often requires much time and memory especially in inter-procedural analysis. Flow-insensitive analysis handles each code line instead of each path. Thus, it is more efficient, but its results may be less accurate. We propose a *hybrid flow analysis* to obtain the advantages of both flow-sensitive and -insensitive analysis. It uses flow-sensitive analysis when its accuracy is expected to be beneficial and falls back to flow-insensitive analysis when full accuracy is not necessary. We will introduce the hybrid flow analysis in Section 3.2.1.

C2: *Sleep-able function extraction.* Determining whether a function can sleep often requires a good understanding of the kernel code. Specifically, for a function defined in the kernel module (referred to as a *module function* subsequently), whether it can sleep depends on whether the called kernel interfaces can sleep. Using this idea, we design a *heuristics-based* method that first collects all kernel interfaces possibly called in atomic context of the kernel module, and then analyzes the kernel source code and comments to identify sleep-able ones. We will introduce this method in Section 3.2.2.

C3: *Filtering out repeated and false bugs.* Some detected bugs may be repeated, because they take the spinlock at the same place and call the same sleep-able function, but only differ in their code paths. Moreover, some detected bugs may be false positives, as the analysis does not consider variable value information, and thus may search some infeasible code paths. We design a *path-check* method that checks the code path of each detected bug to filter out repeated reports and false bugs. We will introduce it in Section 3.2.3.

C4: *Bug fixing recommendation.* After finding real bugs, the user may manually write patches to fix them. Besides, incorrect patches can introduce new bugs [21]. To reduce the manual work of bug fixing, we summarize common patterns for fixing SAC bugs, and propose a *pattern-based* method to automatically generate recommended patches to help fix the bugs. We will introduce this method in Section 3.2.4.

3.2 Key Techniques

3.2.1 Hybrid Flow Analysis

Our hybrid flow analysis is used to identify the code in atomic context. It is based on two points: (1) The analysis is context-sensitive and inter-procedural, in order to maintain the spinlock status and detect atomic context across functions calls. (2) The choice of flow-sensitive or -insensitive analysis is made as follows: *if a module function calls a spin-lock or spin-unlock function (this module function is referred to as a target function) or it is called by an interrupt handler, flow-sensitive analysis is used to analyze each code path from the entry basic block; otherwise, flow-insensitive analysis is used to handle each function call made by the function.* In the first case, flow-sensitive analysis is used to accurately maintain the spinlock status and collect code paths for subsequent bug filtering. In the second case, flow-insensitive analysis is used to reduce analysis cost, because in this case, the spinlock status is expected not to change explicitly.

Our hybrid flow analysis has two steps. The first step identifies target functions and interrupt handler functions, as flow-sensitive analysis is performed in these functions. For target functions, we analyze the definition of each module function and check whether it calls a spin-lock or spin-unlock function. For interrupt handler functions, we identify the calls to interrupt-handler-register kernel interfaces (like *request_irq* in the Linux kernel), and extract interrupt handler functions from the related arguments.

The second step performs the main analysis. Figure 2 presents the procedure *FlowAnalysis*. It maintains two stacks, namely a path stack (*path_stack*) to store the executed code path and a lock stack (*lock_stack)* to store the spinlock status. A flag (*g_intr_flag*) is used to indicate whether the code is in an interrupt handler. If *lock_stack* is not empty or *g_intr_flag* is *TRUE*, the code is in atomic context. *FlowAnalysis* uses *HanCall* to handle a function call and *HanBlock* to handle a basic block. We introduce them as follows:

HanCall. It handles the function call *mycall* with the arguments *path_stack* and *lock_stack*, to check if the definition of the function called by *mycall* needs to be handled, and if so to determine if the flow-sensitive or -insensitive analysis should be used. Firstly, *HanCall* checks if *lock_stack* is empty and *g_intr_flag* is *FALSE* (lines 1-3). If so, no spinlock is held and the code is not in an interrupt handler, and thus *HanCall* returns. Secondly, *HanCall* uses *path_stack* to check if *mycall* has been analyzed (lines 4-6). If so, it returns to avoid repeated analysis. Note that this prevents infinite looping on recursive calls. Thirdly, *HanCall* adds *mycall* into *path_stack*, and gets the called function *myfunc* (lines 7-8). Fourthly, *HowToFunc* (line 9) performs the analyses presented in Sections 3.2.2 and 4.1.3. Fifthly, *HanCall* checks if *myfunc* is a module function (lines 10-12). If not, it returns. Finally, it handles the definition of *myfunc* (lines 13-20). If *myfunc* is a target function or *g_intr_flag* is *TRUE*, flow-sensitive analysis is used to handle its entry basic block using *HanBlock* (lines 13-

```
HanCall(mycall, path_stack, lock_stack)
 1: if lock_stack == ø and g_intr_flag == FALSE then
 2:     return;
 3: end if
 4: if PathHasExisted(mycall, path_stack) == TRUE then
 5:     return;
 6: end if
 7: AddPathStack(mycall, path_stack);
 8: myfunc := GetCalledFunction(mycall);
 9: HowToFunc(myfunc, path_stack, lock_stack, g_intr_flag);
10: if IsModuleFunc(myfunc) == FALSE then
11:     return;
12: end if
13: if IsTargetFunc(myfunc) == TRUE or g_intr_flag == TRUE then
14:     entry_block := GetEntryBlock(myfunc);
15:     HanBlock(entry_block, path_stack, lock_stack);
16: else
17:     foreach call in FunctionCallList(myfunc) do
18:         HanCall(call, path_stack, lock_stack);
19:     end foreach
20: end if
```

```
HanBlock(myblock, path_stack, lock_stack)
 1: if PathHasExisted(myblock, path_stack) == TRUE then
 2:     return;
 3: end if
 4: AddPathStack(myblock, path_stack);
 5: foreach func_call in FunctionCallList(myblock) do
 6:     if func_call is a call to a spin-lock function then
 7          Push func_call onto lock_stack;
 8:     else if func_call is a call to a spin-unlock function then
 9:         Pop an item from lock_stack;
10:     else
11:         HanCall(func_call, path_stack, lock_stack);
12:     end if
13: end foreach
14: if lock_stack == ø and g_intr_flag == FALSE then
15:     return;
16: end if
17: foreach block in SuccessorBlocks(myblock) do
18:     HanBlock(block, path_stack, lock_stack);
19: end foreach
```

```
FlowAnalysis: Main hybrid flow analysis
 1: foreach func in target_func_set do
 2:     lock_block_set := GetLockBlockSet(func);
 3      foreach block in lock_block_set do
 4:         path_stack := ø; lock_stack := ø; g_intr_flag := FALSE;
 5:         HanBlock(block, path_stack, lock_stack);
 6:     end foreach
 7: end foreach
 8: foreach func in intr_handler_func_set do
 9:     path_stack := ø; lock_stack := ø; g_intr_flag := TRUE;
10:     entry_block := GetEntryBlock(func);
11:     HanBlock(entry_block, path_stack, lock_stack);
12: end foreach
```

Figure 2: Hybrid flow analysis.

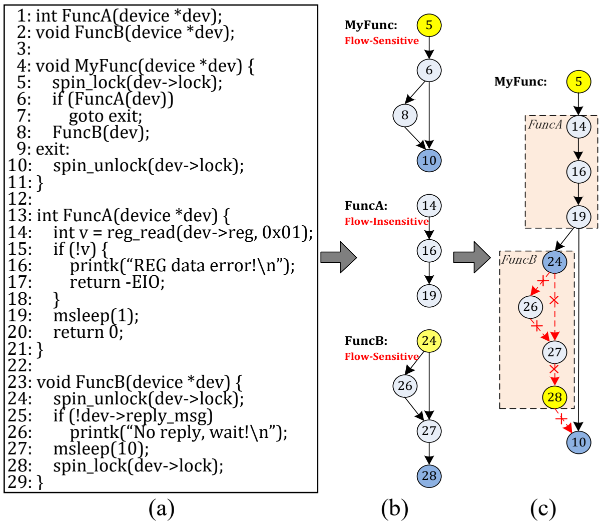
15); otherwise, flow-insensitive analysis is used to handle each function call made by *myfunc* using *HanCall* (lines 16-20).

HanBlock. It handles the basic block *myblock* with the arguments *path_stack* and *lock_stack*, to perform flow-sensitive analysis as well as maintain the spinlock status. Firstly, *HanBlock* uses *path_stack* to check if *myblock* has been analyzed (lines 1-3). If so, it returns to avoid repeated analysis. Secondly, *HanBlock* adds *myblock* into *path_stack* (line 4). Thirdly, *HanBlock* handles each function call in *myblock* (lines 5-13). If the function call is a call to a spin-lock or spin-unlock function, *HanBlock* pushes the call onto or pops an item from *lock_stack*; otherwise, the call is handled by *HanCall*. Fourthly, *HanBlock* checks if *lock_stack* is empty and *g_intr_flag* is *FALSE*. If so, it returns (lines 14-16); otherwise, each successive basic block of *myblock* is handled using *HanBlock* (lines 17-19).

FlowAnalysis. It performs the main analysis, in two steps. Firstly, each target function is analyzed (line 1-7). For a target function, each basic block that contains a spin-lock function call is an analysis entry. In this case, *path_stack* and *lock_stack* are first set to empty, and *g_intr_flag* is set to *FALSE*. Then, the analysis is started by using *HanBlock* to handle this basic block. Secondly, each interrupt handler function is analyzed (line 8-12). In this case, *path_stack* and *lock_stack* are set to empty, but *g_intr_flag* is set to *TRUE*. Then, the analysis is started by using *HanBlock* to handle the entry basic block of the interrupt handler function.

Our hybrid flow analysis has three main advantages: (1) The functions that are possibly called in atomic context can be accurately detected; (2) Detailed code paths and complete spinlock status are maintained, to help accurately detect atomic context; (3) Many unnecessary paths are not considered to reduce the analysis time. However, a main limitation of our analysis is that variable value information is not considered, which may cause false positives in bug detection.

We illustrate our hybrid flow analysis using some simplified driver-like code shown in Figure 3. As shown in Figure 3(a), the module consists of *MyFunc*, *FuncA* and *FuncB*, where *MyFunc* calls *FuncA* and *FuncB*. Because *MyFunc* and *FuncB* both call *spin_lock* and *spin_unlock*, they are target functions and handled by the flow-sensitive analysis; because *FuncA* does not call spin-lock or spin-unlock functions, it is handled by the flow-insensitive analysis. Figure 3(b) presents the call path of each function, with the code line numbers from Figure 3(a) shown in the vertices. Figure 3(c) shows the call paths used in inter-procedural analysis of *MyFunc*. During the analysis, no spinlock is held after the first line of *FuncB* (line 24), thus the following call paths in *FuncB* are not analyzed. In total, only two useful call paths marked in solid edges in Figure 3(c) are handled when analyzing *MyFunc*, and they are the only necessary call paths for atomic context analysis in this case.



```
 1: int FuncA(device *dev);
 2: void FuncB(device *dev);
 3:
 4: void MyFunc(device *dev) {
 5:     spin_lock(dev->lock);
 6:     if (FuncA(dev))
 7:         goto exit;
 8:     FuncB(dev);
 9: exit:
10:     spin_unlock(dev->lock);
11: }
12:
13: int FuncA(device *dev) {
14:     int v = reg_read(dev->reg, 0x01);
15:     if (!v) {
16:         printk("REG data error!\n");
17:         return -EIO;
18:     }
19:     msleep(1);
20:     return 0;
21: }
22:
23: void FuncB(device *dev) {
24:     spin_unlock(dev->lock);
25:     if (!dev->reply_msg)
26:         printk("No reply, wait!\n");
27:     msleep(10);
28:     spin_lock(dev->lock);
29: }
```

Figure 3: Example of hybrid flow analysis.

3.2.2 Heuristics-Based Sleep-able Function Extraction

We use some heuristics to accurately extract sleep-able kernel interfaces in the kernel modules. Firstly, we perform our hybrid flow analysis on the analyzed kernel module(s), to collect all kernel interfaces that are possibly called in atomic context, through *HowToFunc* in Figure 2. The collected information is stored into a database as *intermediate results*, including the function name, constant arguments, file name and so on. Secondly, we use some heuristics to inter-procedurally analyze the call graph of each collected kernel interface, and determine whether it can sleep. If a kernel interface satisfies one of the five criteria, we identify it sleep-able:

- It calls a basic sleep-able function, like *schedule* in the Linux kernel and *sleep* in the NetBSD kernel.
- It is called with a specific constant argument indicating it can sleep, like *GFP_KERNEL* in the Linux kernel and *M_WAITOK* in the FreeBSD kernel.
- It calls a specific macro that indicates the operation can sleep, like *might_sleep* in the Linux kernel.
- The comments in or before it contain keywords like *"can sleep"* and *"may block"*.
- It calls an already identified sleep-able kernel interface in the call graph.

To avoid repeated checking, we maintain two cache lists. If a function is marked as sleep-able, it is added to a *sleep-able* list; otherwise it is added to a *non-sleep* list. When analyzing a function, we first check whether the function is in either of these lists.

After the extraction, we get the sleep-able kernel interfaces that are possibly called in atomic context of the analyzed kernel modules(s). These kernel interfaces can be used to detect SAC bugs in the kernel module(s).

```
FILE: linux-4.11.1/drivers/scsi/ufs/ufshcd.c
504. static int ufshcd_wait_for_register(..., bool can_sleep) {
     ......
515.   if (can_sleep)
516.     usleep_range(...);
517.   else
518.     udelay(...);
     ......
527. }
```

(a) Checking a variable

```
FILE: linux-4.11.1/drivers/block/DAC960.c
783. static void DAC960_ExecuteCommand(...) {
     ......
794.   if (in_interrupt())
795.     return;
796.   wait_for_completion(...);
797. }
```

(b) Checking the return value of a kernel interface

Figure 4: Examples of path checks in drivers.

3.2.3 Path-Check Bug Filtering

We use the detailed code paths recorded in our hybrid flow analysis to filter out repeated and false SAC bugs.

Firstly, we filter out repeated bugs. For each new possible bug, we check whether its entry and terminal basic blocks are the same as those of an already detected bug, and whether they call the same sleep-able kernel interface. If both conditions are satisfied, this possible bug is marked as a repeated bug and is filtered out.

Secondly, we filter out false bugs, which are mainly introduced by the fact that our hybrid flow analysis neglects variable value information. The best strategy is to validate path conditions [6]. But it is often hard to ensure the accuracy and efficiency when control flow is complex, especially across function calls.

By studying the Linux kernel source code, we find a useful and common semantic information for variables: *a conditional that checks a parameter of the containing function or the return value of a specific kernel interface is often used to decide whether sleeping is allowed.* Figure 4 presents two examples in Linux driver code. In Figure 4(a), a conditional checks the function parameter *can_sleep* to decide whether the sleep-able kernel interface *usleep_range* can be called. In Figure 4(b), a conditional checks the return value of the kernel interface *in_interrupt* to check whether the code is executed in an interrupt handler to decide whether the sleep-able kernel interface *wait_for_completion* can be called. Using this semantic information, we design a straightforward strategy to cover common cases. If the code path of a possible bug satisfies one of the two criteria, we mark this bug as a false bug and filter it out:

- The path contains a conditional that checks a parameter of the containing function, and the name of this parameter contains a keyword like *"can_sleep"*, *"atomic"* and *"can_block"*.
- The path contains a conditional that checks the return value of a kernel interface used to check atomic context, like *in_interrupt* in the Linux kernel.

We propose a path-check method that uses the above steps, to automatically and effectively filter out repeated reports and false bugs.

3.2.4 Pattern-based Patch Generation

By studying Linux kernel patches, we have found four common patterns of fixing SAC bugs:

P1: Replace the sleep-able kernel interface with a non-sleep kernel interface having the same functionality, like *usleep_range* ⇒ *udelay* in Figure 4(a).

P2: Replace the specific sleep-able constant flag with a non-sleep flag, like *GFP_KERNEL* ⇒ *GFP_ATOMIC* in Figure 1.

P3: Move the sleep-able kernel interface to some place where a spinlock is not held.

P4: Replace the spinlock with a lock that allows sleeping, like *spin_lock* ⇒ *mutex_lock* and *spin_unlock* ⇒ *mutex_unlock* in the Linux kernel.

These patterns have different usage scenarios and raise different challenges. Firstly, P1 and P2 can be used for all atomic contexts, while P3 and P4 are only used when holding a spinlock. Secondly, P1 and P2 involve simple modifications, while P3 and P4 involve more difficult modifications and are error-prone. Using P3 requires carefully determining where the sleep-able function should be moved to. Using P4 requires modifying all locking and unlocking operations. Thus, using P3 and P4 to automatically generate patches is hard.

We only use P1 and P2 to automatically generate recommended patches, because these patterns are simple and effective. Supporting P3 and P4 is left as future work. The method has three steps. Firstly, the bug is located using its code path, and the relevant fixing pattern (P1 or P2) is selected according to the code. If no relevant pattern is available, no patch is generated. Secondly, the buggy code is corrected by using the selected pattern. Finally, a patch is generated by comparing the corrected code to original code.

This pattern-based method has two advantages. Firstly, it can reduce the manual work of bug fixing. Secondly, by using common fixing patterns, it can ensure the correctness of the generated patches.

4. Approach

Based on the four techniques in Section 3.2, we propose a static approach DSAC, to effectively detect SAC bugs in kernel modules and recommend patches to help fix the detected bugs. We have implemented DSAC with the Clang compiler [49], and perform static analysis on the LLVM bytecode of the kernel module. Figure 5 presents the architecture of DSAC, which has five parts:

- ***Code compiler.*** For a given kernel module, this part compiles all the source files of the kernel module into a single LLVM bytecode file.

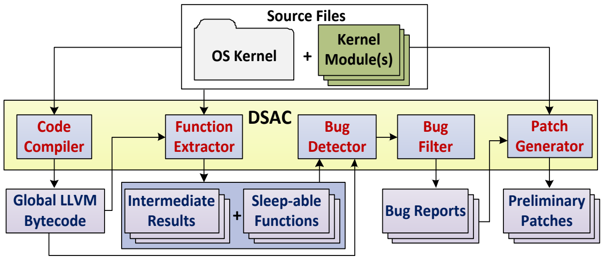


Figure 5: Overall architecture of DSAC.

- ***Function extractor.*** With the LLVM bytecode and the kernel source code, this part uses our hybrid flow analysis and heuristics-based method to generate intermediate results and extract sleep-able kernel interfaces called in the kernel module(s).
- ***Bug detector.*** With the extracted sleep-able kernel interfaces and intermediate results, this part reuses our hybrid flow analysis to automatically detect possible SAC bugs from the LLVM bytecode.
- ***Bug filter.*** This part uses our path-check method to filter out repeated and false bugs and generates reports for the final detected SAC bugs.
- ***Patch generator.*** With the bug code paths and kernel module source code, this part uses our pattern-based method to automatically recommend patches to help fix the bugs.

Based on the architecture, DSAC consists of four phases which are introduced as follows.

4.1 Function Information Collection

In this phase, DSAC performs two steps:

Firstly, the code compiler compiles each source file of the kernel module into a LLVM bytecode file, and then links all bytecode files into a single bytecode file. This single bytecode file includes all module function definitions, thus all analyses of the kernel module can be directly performed on only this single bytecode file.

Secondly, the function extractor performs the hybrid flow analysis to collect the information about functions that are possibly called when holding a spinlock or in an interrupt handler. The information is stored in a MySQL [52] database as the intermediate results, including the function name, constant arguments, file name, etc. The intermediate results will be later used in sleep-able kernel interface extraction and bug detection.

4.2 Sleep-able Kernel Interface Extraction

In this phase, the function extractor first extracts function call graphs of kernel interfaces and comments of these kernel interfaces, and then uses the heuristics-based method to extract sleep-able kernel interfaces. The user can check and modify the extracted sleep-able kernel interfaces as needed.

4.3 Bug Detection

In this phase, DSAC first detects possible SAC bugs, and then filters out repeated reports and false bugs.

Firstly, the bug detector uses the hybrid flow analysis to check whether each extracted sleep-able kernel interface is called in atomic context, which is implemented in *HowToFunc* in Figure 2. If so, a possible bug and its detailed code path to the sleep-able kernel interface call are recorded. To speed up analysis, we use the intermediate results to only check the buggy kernel modules.

Secondly, the bug filter filters out repeated reports and false bugs. Finally, DSAC produces detailed reports for the found bugs (including code paths and source file names), so the user can locate and check the bugs.

4.4 Recommended Patch Generation

In this phase, the patch generator automatically generates recommended patches to help fix the bugs. Then, the user can use the detailed code paths found in the bug reports to write log messages, and finally submit these patches to kernel maintainers.

5. Evaluation

5.1 Experimental Setup

To validate the effectiveness of DSAC, we first evaluate it on Linux drivers, which are typical kernel modules. To cover different kernel versions, we select an old version 3.17.2 (released in October 2014), and a new version 4.11.1 (released in May 2017). Then, to validate the generality of DSAC, we use it to check file systems and network modules in the Linux kernel. Finally, to validate the portability of DSAC, we run it in FreeBSD and NetBSD to check their kernel code.

We run the experiments on a Lenovo x86-64 PC with four Intel i5-3470@3.20G processors and 4GB memory. We compile the code using Clang 3.2. We use the kernel configuration *allyesconfig* to enable all drivers, file systems and network modules for the *x86* architecture.

To run DSAC, the user performs three steps. Firstly, the user configures DSAC for the checked OS kernel, by providing the names of spin-lock and -unlock functions (such as *spin_lock_irq* and *spin_unlock_irq* for the Linux kernel), interrupt-handler-register functions (such as *request_irq* for the Linux kernel), and basic sleep-able kernel interfaces (such as *schedule* for the Linux kernel). Secondly, the user compiles the source code of the kernel modules and OS kernel using the kernel's underlying *Makefile* and DSAC's compiling script. As a result, DSAC produces sleep-able functions and intermediate results. Finally, the user executes DSAC's bug-detecting script to detect bugs and generate recommended patches. The second and third steps are fully automated.

Table 1: Results of extracting sleep-able kernel interfaces.

Description		3.17.2	4.11.1
Code handling	Handled bytecode files	3377	4396
	Source files (.c)	8321	11153
	Source code lines	7392K	9464K
Hybrid flow analysis	Entry basic blocks	32167	37770
	Handled INTR functions	578	673
Heuristic extraction	Recorded functions	3104	3613
	Sleep-able kernel interfaces	70 (51)	94 (63)
Time usage	Original compilation	47m21s	55m34s
	DSAC total	108m43s	129m58s
	DSAC pure	61m22s	74m22s

Table 2: Detected bugs and generated patches in drivers.

Description		3.17.2	4.11.1
Detected bugs	Repeated filtered	479630	629924
	False filtered	282	430
	Final detected	215	340
	Interrupt handling	7	17
	Real	200	320
Patch generation	P1 (replace the function)	-	28 (18)
	P2 (replace the flag)	-	15 (12)
	Total	-	43 (30)
Time usage	Bug detection	6m31s	8m46s
	Patch generation	-	1m02s
	Total	6m31s	9m48s

5.2 Extracting Sleep-able Kernel Interfaces

We first extract the sleep-able kernel interfaces that are called in atomic context of the drivers. Table 1 presents the results for Linux 3.17.2 and 4.11.1. We make the following observations:

1) DSAC can scale to large code bases. It handles 7M and 9M source code lines from 8K and 11K source files. And the analysis is started from many entry basic blocks and many interrupt handler (INTR) functions.

2) Our heuristics-based method can efficiently extract real sleep-able kernel interfaces that are called in atomic context of the analyzed drivers. In Linux 3.17.2 and 4.11.1, 70 and 94 sleep-able kernel interfaces are respectively identified from among 3104 and 3613 different kernel interfaces (candidate functions) that are possibly called in atomic context. We manually check the kernel interfaces identified as sleep-able, and find that all of them can sleep at runtime. Over 97% of the candidate functions are automatically filtered out, thus the manual work of checking these functions is saved.

3) Our code analysis is efficient. DSAC respectively spends around 108 and 129 minutes on handling 8K and 11K driver source files, including the compilation time of these source files using the Clang compiler. Excluding compilation time, DSAC spends 61 and 74 minutes respectively, amounting to less than 0.44 seconds per source file.

4) Many of the extracted sleep-able kernel interfaces are related to resource handling (such as allocation and release). The data in parentheses present the number of these kernel interfaces, which amount to more than 60% of all the sleep-able kernel interfaces.

5.3 Detecting Bugs and Generating Patches

Based on the above extracted sleep-able kernel interfaces, we use DSAC to perform bug detection and recommend patches. Firstly, to validate whether DSAC can find known bugs, we use DSAC to check the drivers in Linux 3.17.2. We do not generate patches in this case, because this kernel version is very old. Secondly, to validate whether DSAC can find new bugs and recommend patches to help fix them, we use DSAC to check the drivers in Linux 4.11.1. We count the bugs according to the pair of entry and terminal basic blocks. To check results' accuracy, we manually check all detected bugs to identify whether they are real bugs. Table 2 shows the results. We have the following findings:

1) Our path-check filtering method is effective in automatically filtering out repeated reports and false bugs.

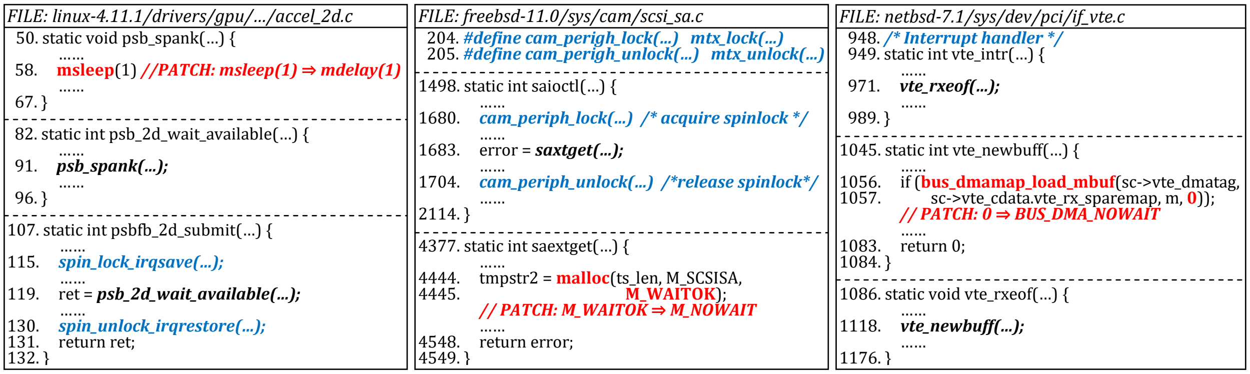
2) Of the 215 bugs reported by DSAC in the drivers of Linux 3.17.2, we have identified 200 as real bugs, 50 of which have been fixed in Linux 4.11.1. By reading the messages in relevant Linux driver mailing lists, we find that kernel maintainers confirmed that these fixed bugs could cause serious problems, like system hangs. The results indicate DSAC can indeed find known bugs.

3) Of the 340 bugs reported by DSAC in the drivers of Linux 4.11.1, we have identified 320 as real bugs. 150 bugs are inherited from the legacy code in 3.17.2, and 170 bugs are introduced by new functionalities and new drivers. We have reported all the bugs that we identified as real to kernel maintainers. As of January 2018, 209 bugs have been confirmed, and replies for the other bugs have not been received. The results indicate DSAC can indeed find new real bugs.

4) DSAC can accurately find real bugs in our evaluated driver code. The false positive rates are respectively only 7.0% and 5.9% in the drivers of Linux 3.17.2 and 4.11.1, based on our identification of real bugs. Reviewing the driver source code, we find these false positives are mainly introduced by the fact that some invalid code paths are searched by our hybrid flow analysis and our path-check method does not filter them out.

5) Few of the detected bugs are in interrupt handlers (7 bugs in 3.17.2, and 17 bugs in 4.11.1). Indeed, driver developers often write clear comments to mark the driver functions that are called from an interrupt handler, to prevent calling sleep-able functions in these functions.

6) DSAC automatically and successfully generates 43 patches that it recommends to help fix 82 real bugs in Linux 4.11.1. Table 2 classifies the patches by the pattern in Section 3.2.4 that is used. We manually review these patches, add appropriate descriptions, and then submit them to the relevant kernel maintainers. As of January 2018, 30 patches have been applied, noted in



```
FILE: linux-4.11.1/drivers/gpu/.../accel_2d.c
 50. static void psb_spank(...) {
         ......

Table 3: Bug distribution according to driver class.

Driver Class	scsi	network	staging	gpio	others
Bugs	103 (32%)	84 (26%)	62 (19%)	12 (4%)	59 (18%)

parentheses in Table 2. 2 patches were not directly applied as the maintainers wanted to fix the bugs in other ways (such as P3 and P4). There has been no reply yet for 11 patches. There are still 238 real bugs for which DSAC cannot recommend patches, as they do not match P1 or P2. Most of these bugs can be fixed using P3 or P4. But those patterns require more difficult changes, and DSAC is not currently able to automatically apply them. In general, the results indicate that DSAC can generate a number of correct patches to reduce the manual work of bug fixing.

7) Bug detection and patch generation are efficient, requiring less than 10 minutes. The reasons include that intermediate results are used to reduce repeated analysis and our hybrid flow analysis is efficient.

Reviewing the results, we find two interesting things. Firstly, most of the detected bugs involve multiple functions. Indeed, driver developers may easily forget that the code is in atomic context across multiple function calls. Secondly, many of the detected bugs are related to resource allocation and release, because many extracted sleep-able functions relate to this issue.

We also classify the 320 real bugs found by DSAC in Linux 4.11.1 drivers, according to driver class. Table 3 shows the top results. We find that SCSI and network drivers share 58% of all bugs.

Table 4: Results of Linux *fs* and *net*, FreeBSD and NetBSD.

Description		**fs & net**	**FreeBSD**	**NetBSD**
Code handling	Handled bytecode files	925	632	710
	Source files	2506	1615	1977
	Source code lines	2013K	1759K	1896K
Function extraction	Recorded functions	1927	582	304
	Sleep-able kernel interfaces	34	12	10
Bugs & patches	Filtered bugs	682081	508	2414
	Final detected bugs	42	39	7
	Real bugs	39	35 (26)	7 (7)
	Generated patches	5	10	3
Pure time usages		32m45s	49m12s	43m38s

Figure 6(a) shows a real bug detected by DSAC in the *gma500* driver of Linux 4.11.1, which has been confirmed by the developer. The function *psbfb_2d_submit* first calls *spin_lock_irqsave* to acquire a spinlock (line 115), and then it calls *psb_2d_wait_available* (line 119) that calls *psb_spank* in definition (line 91). The function *psb_spank* calls *msleep* (line 58) that can sleep. To help fix the bug, our pattern-based method recommends a patch that replaces *msleep* with *mdelay* (P1), and this patch has been applied by the kernel maintainer. Part of the DSAC's report for this bug is listed above Table 3.

5.4 Generality and Portability

We use DSAC to check file systems and network modules in Linux 4.11.1. Then we run DSAC in FreeBSD 11.0 and NetBSD 7.1 to check their kernel code. Table 4 shows the results. We have the following findings:

1) DSAC works normally when checking Linux file systems and network modules and other OS kernels. DSAC can handle their source code in a modest amount of time. It can extract real sleep-able kernel interfaces and filter out many repeated reports and false bugs.

2) DSAC in total finds 81 real bugs out of the 88 detected bugs. The false positive rate is thus 8.0%. The false positives are again due to searching invalid code paths. As of January 2018, 63 of these bugs have been confirmed by kernel developers. Figure 6(b) and (c) present two real SAC bugs found by DSAC in FreeBSD *scsi_sa* and NetBSD *if_vte* drivers. These bugs involve respectively a spinlock and an interrupt handler.

3) DSAC in total generates 18 recommended patches to help fix 59 real bugs. We manually add appropriate descriptions and submit them to kernel maintainers. As of January 2018, 13 of the patches have been applied.

Reviewing the results, we find two interesting things. Firstly, compared to the Linux kernel, fewer SAC bugs are detected in FreeBSD and NetBSD. The main reason is that in FreeBSD and NetBSD, many kernel interfaces that can sleep are carefully designed to avoid SAC bugs. For example, the FreeBSD *msleep* function takes the held spinlock as an argument and unlocks the spinlock before actually sleeping and then locks it again. Secondly, in FreeBSD and NetBSD, most of the detected bugs are in drivers, as shown in the parentheses on "Real bugs" line of Table 4. It shows that drivers remain a significant cause of system failures [39].

5.5 Sensitivity Analysis

DSAC performs flow-insensitive analysis to reduce time usage in specific cases when doing so is expected to not affect accuracy, and also maintains a lock stack to accurately identify the code in atomic context. To show the value of these two techniques, we modify DSAC to remove each of them, and evaluate each modified tool on a typical SCSI driver *fnic (drivers/scsi/fnic/)* of Linux 4.11.1. Original DSAC checks the driver in three seconds, and finds two real confirmed SAC bugs.

Flow-insensitive analysis. We use a full flow-sensitive analysis rather than the hybrid flow analysis. It finds the two SAC bugs too, but it spends two minutes, which is much longer than original DSAC.

Lock stack. We only keep a single bit indicating whether a lock is held rather than the lock stack during analysis. It also spends three seconds, but does not find any bugs. Indeed, the two bugs exist when two spinlocks are held and just one spinlock has been released, thus keeping a single bit cannot identify this atomic context.

5.6 Summary of Results

Our experiments show three significant results of using DSAC on the Linux, FreeBSD and NetBSD kernels:

- 401 new real bugs are found, of which 272 have been confirmed by kernel developers.
- Only 27 reports are false positives. Thus the overall false positive rate of bug detection is only 6.3%.
- 61 recommended patches are generated, of which 43 have been applied by kernel maintainers.

6. Comparison to Previous Approaches

Several previous approaches [2, 9, 16, 34] have considered SAC bugs. Among them, we select the *BlockLock* checker [34] to make a detailed comparison. We select this approach because: (1) It is a state-of-the-art tool to detect SAC bugs in the Linux kernel. (2) It is open-source and its bug reports are available [54]. In design, DSAC has some key improvements over *BlockLock*:

Code analysis. *BlockLock* only uses one bit of context information to check if a lock is held, so it may not accurately identify the code in atomic context when multiple locks are taken but only some of them are released. DSAC maintains a complete lock stack and performs context-sensitive analysis, thus it can accurately detect all code in atomic context. *BlockLock* is also not sensitive to the module *Makefile*, and thus may choose the wrong definition when unfolding a function call if the called function has multiple definitions. DSAC uses the module *Makefile* to accurately identify the definition of each function. And DSAC can detect SAC bugs in interrupt handlers and involving sleeping operations other than a call to an allocation function with *GFP_KERNEL*, which are not considered by *BlockLock*.

Sleep-able function extraction. *BlockLock* regards all functions called in the kernel as candidate functions to extract sleep-able functions. This strategy entails checking each function in the kernel inter-procedurally, so it may require much time. DSAC only treats the kernel interfaces possibly called in atomic context of the analyzed kernel module(s) as candidate functions, and skips the other functions not called in atomic context.

False bug filtering. *BlockLock* does not consider variable value information to validate path conditions, which may cause a number of false positives. DSAC checks the detailed code path of each possible bug, and filters out false bugs using useful and common semantic information for variables in atomic context.

Patch generation. *BlockLock* only reports bugs, but it does not help fix the bugs. DSAC uses common fixing patterns to generate recommended patches to help fix the bugs. The produced code paths of the bugs are also useful to help the user write log messages in the patches.

We also compare the results of *BlockLock* and DSAC, with two steps. Firstly, we download the bug reports of *BlockLock* on Linux 2.6.33 drivers, and get 49 reported bugs. We select the bugs related to the *x86* architecture based on driver *Kconfig* files. We get 31 reported SAC bugs (25 real bugs and 6 false bugs). Secondly, we use DSAC to check the Linux 2.6.33 driver source code. We use the kernel configuration *allyesconfig* to enable all drivers for the *x86* architecture. DSAC reports 42 sleep-able kernel interfaces and 228 reported SAC bugs. We manually check the bugs and find that 208 are real.

By manually comparing the bug reports shows: (1) 53 real bugs reported by DSAC are equivalent to 23 real bugs reported by *BlockLock*. DSAC reports more bugs because it detects sleep-able kernel interfaces, while *BlockLock* detects sleep-able functions. Thus, if a function defined in the kernel module calls several sleep-able kernel interfaces in atomic context, DSAC reports all these kernel interfaces, while *BlockLock* only reports this function. The two remaining real bugs reported by *BlockLock* are missed by DSAC, as Clang-3.2 cannot successfully compile the related driver source code. (2)

DSAC filters out all false bugs reported by *BlockLock*. (3) DSAC reports 155 real bugs missed by *BlockLock*. Most of these bugs involve multiple source files, and *BlockLock* cannot handle them very precisely. And 18 bugs are related to interrupt handling, which is not considered by *BlockLock*. (4) The false positive rate of DSAC is 8.8%, which is lower than that of *BlockLock*.

However, compared to *BlockLock*, an important limitation of DSAC is that its results are specific to a single kernel configuration. *BlockLock* is based on Coccinelle [33], which does not compile the source code. Thus it can conveniently check all source files without any kernel configuration. DSAC is based on LLVM, which compiles the source code with a selected kernel configuration. Thus, the 18 bugs found by *BlockLock* for *non-x86* architectures are missed by DSAC.

7. Limitations and Future Work

DSAC still has some limitations. Firstly, DSAC analyzes LLVM bytecode in which macros are expanded, thus the user needs to configure DSAC in terms of expanded versions of the functions and constants that are defined by macros. We plan to introduce source code information to address this issue. Secondly, DSAC cannot handle function pointers. We plan to use alias analysis [22, 46] to analyze them. Thirdly, as is typical for static analysis, the path-check method cannot filter out all invalid code paths produced by the hybrid flow analysis, which can introduce false positives. We plan to improve our path-check method by checking path conditions more accurately. Finally, the bug-fixing patterns P3 and P4 need to be supported, e.g., we plan to add the analysis for other kinds of locks to support P4.

8. Related Work

8.1 Detecting Concurrency Bugs

Many approaches [7, 14, 19, 28, 32, 38, 42, 43] have been proposed to detect concurrency bugs in user-mode applications. Some of them [7, 19, 42] use dynamic analysis to collect and analyze runtime information to detect concurrency bugs. But the code coverage of dynamic analysis is limited by test cases. Others [14, 32, 38, 43] use static analysis to cover more code without running the tested programs. But static analysis often introduces false positives. Some approaches [8, 26, 28] combine static and dynamic analysis to achieve higher code coverage with fewer false positives. Even though DSAC uses static analysis, it also exploits complementary information such as semantic information for variables to check code paths to filter out false positives.

To improve OS reliability, some approaches [13, 15, 17, 18, 40, 41, 44] detect some kinds of concurrency bugs like data races, but they do not detect SAC bugs. Several approaches [2, 9, 16, 34, 53] can detect common kinds of OS kernel bugs, including SAC bugs. But they do not specifically target SAC bugs, thus they may miss many real bugs or report many of false positives. For example, *BlockLock* [34] has an overall false positive rate of 20%, while DSAC has a lower one of 6.3%, and it also misses some real bugs found by DSAC.

8.2 Checking API Rules

Checking API rules is a promising way of finding deep and semantic bugs in the OS kernel. Some approaches [3, 5, 30, 31] use specified and known API rules to statically or dynamically detect API misuses. For example, with known paired reference count management functions, RID [30] uses a summary-based inter-procedural analysis to detect reference counting bugs. To find implicit API rules, some approaches [4, 23, 24, 27, 37, 45, 47] do specification mining by analyzing source code [24, 27, 37, 47] or execution traces [4, 23, 45], and then use the mined API rules to detect violations.

Most of these approaches focus on the temporal rules of common API usages, such as resource acquiring and releasing pairs [37, 45] and error handling patterns [4, 24], but these approaches have not targeted SAC bugs.

8.3 Improving Kernel Module Architecture

To prevent concurrency bugs, several improved kernel module architectures have been proposed, typically for device drivers. The active driver architecture [1, 36] runs each driver in a separate thread, which can serialize access to the driver and eliminate the possibility of concurrency bugs. In this way, the driver works serially and does not need to use locks, thus many common concurrency bugs will never occur. The user-mode device-driver architecture [20, 25, 35] runs each driver in a separate user-mode process. This architecture protects the OS kernel against crashes caused by driver code.

These approaches have a main limitation, namely that the driver code must be manually rewritten.

9. Conclusion

In this paper, we have proposed DSAC, a static approach, to effectively detect SAC bugs and automatically recommend patches to help fix them. DSAC uses four key techniques: (1) a hybrid flow analysis to identify the code in atomic context; (2) a heuristics-based method to extract sleep-able kernel interfaces; (3) a path-check method to filter out repeated reports and false bugs; (4) a pattern-based method to automatically generate recommended patches to help fix the bugs. We have used DSAC to check the kernel code of Linux, FreeBSD and NetBSD, and find 401 new real bugs. As of January 2018, 272 of them have been confirmed, and 43 of the patches generated by DSAC have been applied.

Coccinelle: 10 Years of Automated Evolution in the Linux Kernel

Julia Lawall
Sorbonne University/Inria/LIP6

Gilles Muller
Sorbonne University/Inria/LIP6

Abstract

The Coccinelle C-program matching and transformation tool was first released in 2008 to facilitate specification and automation in the evolution of Linux kernel code. The novel contribution of Coccinelle was that it allows software developers to write code manipulation rules in terms of the code structure itself, via a generalization of the patch syntax. Over the years, Coccinelle has been extensively used in Linux kernel development, resulting in over 6000 commits to the Linux kernel, and has found its place as part of the Linux kernel development process. This paper studies the impact of Coccinelle on Linux kernel development and the features of Coccinelle that have made it possible. It provides guidance on how other research-based tools can achieve practical impact in the open-source development community.

1 Introduction

Today, everyone uses the Linux kernel, whether on a mobile phone (86% of the smartphones sold in the first quarter of 2017 were running Android [22]), in the cloud (at the end of 2016, 92% of virtual machine instances on Amazon's Elastic Compute Cloud (EC2) were running Linux), or on a supercomputer (at the end of 2017, all of the top 500 supercomputers were running Linux [63]). To support these diverse computing environments, the size of the Linux kernel has been steadily growing, reaching 16.5 million lines of code in the recently released version 4.15 (Jan. 2018). Furthermore, the existing source code of the Linux kernel is continually changing, with around 13,000 commits per release recently, to improve security, performance or maintainability, as well as to provide support for new services such as new kinds of devices, file systems, or hardware architectures.

A stumbling block in this continual revision of the Linux kernel is that ultimately some developer has to modify the source code. Developers have limited time, may not fully understand what a given change entails, and are prone to making mistakes, particularly when changes affect many code sites, pervasively, across multiple kernel subsystems. These problems are further compounded by the fact that the Linux kernel has a widely dispersed and very diverse set of developers, ranging from core maintainers, with many years of experience, to occasional contributors, to developers of out-of-tree code who do not participate in the Linux kernel developer community. Indeed, while over 1700 developers have contributed to each recent release, in each case a third or more of these developers have contributed only a single patch to that release. A potential solution is to formally specify changes and automate them. To be used in practice, such an approach must fit with the background and habits of the developers themselves.

The Coccinelle C-program matching and transformation tool was first released in 2008 to facilitate specification and automation of the evolution of Linux kernel code [44]. Coccinelle was built around the observation that Linux kernel developers already have a precise notation for describing changes with which they are very familiar, the *patch* [36]. A patch is an extract of source code in which some lines are annotated with `-` or `+` indicating that the line should be removed or added, respectively. All contributions to the Linux kernel pass in the form of patches through mailing lists where they are commented on by other developers, and thus developers are used to seeing and understanding them. Exploiting this background of kernel developers, Coccinelle is designed around a domain-specific language (DSL), SmPL (Semantic Patch Language), for expressing changes in terms of an abstracted form of patch, referred to as a *semantic patch*. Unlike a patch, which is tied to specific lines and files in the source code, a single semantic patch can update all relevant locations in the entire code base.

Today, Coccinelle has been under development for 12 years. 59 semantic patches are part of the Linux kernel source tree, and over 6000 Linux kernel commits, including 900 from Linux kernel maintainers, use Coccinelle. Coccinelle retains as a guiding principle the notion of an abstracted patch. Nevertheless, it has grown, both in terms of expressiveness and to improve performance, based on lessons learned from the experiences of Linux developers and other users. At the same time, it has successfully integrated into the Linux kernel community.

Coccinelle has been used in previous research [30, 31, 34, 46]. This paper instead focuses on its evolution and impact. We examine its initial design (Sec. 2), and how that design has been refined in response to experience with the tool and feedback from users (Sec. 3). We then evaluate performance (Sec. 4) and the benefit of our expressivity extensions (Sec. 5), quantify the impact of Coccinelle in the Linux community (Sec. 6), and give an overview of its wider use (Sec. 7). Finally, we present some related work (Sec. 8) and conclude (Sec. 9), with lessons learned about dissemination of a research tool.

2 Initial Design of Coccinelle

Coccinelle development began in 2006. It was first made publicly available in binary in 2007 and in open source in 2008. We first review the original design decisions for Coccinelle, in terms of goals, expressivity, performance, correctness guarantees, and dissemination.

2.1 Goals

Coccinelle was initially designed to solve a specific problem, that of porting Linux device drivers from Linux 2.4, a previous stable version, to stable version Linux 2.6, which had been released shortly before the start of the project. The initial design was motivated by an earlier paper on *collateral evolutions* in the Linux kernel [45], *i.e.*, evolutions needed in API clients in response to changes in the API interface. The examples from that paper showed that to automate Linux kernel collateral evolutions it would be necessary to support transformations on scattered parts of the source code with various kinds of connections between them, including intraprocedural control-flow paths with specific properties. As a small research project could not encode the entire porting activity, these kinds of connections, derived from program-analysis concepts, would need to be expressed in a way that would be accessible to Linux driver developers, who could carry on the work. Targeting driver developers furthermore implied that Coccinelle would have to allow the user to reason about the code as it is shown to him, without simplification to an internal representation, and that it would have to treat a very large subset of C constructs, including various gcc extensions, according to the needs of arbitrary Linux kernel device driver code. Finally, the generated code would have to retain the structure of the original source code, including comments and whitespace, to ensure the code's continuing maintainability.

2.2 Design decisions affecting expressivity

Coccinelle provides a transformation language SmPL (Semantic Patch Language) and an engine for applying SmPL semantic patches to C code. SmPL was conceived as a code pattern-matching language, mimicking the patch syntax. A SmPL semantic patch consists of a series of rules, analogous to patch hunks, each providing a code pattern to match or transform. Patterns are comprised of concrete syntax, "...", and metavariables. Concrete syntax matches itself, "..." matches a possibly empty sequence of arbitrary terms, *e.g.*, the list of statements between two other statements, and metavariables match arbitrary terms of a particular type. Metavariables are declared in a rule header and are used as ordinary variables in the pattern, to make the patterns close to the source code. Ideally, a Linux kernel developer should be able to copy a typical code example and add metavariable declarations, "...", and - and + annotations, to obtain a transformation rule with minimal effort.

The semantic patch in Figure 1 illustrates the various features of SmPL. This semantic patch completes an evolution and associated collateral evolutions that had been initiated by a Linux developer. The evolution changed the type of a callback function, by removing its third parameter. This required additionally removing the third argument from direct calls to this function. This change is challenging because the names of the affected functions are all different, implying that grep may not be sufficient to find all occurrences. A common strategy is to identify code to fix by compiler errors, iterating until the kernel compiles successfully. In this case, some of the direct calls had been overlooked due to being under ifdefs or in the support for obscure architectures.

The semantic patch consists of two rules, on lines 1-7 and lines 8-14, respectively. The first rule, named rule1, declares three identifier metavariables fn, irq and dev_id, representing the name of the function to match and the names of its two parameters, respectively. The rest of the first rule is a pattern that matches a function definition, in which the parameters and return value are indicated to have specific types (lines 5-6) and the body is allowed to be an arbitrary sequence of statements (line 7). The second rule, which has no name, declares four metavariables: the function name `fn`, whose value is explicitly inherited from the previous rule (line 9), and three expression metavariables, `E1`, `E2`, and `E3`, representing arbitrary argument expressions (line 10). The rest of this rule matches a call to the function that was identified in the first rule. In this call, the third argument is indicated to be removed (line 13). A wider variety of semantic patches is illustrated in various publications [31, 43, 50] and at the Coccinelle website [10, 11].

To apply a semantic patch to a code base, Coccinelle processes the C source code files one at a time. On each file, it applies the first rule of the semantic patch to each function or other top-level declaration, then applies the second rule to the code resulting from the first rule application, etc. Based on the needs observed in the prior collateral evolution study, the processing of a function is based on its intraprocedural control-flow graph. Thus, at the statement level, *e.g.*, line 7 of Figure 1, "..." follows intraprocedural control-flow paths, using a semantics based on a variant of CTL model checking [5]. By default, a pattern must match all control-flow paths starting from the control-flow graph node matching the beginning of the pattern, to ensure that the semantic patch describes a consistent view of the program behavior. For example, when a pattern such as `A(); ... B();` matches code including a conditional, `B();` must be reachable from `A();` via both branches of the conditional. Alternatively, a rule or an individual instance of "..." can be annotated with `exists` to indicate that only the existence of a matching path is required. By default, "..." cannot contain any code that is matched by the code pattern immediately preceding or following it, *e.g.*, to allow matching a call to a locking function and to the unlocking call closest to it, as needed due to the fine-grained locking found in the Linux kernel. Finally, a metavariable must match identical terms within a single control-flow path, but may match different terms in different control-flow paths, *e.g.*, different conditional branches [5].

2.3 Design decisions affecting performance

Coccinelle is intended to be used by a Linux developer in the course of his ordinary work, whenever a recurring transformation is needed. Accordingly, it must be usable on a standard laptop without much disruption. A number of the initial design decisions were guided by this goal.

The Linux kernel is very large, and indeed has more than tripled in size between Feb. 2007 (version 2.6.20, 5M LOC) and Jan. 2018 (version 4.15, 16.5M LOC). Processing the entire code base and achieving reasonable performance on a developer's laptop, thus requires making some tradeoffs. To reduce running time, Coccinelle focuses on regions of code that are most likely to be relevant for collateral evolutions, at the expense of the rest. A key observation is that an individual Linux kernel file typically addresses a problem at a given level of abstraction, while references to other files, via `#include` or function calls, typically move to a lower level of abstraction. Thus, the contents of header files and called functions may be less relevant for collateral evolutions.

Based on the above observation, by default, Coccinelle processes only `.c` files, includes only header files that are located in the same directory as the `.c` file or that have the same name as the `.c` file, and does not perform interprocedural analysis. Command-line options are provided to additionally process header files, independently of any files into which they may be included, and to include header files directly referenced in a `.c` file or all header files referenced recursively. The latter options, however, increase the amount of code processed, and thus the processing time. The use of these strategies is thus left up to the user, who is expected to know whether such information is relevant to the desired evolution. Finally, interprocedural analysis within a single file can be encoded up to a finite depth using a series of SmPL rules, each of which matches the definition of a function for which a function call was identified by a previous rule. More general interprocedural analysis originally required the use of external scripts to collect the names of called functions and to restart Coccinelle to process their definitions.

The only program analysis performed by Coccinelle is type inference. This analysis is best-effort, as non-inclusion of header files means that type information may be unavailable. Although the type information is incomplete, the inclusion of type information makes Coccinelle very useful for tasks such as finding where a field of a particular type of structure is referenced, without knowing the name of the variable pointing to that structure. Coccinelle performs no alias analysis or other form of dataflow analysis. Semantic patches that require control over aliases have to implement it explicitly, *e.g.*, by declaring that the code region matched by "..." cannot store the address of a given variable. This approach saves execution time, as the analysis is only performed if and to the extent that it is expected to be useful, and improves the predictability of the tool, as the semantic patch writer knows the strengths and limitations of the analysis.

2.4 Design decisions affecting correctness guarantees

Automatic program transformation has the potential to update code at a large scale reliably and efficiently, but it can also introduce pervasive bugs across a code base, if the transformation rules are incorrect or are implemented incorrectly by the transformation engine. Coccinelle only checks that a rule preserves the structural well formedness of the code, *e.g.*, ensuring that a statement is replaced by a statement, an expression by an expression, etc. It does not check for semantic correctness. This enables encoding bug fixes, which are intrinsically not semantics preserving. Furthermore, it enables efficiently applying rules, without complicated, typically interprocedural, analysis to show correctness. The goal of Coccinelle is to allow the user to express his knowledge about the software and the required changes, in terms of code fragments that resemble the affected code and that can be easily checked to conform to the user's intent.

2.5 Dissemination strategy

Reaching potential users is always a challenge for research projects. An open-source development context provides a diverse audience, which increases the chance that individual users will pick up new approaches, but makes it harder to impose a new approach on the entire developer base than in a monolithic industry setting. This is particularly the case of the Linux kernel developer community, which puts few restrictions on the tools used by developers to create and manage code.

To validate the utility of Coccinelle and to encourage its use by Linux developers, the Coccinelle developers took the strategy of showing by example. The first submitted patches (*e.g.*, 632155e65944 on June 1, 2007 [61]) exploited only the Coccinelle parser [42]. Indeed, as Coccinelle does not expand macros or reduce ifdefs, its parser can find errors that are overlooked in typical compile testing. The first submitted patch generated by a semantic patch was 0da2f0f164f0 (July 5, 2007). This patch was created using the semantic patch of Figure 1, and included the semantic patch in the commit log. It updated five files in the `net`, `atm`, and `usb` directories.

The next patch dd00cc486ab1 based on a semantic patch was submitted on July 6, 2007, changing a call to the memory allocator `kmalloc` followed by a `memset` to clear the memory into a single call to the function `kzalloc`, added in 2005. This patch affected 166 calls distributed over 146 files. The semantic patch in the log message received the comment "Cool!" from a developer,[1] but the patch ran afoul of the Linux kernel requirement that patches on different parts of the kernel be submitted separately to the relevant maintainers. Indeed, Coccinelle had shifted the burden from performing the change, which was now fully automated, to routing the individual changes to the proper maintainers, for which no automatic support was then available.

The first patches explicitly mentioning "Coccinelle" were submitted in December 2007, fixing various missing resource-release errors (76832d841643, etc.). These attempted to set a precedent for how the tool should be used, by including the URL of the tool, as well as the XML-like tags `<smpl>` and `</smpl>` around the semantic patch, to ease the tracking of the use of the tool. The first commits from outside the group of Coccinelle developers, 77bbadd5ea89 and 52fd8ca6ad41, came in July 2008, from the developer of the kernel-level memory checker `kmemcheck`. These patches corrected the type of a flag passed to various lock-related function calls. Coccinelle was released as open source in October 2008.

3 Evolutions in the Coccinelle Design

In retrospect, the design decisions presented in the previous section reflect a number of fundamental hypotheses about how to design a program transformation system that will be useful to and used by kernel developers:

Expressivity: Linux kernel developers will find it easy and convenient to describe needed code changes in terms of fragments of removed and added code.

Performance: Many interesting Linux kernel evolutions can be implemented reliably without incurring the cost of collecting and correlating information in multiple C files. Indeed, Linux kernel development relies on humans, who typically focus on one file at a time, and thus all relevant information should be directly apparent in a single C file.

Correctness: Proving correctness is not necessary because Linux kernel developers can easily incorporate their knowledge of kernel invariants into a semantic patch. Giving the developer control over the rules implies that the developer can control the rate of false positives, and can easily check for them in the results.

Dissemination: It is effective to show how a tool can be useful, rather than attempting to impose its use.

While Coccinelle still builds on these hypotheses, experience in using the tool and feedback from Linux kernel developers have provided lessons that have motivated various evolutions. We highlight those that have had the greatest impact on the use and usability of the tool.

3.1 Expressivity evolutions

Many changes, both simple and complex (*e.g.*, Figure 1), can be expressed purely in terms of code structure. Some kinds of changes, however, require more semantic information. Two evolutions that have greatly enhanced the expressivity of Coccinelle have been the introduction of *position variables* and *scripting rules*.

Position variables. A position variable is a Coccinelle metavariable that matches the position where a term occurs in a file. Position variables allow rematching the

Figure 3: Drop spurious semicolon after if header

same code in a later rule, as well as ensuring that a match in one rule is different than a match in an earlier rule.

Figure 2 illustrates the use of position variables to convert calls to `init_timer` to `setup_timer` when the `init_timer` call is followed by initializations of the timer `data` and `function` fields. The first two rules (lines 1-15) identify instances of the same `init_timer` call with two different properties (the `when` annotations in lines 6 and 14 indicate assignments that should not occur in the matched region). The last rule (lines 16-29) transforms `init_timer` calls that satisfy both properties. This rule includes a disjunction, such that all of the relevant code fragments can be transformed at once, wherever they occur, as once a transformation takes place, all previously bound position variables are invalidated.

Scripting language interface. The scripting language interface was initially motivated by the goal of using Coccinelle for bug finding [56]. While bugs that mainly depend on the code structure, such as use after free, could be found, the pattern-matching features of Coccinelle were not sufficient to detect bugs such as buffer overflows that require reasoning about variable values.

To allow reasoning about arbitrary information, support was added in 2008 for scripting-language rules. The first language supported was Python, which was expected to be familiar to Linux developers. Coccinelle is implemented in OCaml, and OCaml scripting was added in 2010, for the convenience of the Coccinelle developers. Scripts were originally designed to filter sets of metavariable bindings established by previous rules. Figure 3 shows an example, which drops a semicolon after an `if` header if the subsequent statement is indented, suggesting that the latter statement is intended to be the `if` branch. A script rule compares the indentation of the two statements (line 11) and discards metavariable binding environments (line 12) in which the conditional is aligned with or to the right of the subsequent statement.

Ultimately, the original motivation for scripting, *i.e.*, finding bugs such as buffer overflows, was not successful. The code patterns were small and generic, and the scripts implementing the required analyses were complex. Still, scripting has been a major leap forward for the expressiveness of Coccinelle, and new scripting functionalities have been added as new needs have emerged. Early on, libraries were added for generating formatted error messages. In 2009, `initialize` and `finalize` scripts were introduced to allow defining state global to the processing of all files, to facilitate the collection of statistics. In 2010, scripts became able to create new code fragments to be stored in metavariables and inherited by subsequent rules. In 2016, to improve performance and reduce semantic patch size, it became possible to add script code to metavariable declarations, to define predicates that would discard metavariable bindings early in the matching process. Finally, scripting enables *iteration*, which allows a semantic patch to submit new “jobs” to the Coccinelle engine, in order to perform analysis across multiple files.

3.2 Performance evolutions

While avoiding including header files reduces the volume of code to process, the Linux kernel remains a large and growing code base. Furthermore, parsing the code without relevant macro definitions from header files involves using heuristics, which can increase the parsing time. Thus, further optimizations were needed.

Indexing. An early observation was that performance could be improved by not parsing files that could not be matched by the semantic patch. Indeed, many semantic patches contain keywords such as the names of API functions that must be present for the semantic patch to match and that occur only a moderate number of times in the Linux kernel. Coccinelle initially used the Unix command `grep` to find the files containing these keywords, but this was still slow, given the large code size.

A second approach was to use `glimpse` [24] to prepare an index in advance, and then to only process the files indicated by the index. As the index is smaller than the kernel source code and is organized efficiently, the use of glimpse substantially improves performance, particularly for semantic patches that involve kernel API functions. Nevertheless, glimpse was originally only freely available to academic users, had to be manually installed, and creating an index on each kernel update is time-consuming. In 2010, this was complemented by support for id-utils, which is part of many Linux distributions and for which index creation is much faster. In 2013, the support for users who do not have an index available was rewritten to essentially reimplement the grep operation in OCaml, reducing system calls and better taking into account the specific needs of Coccinelle.

Parallelism. By default Coccinelle works on each .c file independently, and thus is ripe for parallelism. Nevertheless, when Coccinelle was first developed, there was no convenient support for parallelism in OCaml. Instead, the Coccinelle distribution included a shell script to launch multiple Coccinelle instances in parallel, each covering a different part of the code base. Users, however, were uneasy about using Coccinelle via an external script. Furthermore, processing different files can require very different amounts of time, and the lack of load balancing in this static solution meant that many cores could end up idle. Meanwhile, the Parmap OCaml parallelization library [14] became available, and between 2015 and 2017 increasing support was provided for parallelism, still at the .c file level, within Coccinelle itself.

Supporting finer grained parallelism, at the function level, was also considered. Initial experiments, however, suggested that the cost of passing around the state built up within the matching of a given file outweighed the benefits of parallelism. In contrast, Coccinelle treats each file independently, so the amount of state that needs to be passed between processes is minimal.

3.3 Correctness guarantee evolutions

Unlike the other cases, there have been no major evolutions in the view of transformation correctness. After having created over 450 semantic patches that have led to kernel patches, the Coccinelle developers have found that the original hypothesis that giving the developer control over the rules enables them to easily check the results is mostly sufficient. The few errors, *e.g.*, [53], have come from misunderstanding of kernel invariants that would require a prohibitively complex and time consuming semantic analysis to infer and check. Kernel maintainers have indeed concluded in some cases that it was the original code that was written in an error prone way [38].

3.4 Dissemination strategy evolutions

Showing the value and capabilities of Coccinelle by the example of submitted patches generated initial interest in the tool. As the expressivity of Coccinelle evolved to permit the specification of more complex changes, it became apparent that it would also be beneficial to more directly teach developers how to use Coccinelle, and to enable Coccinelle users to interact with each other.

Four workshops were organized on the use of Coccinelle and advertised on the Coccinelle mailing list, attracting industry participants. The Coccinelle developers also presented the tool and offered tutorials in a variety of developer conferences, including those targeting open-source enthusiasts (*e.g.*, FOSDEM) and those specifically targeting Linux kernel developers (*e.g.*, Linux Plumbers). These presentations focused on the user-visible aspects of Coccinelle, such as how to write semantic patches and what results could be achieved, rather than the details of the internal design of the system, which were presented in research venues [5].

The work on Coccinelle was also picked up by the Linux Weekly News (LWN), which is the standard reference for issues around the development of the Linux kernel and other open-source software. Tutorial articles on Coccinelle appeared in 2009 [25] and 2010 [52], authored not by the Coccinelle developers, but by well-known kernel developers. LWN has also reported on various talks about Coccinelle [12, 16].

4 Performance Evaluation

Coccinelle is intended to be used by a kernel developer as part of the normal development process, on a standard professional laptop. Accordingly, Coccinelle's performance should be acceptable in this setting. We illustrate the performance on a Lenovo Thinkpad T460s with two hyperthreaded 2.30GHz cores (Intel(R) Core(TM) i5-6200U CPU), a 3M cache, and 12G RAM. Our experiments focus on the 59 semantic patches found in the Linux 4.15 kernel, using the report mode, which is supported by all these semantic patches.[2] Times are based on a single run, with a timeout of 30 seconds per file. We use id-utils indexing. Figure 4 presents the elapsed time when running the semantic patches on the Thinkpad laptop, using both cores, with hyperthreading. The semantic patches are sorted in order of increasing running time.

For the Linux kernel, there is a precise performance point of reference that is familiar to the kernel developer; the time to perform a complete compile of the Linux kernel itself. The elapsed time for full kernel compilation on the Thinkpad laptop with 4 threads (hyperthreading) with make clean; make allyesconfig; make, is 54 minutes. Based on the results shown in Figure 4,

[2] The semantic patches and Coccinelle version used contain some performance improvements that will appear in Linux 4.18 and Coccinelle 1.0.7, respectively.

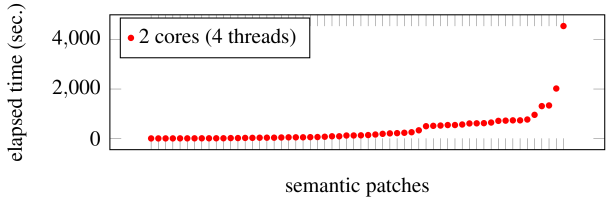

Figure 4: Elapsed time per semantic patch in the Linux 4.15 kernel on the Thinkpad laptop

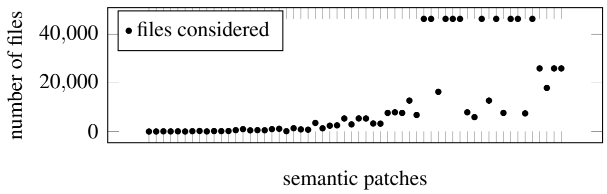

Figure 5: Files considered per Linux semantic patch.

all but one of the semantic patches complete within this time. The remaining semantic patch requires 75 minutes.

The timeout per file affects performance. In our experiment, Coccinelle timed out on 52 files, of 705,179 files considered, giving a timeout rate of 0.007%. Typically files on which timeouts occur contain complex code such as long sequences of loops and conditionals. These files can be analyzed separately, when more time is available.

Figure 5 shows the impact of indexing using id-utils on the number of files considered. The largest number of files considered is 46,336, in 10 cases, where no keywords are inferred from the semantic patch. These are associated with larger, but not the largest, execution times. At the far right of the graph, between 5000 and 26,000 files are considered, but the cost of tracing through all possible intraprocedural execution paths overwhelms the savings obtained by processing fewer files.

In terms of header files, 43 of the semantic patches specify that no include files should be considered. 11 specify to use the default (local and same-named files), and 1 specifies that all explicitly included should be taken into account. To assess the cost and benefit of including header files, we take the 44 semantic patches from the Linux kernel that complete in our test configuration in under 10 minutes and test them with options forcing the inclusion of no header files, the default, and all explicitly included header files. As compared to inclusion of no header files, the default increases the run time by up to 90% and the inclusion of all explicitly included header files increases the run time by up to 10x. The number of reports ranges from 1631 for no headers to 1691 for all headers, with most of the few differences on `.h` files.

The performance studied here is only relevant when scanning the entire kernel. When checking a single modified file, the time should rarely exceed a few seconds per semantic patch. Indexing may identify some semantic patches as irrelevant, reducing the execution time.

5 Expressivity Extension Evaluation

The position variable and scripting extensions increase the expressivity of SmPL, but add concepts that are not found in C code and thus are not already familiar to Linux developers. We thus assess the degree to which these features are used in practice. We note, however, that our only source of information about semantic patches is from those found in the Linux kernel and from those included in commit messages. This information may be incomplete, because developers can omit or simplify semantic patches in the commit message

All of the semantic patches found in the Linux kernel use positions and scripts in order to generate output in the report mode. 20 semantic patches were contributed by developers from outside the Coccinelle team. 3325 commits up through Linux 4.15 contain semantic patches in the commit message. Of these 586 (18%) contain position variables and 165 (5%) contain scripts. 43% of the latter commits come from outside the Coccinelle team.

6 Impact on Linux

Over the past 10 years, Coccinelle has been increasingly applied to the Linux kernel, by both Coccinelle developers and Linux kernel developers. As of Linux 4.15, over 6000 commits in the Linux kernel are based on the use of Coccinelle. In this section, we give an overview of the impact of Coccinelle on the Linux kernel. Graphs by subsystem reflect commits up through the release of Linux 4.15 (Jan. 2018). Graphs by year end with 2017.

6.1 Changed lines per subsystem

Figure 6 shows the number of lines removed and added by commits using Coccinelle in various kernel subsystems. The most affected is `drivers`, with 57,882 removed lines and 77,306 added lines, followed by `arch`, `fs`, `net`, `sound`, and `include`, all of which are affected by thousands of removed or added lines. The predominance of `drivers` is not surprising, given that `drivers` makes up 67% of the Linux 4.15 kernel source code. `drivers` has also been a target for other bug finding and code reliability tools [35, 37, 48, 51, 57].

Figure 7 compares the numbers of removed and added lines to the number of code lines (non-blank, non-comment, measured using SLOCCount [54]) found in Linux 4.15. The rate of Coccinelle-motivated changed

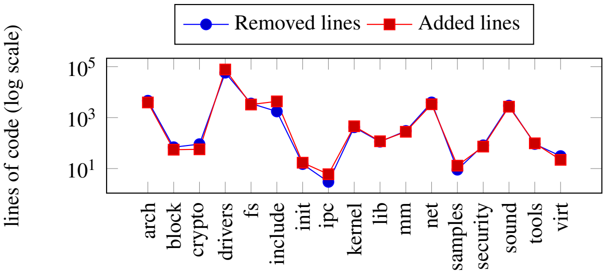

Figure 6: Number of lines removed and added by commits using Coccinelle, by subsystem

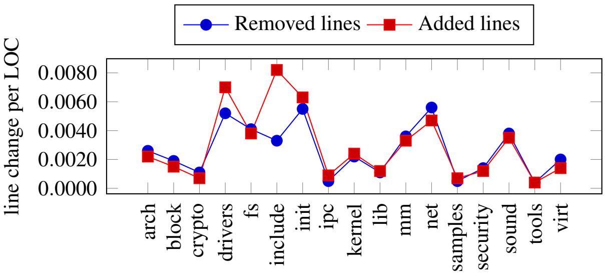

Figure 7: Lines removed and added by commits using Coccinelle per Linux 4.15 line of code, by subsystem

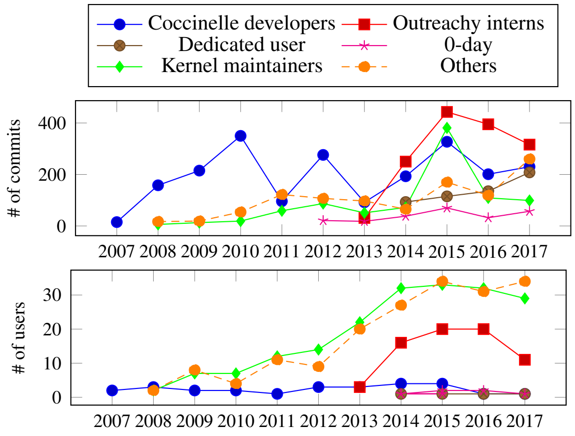

Figure 8: Number of commits using Coccinelle from various categories of Coccinelle users (top) and number of Coccinelle users in various categories having at least one commit using Coccinelle (bottom)

lines in drivers remains high, but the results show the applicability of Coccinelle across the kernel.

6.2 Categories of users over time

A variety of kinds of developers contribute to the Linux kernel, by submitting patches. Among those who mention Coccinelle in their commit logs, we distinguish six categories of Coccinelle users:

Coccinelle developers. These are members of the Coccinelle development team, and persons employed by the team to disseminate Coccinelle.

Outreachy interns. The Linux kernel participates in the Outreachy internship program [41] and interns may use Coccinelle in the application process or the internship.

Dedicated user. This is a single developer who uses Coccinelle in the kernel for a small collection of widely relevant simple changes.

0-day. This is an automated testing service at Intel that builds and boots the Linux kernel for multiple kernel configurations, on each commit to hundreds of git trees. The service also runs a number of static analysis tools, including Coccinelle, on the result of each commit.

Kernel maintainers. These are kernel developers who receive and commit patches, and are generally responsible for some subsystem's continued well being. We identify maintainers as developers who are named in the Linux 4.15 MAINTAINERS file (1170 developers) or who are the committer of some patch. Normally, kernel patches are transmitted by email, and only maintainers or developers the maintainers specifically designate commit to git trees that are pulled into a mainline release. Thus, being a committer is a sign of community respect.

Others. These are other Linux kernel contributors. These contributors may be frequent or occasional.

The top of Figure 8 shows the number of commits per year using Coccinelle from various kinds of Coccinelle users, while the bottom shows the number of Coccinelle users involved in each category. The first commits (2007) were from the Coccinelle development team. Use from maintainers and other kernel contributors started in the two years afterwards. The number of commits from maintainers has grown steadily, except for a major peak in 2015, when several maintainers undertook cross-tree refactoring projects using Coccinelle. The number of other kernel contributors has gone up and down, but shows an upward trend. These numbers may be underestimated, however, as some developers have revealed when asked that they used Coccinelle for repetitive changes, but did not mention it in the commit.[3]

The Linux developers who are most likely to have need for Coccinelle are those who perform large scale changes across the code base. To approximate this set of developers, we consider those who have at least one commit that touches at least 100 files, since Linux 3.0 (July 2011), *i.e.*, the period in which Coccinelle was becoming more established. There are 88 such developers, of which 67 (76%) are maintainers. All but two of the others are in the Other category. 39 (44%) of these develop-

[3] https://marc.info/?l=kernel-janitors&m=150403263119030&w=2

ers overall and 31 (46%) of these maintainers have commits using Coccinelle. Of the 88 developers, 27 (31%) have 1-5 commits using Coccinelle, 9 (10%) have 6-100 such commits, and 3 (3%) have more than 100. Among the 67 maintainers, 21 (31%) have 1-5 commits using Coccinelle, 8 (12%) have 6-100 such commits, and 2 (3%) have more than 100. These numbers suggest that Coccinelle is well known among the Linux kernel developers and maintainers who can benefit from it most.

Finally, we consider the most established kernel contributors. We collect the set of maintainers from the Linux 4.15 MAINTAINERS file and the set of developers who have committed at least one patch between Linux 3.0 and Linux 4.15. 45 have at least 10 years of experience as committers and 117 have committed at least 1000 patches. 29% and 32% of these, respectively, have created at least one patch that uses Coccinelle. These numbers reflect the knowledge of Coccinelle at the core of the Linux kernel developer community.

6.3 Changes performed using Coccinelle

Coccinelle facilitates performing changes across the kernel, that may cover code managed by multiple maintainers. Some examples are as follows:

TTY. Remove an unused function argument. One commit (429b474990cb) in 2015, affecting 11 TTY driver files. The author is not a maintainer, but has over 350 commits in the Linux kernel, since 2013.

IIO. Add missing `__devinit` and `__devexit` annotations. One commit (8e8287526844) in 2012 affecting 28 new IIO driver files. The author is an IIO maintainer.

DRM. Eliminate a redundant field in a data structure. One commit (438b74a5497c) in 2016 affecting 54 direct rendering manager (DRM) files. The author is a maintainer, but not for the affected files.

Interrupts. Prepare to remove the `irq` argument from interrupt handlers, and then remove that argument. 40 commits (*e.g.* f4acd122a738) in 2015, affecting 188 files (mostly `drivers`, `arch`). The author is a core Linux developer with over 3500 commits in the Linux kernel since the start of the Linux kernel's usage of git (2005).

More generally, Figure 9 characterizes as cleanups or bug fixes the complete set of patches that use Coccinelle from maintainers. Typical cleanups address generic C issues, such as useless double semicolons, as well as introductions of new APIs and refactorings in preparation for the introduction of new APIs. Commonly identified bugs include memory leaks, allocation of a memory region of the size of a pointer rather than the size of the referenced structure, and storing a potentially negative value in a variable of type `unsigned int` and then checking whether the value is less than zero.

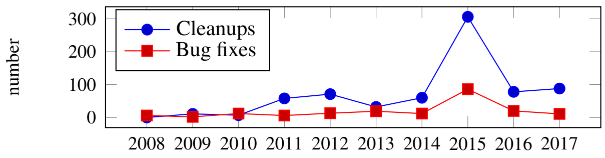

Figure 9: Cleanup vs. bug fix changes among maintainer patches using Coccinelle

As noted in Section 2.5, Coccinelle facilitates making changes that affect the entire Linux kernel source tree, and in particular subsystems managed by different maintainers. While the initial problem of knowing who maintains which part of the kernel was resolved in 2009 by the introduction of the `get_maintainer.pl` script, it is not always clear who should actually commit the changes, particularly when there are dependencies between the resulting patches. The problem of managing cross-tree changes was a proposed topic at the 2017 Linux Kernel Maintainers Summit. Preliminary discussions included proposing the use of Coccinelle for refreshing cross-tree changes when patch sets are incompletely applied [3].

6.4 Semantic patches in the Linux kernel

Since 2010, the Linux kernel has hosted a set of semantic patches in its `scripts/coccinelle` directory. Semantic patches are categorized as being related to APIs (17), resource release (7), iteration (5), locking (4), NULL values (4), test expressions (4) and others (18). The kernel Makefile contains a `coccicheck` target that runs one or all of these semantic patches on the entire kernel or some portion thereof. Kernel developers may thus easily use Coccinelle to check their work, without learning SmPL. Such use, however, is not visible in the kernel history.

As of Linux v4.15, there are 59 semantic patches in the Linux kernel. Figure 10 shows the number of commits including new semantic patches per year, as contributed by various categories of users. Semantic patches were initially contributed by the Coccinelle developers. Recently, 2-3 have been contributed each year, and a few more requested, by the wider kernel community.

6.5 0-day build testing service

Intel's 0-day testing service [26, 60] runs a number of static analyses on commits to hundreds of Linux kernel git trees, both public and private. Kernel developers may check their changes themselves on only one configuration and then rely on the 0-day service for the rest. Coccinelle-based reports generated by the 0-day build testing service come in two forms. If the semantic patch producing the report is able to propose a fix for the identified problem, then the report contains this patch. The

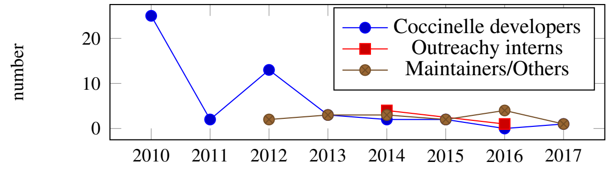

Figure 10: Number of commits adding a semantic patch to the Linux kernel source tree per year

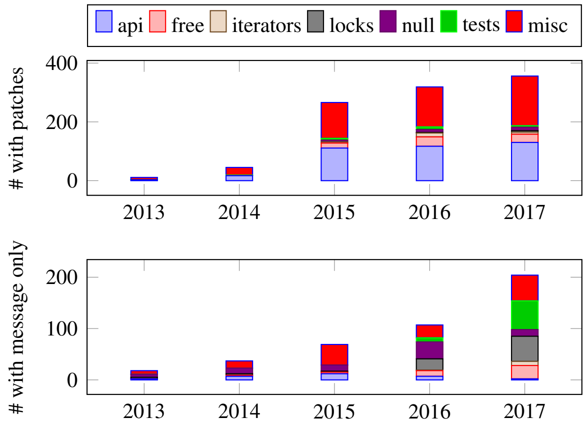

Figure 11: 0-day reports mentioning Coccinelle per year

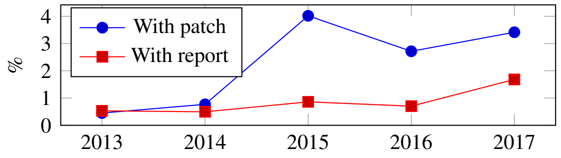

Figure 12: % of 0-day reports mentioning Coccinelle

remaining Coccinelle-based reports contain a textual error or warning message, accompanied by a code extract highlighting the relevant lines, as indicated by the semantic patch. Figure 11 shows the number of public reports that mention Coccinelle in various categories, distinguishing between those that include a patch or only a message. Figure 12 likewise shows the percentage of all public reports mentioning Coccinelle. The most common type of report including a patch removes a field initialization in drivers that is redundant with respect to the driver core (244 patches). The most common type of report including only a message detects missing unlocks (68 reports). The latter reports are manually checked by a Coccinelle developer and have few false positives. Both semantic patches involve kernel-specific features.

7 The Coccinelle Community

A measure of the long term potential impact of a project is the willingness and ability of external developers to contribute to the project's development and maintenance. Today Coccinelle amounts to over 84,000 lines of OCaml code. 25 developers have contributed to Coccinelle, with over 3000 commits over 12 years for one developer, almost 1000 in the first few years for another developer, and 200-300 commits in the last few years for several others. All of the contributors with more than 5 commits have been somehow affiliated with the core development team, as either an employee or a guest. These numbers are likely related to the fact that the implementation language of Coccinelle, OCaml, is not widely used in the target developer community, and to the interdisciplinary nature of Coccinelle, which builds on programming-language concepts but targets the systems developer community. The small number of contributions by external developers may be a source of long term fragility. Nevertheless, the fact that several developers have joined the project in recent years and each made around 200 or more commits suggests that the code is accessible to developers who did not initiate the project.

Coccinelle is packaged with a number of Linux distributions, such as Ubuntu [62], Debian [15], Fedora [18], Gentoo [23], and Archlinux [1]. It is also available for FreeBSD [21] and NetBSD [40]. The full commit history is available at Github [8]. Although Coccinelle is developed using OCaml, there has been an effort to limit the amount of dependence on the traditional OCaml culture and infrastructure. Some needed OCaml libraries are bundled with the Coccinelle distribution, in case they are not available on the local machine. Once Coccinelle is installed, it is fully usable, via the C-like SmPL language and Python scripting, without knowing OCaml.

Although Coccinelle is mainly used on the Linux kernel, it is also used on other software projects. RIOT [49], qemu [47] and systemd [58] include semantic patches in their source code distributions. Patches mentioning Coccinelle are also found in the commit histories of systems software projects such as cpython (d1302c01544 and 228b12edcce) [13], wine (f6ced24999f etc.) [64], and even one in Firefox (ab4e3a0d4213) [19]. The latter used Coccinelle's rudimentary support for C++.

8 Related Work

Academic software development tools. Other academic software development tools that have had an impact on industry practice include CIL [39], LLVM [29], and Metal [17]. CIL provides basic parsing and visitor infrastructure for processing C code, and is used for rapid prototyping as well as being at the base of mature tools such as Frama-C [20]. LLVM is a compiler infrastructure that originally targeted providing good support for static, link-time, and run-time optimization, and has evolved into a common alternative to gcc, due to its customizability, speed and space efficiency, and permissive license [7]. Neither has specifically targeted the Linux kernel and its particular coding style. Indeed, LLVM still does not fully support Linux kernel code, despite a long refactoring effort [33]. Both tools have furthermore focused on building a user community rather than taking on the challenge of integrating into an existing one.

Metal is an automata-based tool for scanning large systems source code bases for faults such as use after free and inconsistent locking. It was never made publicly available. Instead, it was the foundation of the highly successful static analysis tool Coverity [2]. Coverity has been used on the Linux kernel more or less over the years, depending on the degree to which its results have been made freely available. Nevertheless, the freely available results address generic C issues, rather than Linux specific properties.

Development tool impact analysis. Koyuncu *et al.* [28] compare properties of Linux kernel patches that are entirely manually generated, manually generated in response to a tool report, and tool generated according to a manually written transformation rule. The patches in the third category are primarily generated by Coccinelle. They find that manually generated patches are accepted more quickly than tool-supported patches, but that the acceptance rate of the latter is increasing. In contrast, we study what kinds of Linux kernel developers use Coccinelle, for what purpose, and what features of Coccinelle have led to its acceptance.

Other tools used on the Linux kernel. Checkpatch is a regular-expression based style checker, whose use is required by the Linux kernel patch submission checklist [32]. It does not have a global view of the code, so it cannot detect inconsistencies that involve multiple code fragments, such as a variable declaration and its use.

Sparse [4] was an effort by Linus Torvalds to develop an open source static checker for the Linux kernel, in response to Metal. Sparse processes developer-provided annotations, enabling it to, *e.g.*, detect endianness issues. Smatch [55] grew out of sparse as a more flexible bug finding tool. Like Coccinelle, Smatch is scriptable, but rules are expressed at the abstract-syntax tree level rather than at the source code level. Thus, the user needs to know about internal representations. Smatch also does only bug finding, not transformation. On the other hand, Smatch tracks variable values, while Coccinelle reasons only in terms of code structure. Thus, smatch can find bugs such as off-by-one errors that are difficult to find using Coccinelle. Thousands of commits in the Linux kernel are derived from the use of smatch, but the creation of new rules is mostly limited to the tool author.

Another academic effort on improving Linux kernel code is the Linux Driver Verification project [27]. It centers around developing infrastructure and rule sets making it possible to apply verification tools such as CPAchecker and BLAST to the Linux kernel. A few hundred commits in the Linux kernel are based on its results. The Undertaker project [6, 59], in contrast to the other tools, finds bug in the use of configuration variables.

9 Lessons Learned

In this paper, we have reviewed the evolution of the program transformation tool Coccinelle and its impact on the Linux kernel. The experience of Coccinelle can help guide other projects that want to have an impact on an open source systems developer community.

First, visibility is necessary. The Coccinelle developers taught by example, by using Coccinelle to make a sustained contribution to the Linux kernel. At the same time, they organized workshops on the use of Coccinelle and presented Coccinelle in a variety of developer conferences, both focusing on the user-visible aspects of Coccinelle, to make the tool accessible to developers.

Second, the tool must be easy to install and freely available. Coccinelle is implemented in OCaml, but targets C developers. There has been a concerted effort to minimize reliance on OCaml infrastructure. The cost is a complex build system, but it reduces the chance that users will immediately abandon Coccinelle because it is difficult to install. Likewise, Coccinelle is freely available (GPLv2), with no registration requirement.

Third, the tool must be easy to use and robust, with support to quickly address problems encountered by users. While many research prototypes are only robust enough to complete an evaluation for a paper submission, users will try it on all kinds of code, and use it in unanticipated ways. A strength of Coccinelle is its lax C parser, motivated by the need to parse code without reliance on header files. This has the side effect of allowing it to adapt to C variants used by different projects. On the other hand, many users have mentioned that the documentation, consisting mainly of a BNF, some examples and some tutorial presentations, is hard to understand. Nevertheless, Coccinelle has an active mailing list [9] on which user problems are quickly addressed. Fixes are made available quickly via Github [8].

Finally, in a research setting, there is a constant temptation to make a tool do more, until the resulting complexity causes the tool to collapse under its own weight. While new features have been added to Coccinelle, the tool has remained within the scope of pattern matching-based transformation of C code. This focus has allowed it to grow and achieve practical success in this area.

Albis: High-Performance File Format for Big Data Systems

Animesh Trivedi, Patrick Stuedi, Jonas Pfefferle, Adrian Schuepbach, and Bernard Metzler
IBM Research, Zurich

Abstract

Over the last decade, a variety of external file formats such as Parquet, ORC, Arrow, etc., have been developed to store large volumes of relational data in the cloud. As high-performance networking and storage devices are used pervasively to process this data in frameworks like Spark and Hadoop, we observe that none of the popular file formats are capable of delivering data access rates close to the hardware. Our analysis suggests that multiple antiquated notions about the nature of I/O in a distributed setting, and the preference for the "storage efficiency" over performance is the key reason for this gap.

In this paper we present Albis, a high-performance file format for storing relational data on modern hardware. Albis is built upon two key principles: (i) reduce the CPU cost by keeping the data/metadata storage format simple; (ii) use a binary API for an efficient object management to avoid unnecessary object materialization. In our evaluation, we demonstrate that in micro-benchmarks Albis delivers $1.9 - 21.4\times$ faster bandwidths than other formats. At the workload-level, Albis in Spark/SQL reduces the runtimes of TPC-DS queries up to a margin of $3\times$.

1 Introduction

Relational data management and analysis is one of the most popular data processing paradigms. Over the last decade, many distributed relational data *processing* systems (RDPS) have been proposed [15, 53, 29, 38, 35, 24]. These systems routinely process vast quantities of (semi-)structured relational data to generate valuable insights [33]. As the volume and velocity of the data increase, these systems are under constant pressure to deliver ever higher performance. One key factor that determines the performance is the data access rate. However, unlike the classic relational database management systems (RDBMS) which are jointly designed for optimal data storage and processing, modern cloud-based RDPS systems typically do not manage their storage. They leverage a variety of external file formats to store and access data. Figure 1 shows a typical RDPS stack in the cloud. This modularity enables RDPS systems to access data from a variety of sources in a diverse set of deployments. Examples of these formats are Parquet [10], ORC [9], Avro [6], Arrow [5], etc. These formats are now even supported by the RDBMS solutions which add Hadoop support [49, 41, 31]. Inevitably, the performance of a file format plays an important role.

Figure 1: Relational data processing stack in the cloud.

Historically, file formats have put the top priority as the "storage efficiency", and aim to reduce the amount of I/O as much as possible because I/O operations are considered slow. However, with the recent performance advancements in storage and network devices, the fundamental notion of *"a fast CPU and slow I/O devices"* is now antiquated [44, 40, 54]. Consequently, many assumptions about the nature of storage in a distributed setting are in need of revision (see Table 1). Yet, file formats continue to build upon these antiquated assumptions without a systematic consideration for the performance. As a result, only a fraction of raw hardware performance is reflected in the performance of a file format.

In this paper, we re-visit the basic question of storage and file formats for modern, cloud-scale relational data processing systems. We first start by quantifying the impact of modern networking and storage hardware

Assumption	Implications	Still valid in a modern setup?
1. I/O operations are orders of magnitude slower than the CPU	Use compression and encoding to reduce the amount of I/O required	No, with high-performance devices, the CPU is the new performance bottleneck [54, 20]
2. Random, small I/O accesses are slow	Use large block sizes to make large sequential scans [30, 29]	No, modern NVMe devices have high-performance for random, small accesses
3. Avoid remote data access	Preserve locality by packing data in discrete storage blocks [25]	No, fast I/O devices with network protocols (e.g., NVMeF) make remote storage as fast as local [26, 34]
4. Metadata lookups are slow	Decrease the number of files and blocks needed to store data [30]	No, high-performance distributed storage systems can do millions of lookups per second [50]
5. The final row representation is not known	Provide object/data-oriented API for row and column data types	No, the final row/column representation is often known (e.g., Spark `UnsafeRow`) and a binary API can be used

Table 1: Assumptions (1–2 are local, and 3–5 are distributed) and their implications on storing relational data.

on the performance of file formats. Our experiments lead to three key findings. First, no popular file format we test can deliver data access bandwidths close to what is possible on modern hardware. On our 100 Gbps setup, the best performer delivers about ⅓rd of the bandwidth of the networked storage. Secondly, the CPU is the new bottleneck in the data access pipeline. Even in the presence of high-performance I/O hardware, file format developers continue to trade the CPU performance for "efficient" I/O patterns. Although this decision made sense for disks and 1 Gbps networks, today, this leads to the CPU being kept busy with (de)compressing, en/decoding, copying data, managing objects, etc., while trying to keep up with incoming data rates. Lastly, at the distributed systems level, strict adherence to locality, preference for large sequential scans, penchant to decrease the number of files/blocks, and poor object management in a managed run-time result in a complex implementation with a very high CPU cost and a poor "COST" score [37].

Based upon these findings, in this paper, we propose Albis, a simple, high-performance file format for RDPS systems. Albis is developed upon two key principles: (i) reduce the CPU cost by keeping the data/metadata storage format simple; (ii) use a binary API for an efficient object management to avoid unnecessary object materialization. These principles then also simplify the data/file management in a distributed environment where Albis stores schema, metadata, and data in separate files for an easy evolution, and does not enforce a store like HDFS to use local blocks. In essence, Albis's top priority is to deliver performance of the storage and network hardware without too much intrusion from the software layer. Our specific contributions in this paper are:

- Quantification of the performance of popular file formats on modern hardware. To the best of our knowledge, this is the first systematic performance evaluation of file formats on 100 Gbps network and NVMe devices. Often, such evaluations are muddied in the description of the accompanying relational processing system, which makes it hard to understand where the performance bottlenecks in the system are.
- Revision of the long held CPU-I/O performance assumptions in a distributed setting. Based upon these revisions, we propose Albis, a high-performance file format for relational data storage systems.
- Evaluation of Albis on modern hardware where we demonstrate that it can deliver performance within 15% (85.5 Gbps) of the hardware. Beyond microbenchmarks, we also integrate Albis in Spark/SQL and demonstrate its effectiveness with TPC-DS workload acceleration where queries observe gains up to 3×.

2 File Formats in the Age of Fast I/O

The choice of a file format dictates how multi-dimensional relational tables are stored in flat, one-dimensional files. The initial influential work of column-oriented databases have demonstrated the effectivness of column storage for disks [51, 12]. This has led to the development of a series of columnar file formats. The most prominent of them are Apache Parquet [10], Optimized Row Columnar (ORC) [9], and Arrow [5]. All of these columnar formats differ in their column/storage encoding, storage efficiency, and granularity of indexing. Apart from providing a row-at-a-time API, all of these formats also have a high-performance vector API for column data. In this paper, we use the vector API for evaluation. In contrast to column-storage, we also consider two popular row-oriented formats. JSON [11] is a simple data representation that encodes schema and data together. JSON is widely supported due to its simplicity. The other format is Avro [6] that decouples schema and data presentation where both can evolve independently.

2.1 The Mismatch Assumptions

In this section, we re-visit the basic assumptions made about the nature of I/O and what impact they have on the

	1 GbE	100 GbE	Disk	NVMe
Bandwidth	117 MB/s	12.5 GB/s	140 MB/s	3.1 GB/s
`cycles/unit`	38,400	360	10,957	495

Table 2: Bandwidths and `cycles/unit` margins for networking and storage devices. A unit for network is a 1,500 bytes packet, whereas for storage it is a 512 bytes sector. `Cycles/unit` roughly denote the number of free CPU cycles for every data unit for a 3 GHz core. As a reference, a DRAM-access would be around 100 cycles.

file format design in the presence of modern hardware. This discussion is summarized in Table 1.

1. I/O operations are orders of magnitude slower than the CPU: During the last decade, we have witnessed the rise of high-performance storage and networking devices like 40 and 100 Gbps Ethernet, and NVMe storage. Once the staple of high-performance computing clusters, these devices and associated APIs can now be found in commodity cloud offerings from multiple vendors [3, 2, 1]. At the same time, the CPU performance improvements have stalled due to various thermal and manufacturing limits. Hence, the CPU's margin for processing incoming bytes has shrunk considerably [45, 21, 16, 54]. In Table 2 we summarize the bandwidths for state-of-the-art I/O devices from a decade ago and now. We also show the `cycles/unit` metric as an estimate of the CPU budget for every incoming unit of data. For the network, the unit is a 1,500 bytes packet, and for storage it is a 512 bytes sector. For a 3 GHz core (ignoring the micro-architectural artifacts), the number of cycles per second is around 3×10^9. The table shows that in comparison to a decade ago, CPU cycle margins have shrunk by two orders of magnitude.

2. Random, small I/O accesses are slow: Disk seeks are slow and take $\sim$10s of milliseconds, a cost that cannot be amortized easily for small accesses. Hence, disk-based file formats advocate using large I/O segments, typically a multiple of the underlying storage block, e.g., 128 or 256 MB [30]. However, NVMe devices can deliver high bandwidth for random, small I/O patterns. In our investigation (discussed in the next section), we find that the continuing use of large I/O buffers is detrimental to the cache behavior and performance. For example, on a 16 core machine with a 128 MB buffer for each task, the memory footprint of a workload would be 2 GB, a much larger quantity than the modern cache sizes.

3. Avoid remote data access: Modern NVMe devices can do 2-3 GB/s reads and 1-2 GB/s writes. At the same time, the availability of high-performance networks (40 and 100 Gbps) and efficient network protocols like NMVe-over-Fabrics, means that the performance gap between a local flash and remote flash is negligible [26, 34]. Hence, various proposed modifications to block placement strategies in Hadoop [25], and design decisions to pack schema, data, and metadata in the same block to avoid remote storage, can be relaxed.

4. Metadata lookups are slow: In any distributed storage, the number of metadata lookups is directly proportional to the number of blocks in a file. A lookup is an RPC that took 100-1,000 μs over 1 Gbps networks. This high cost has led to the decision to reduce the number of files (or blocks) by using complex block management strategies, type-specific encoding, packing data and schema in packed blocks, which in essence trades CPU for the I/O. However, modern storage solutions like Apache Crail [8] and RAMCloud [42] can do millions of metadata lookups/sec [50].

5. The final data representation is not known: File formats often assume that the final data representation in an RDPS engine is not known, and hence, a format must materialize the raw objects when reading and writing data. This decision leads to unnecessary serialization and object allocation, which hampers the performance in a managed run-time environment like Java.

2.2 Putting it Together: Performance

In this section, we quantify the cumulative effect of the aforementioned assumptions on the read performance of file formats on modern hardware. For this experiment, we read and materialize values from the `store_sales` table (the largest table) from the TPC-DS (scale=100) dataset. The table contains 23 columns, which consist of 10 integers, 1 long, and 12 decimal values. The input table is stored in the HDFS file system (`v2.7`) in Parquet (`v1.8`), ORC (`v1.4`), Arrow (`v0.8`), Avro (`v1.7`), and JSON formats. The goal of the experiment is to measure how fast we can materialize the values from a remote storage. The experiment is run between 2 machines (with dual Xeon E5-2690, 16 cores) connected via a 100 Gbps network. One machine is used to run the HDFS namenode and a datanode. This machine also contains 4 enterprise-grade NVMe cards, with a cumulative bandwidth of 12.4 GB/sec. The other machine runs the benchmarking code[1] on all 16 cores in parallel.

Figure 2 shows our findings. Here, the y-axis shows the effective *goodput* calculated by dividing the total incoming data size by the runtime. Notice that the incoming *data size* is different from the *file size*, which depends upon the file format used. We cannot use the file size for the bandwidth calculation because formats such as JSON use text encoding with interleaved schemas, thus making their file sizes up to 10× larger than the actual data size. In order to measure the actual data content, we count how

[1] The benchmarking code is open-sourced at `https://github.com/animeshtrivedi/fileformat-benchmarks`.

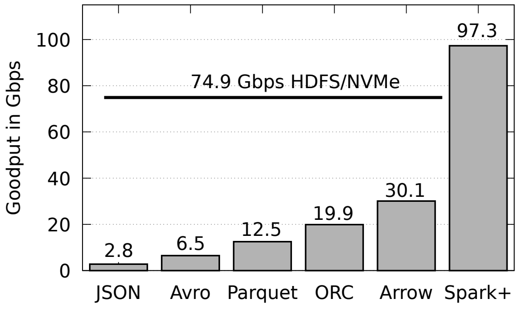

Figure 2: Reading bandwidths for various file formats.

		512M	256M	128M	64M	32M
Goodput (in Gbps)	Parq.	7.3	9.5	12.5	12.8	12.1
	ORC	13.6	17.5	19.9	20.2	20.1
Instructions/ row	Parq.	6.6K	6.7K	6.6K	6.6K	6.6K
	ORC	5.0K	4.9K	4.9K	4.8K	4.8K
Cache misses/ row	Parq.	11.0	10.6	9.2	7.1	6.5
	ORC	7.8	5.5	4.6	4.4	4.1

Table 3: Goodputs, instructions/row, and cache misses/row for Parquet (Parq.) and ORC with varying block sizes on a 16-core Xeon machine.

many integers, longs, and doubles the table contains, excluding the null values. We use this as the reference data point for the goodput measurements. We also show the data ingestion bandwidth of Spark/SQL [15] (as `spark+`) when the data is generated on the fly. The solid line represents the HDFS read bandwidth (74.9 Gbps) from the remote NVMe devices[2].

There are three key results from our experiment. First, as shown in Figure 2, none of the file formats that we test delivers bandwidth close to the storage performance. There is almost an order of magnitude performance gap between the HDFS (74.9 Gbps) and JSON (2.8 Gbps) and Avro (6.5 Gbps) performances. Columnar formats with their optimized vector API perform better. The best performer is Arrow, which delivers 40.2% of the HDFS bandwidth. Interestingly, Arrow is not for disks, but for in-memory columnar data presentation. Its performance only supports our case that with modern storage and networking hardware, file formats need to take a more "In-Memory"-ish approach to storage. In the same figure, we also show that in isolation from the storage/file formats, Spark/SQL can materialize `store_sales` rows from raw integers, longs, and doubles at the rate of 97.3 Gbps. Hence, we conclude that file formats are a major performance bottleneck for accessing data at high rates.

Secondly, the performance of these file formats are CPU limited, an observation also made by others [20]. When reading the data, all 16 cores are 100% occupied executing the thick software stack that consists of kernel code, HDFS-client code, data copies, encoding, (de)serialization, and object management routines. In Table 3 we present further breakdown of the performance (1^{st} row) with required instructions per row (2^{nd} row) and cache misses per row (3^{rd} row) for Parquet and ORC file formats when varying their block sizes. As shown, the use of large blocks (256 MB and 512 MB) always leads to poor performance. The key reason for the performance loss is the increased number of cache misses that leads to stalled CPU cycles. As we decrease the block size from 512 to 32 MB, the performance increases up to 128 MB, though the number of cache misses continues to decrease. At smaller block sizes (128 – 32 MB), the performance does not further improve because it is bottlenecked by the large number of instructions/row (remains almost constant as shown in the 2^{nd} row) that a CPU needs to execute. In further experiments, we use a 128 MB block size as recommended in the literature.

Thirdly, these inefficiencies are scattered throughout the software stack of file formats, and require a fresh and holistic approach in order to be fixed.

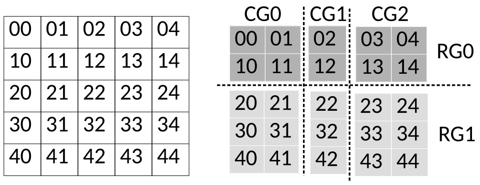
Summary: We have demonstrated that despite orders of magnitude performance improvements in networked-storage performance, modern file formats fail to deliver this performance to data processing systems. The key reason for this inefficiency is the belief in the legacy assumptions where CPU cycles are still traded off for I/O performance, which is not necessary anymore. Having shown the motivation for our choices, in the next section we present Albis, a high-performance file format.

3 Design of Albis File Format

Albis is a file format to store and process relational tabular data for read-heavy analytic workloads in a distributed setting. It supports all the primitive fixed (`int, timestamp, decimal, double`, etc.) and variable (`varchar` or `byte[]`) data types with simple and nested schemas. A nested schema is flattened over the column names and data is stored in the schema leaves. Albis's design is based upon the following choices:

- **No compression or encoding:** Albis decreases the CPU pressure by storing data in simple binary blobs without any encoding or compression. This decision trades storage space for better performance.
- **Remove unnecessary object materialization by providing a binary API:** The data remains in the binary format unless explicitly called for materialization. A

[2] Even though this is not 100 Gbps, it is the same bandwidth that HDFS can serve locally from NVMe devices. Hence, the assumption about the equality of local and remote performance holds.



/table1/schema
/table1/rg0/cg0/{data,mdata}.ab → [00,01]:[10,11]
/table1/rg0/cg1/{data,mdata}.ab → [02]:[12]
/table1/rg0/cg2/{data,mdata}.ab → [03,04]:[13,14]
/table1/rg1/cg0/{data,mdata}.ab → [20,21]:[30,31]:[40,41]
/table1/rg1/cg1/{data,mdata}.ab → [22]:[32]:[42]
/table1/rg1/cg2/{data,mdata}.ab → [23,24]:[33,34]:[43,44]

Figure 3: Table partitioning logic of Albis and corresponding file and directory layout on the file system.

reader can access the binary data blob for data transformation from Albis to another format (such as Spark's `UnsafeRow` representation) without materializing the data. This design choice helps to reduce the number of objects. A binary API is possible because the row data is not group compressed or encoded which requires the complete group to be decoded to materialize values.

- **Keep the metadata/data management simple:** Albis stores schema, data, and metadata in separate files with certain conventions on file and directory names. This setup helps to avoid complex inter-weaving of data, schema, and metadata found in other file formats. Due to the simple data/metadata management logic, Albis's I/O path is light-weight and fast.

In order to distribute storage and processing, Albis partitions a table horizontally and vertically as shown in Figure 3. The vertical partitioning (configurable) splits columns into *column-groups (CGs)*. At the one extreme, if each column is stored in a separate column group, Albis mimics a column store. On the other hand, if all columns are stored together in a single column group, it resembles a row store. In essence, the format is inspired by the DSM [23] model without mirroring columns in column groups. Horizontal partitioning is the same as sharding the table along the rows and storing them into multiple *row-groups (RGs)*. A typical row group is configurable either based on the number of rows or the size (typically a few GBs). The number and ordering of the row and column groups are inferred from their names as shown in Figure 3. Albis does not maintain any explicit indexes. Row data in various column groups are matched together implicitly by their position in the data file. The data, metadata, and file management and naming convention of Albis is similar to BigTable [22]. In the following sections, we discuss the storage format, read/write paths, support for data/schema evolution, and concerns with distributed data processing systems in detail. Table 4 shows the abridged Albis API.

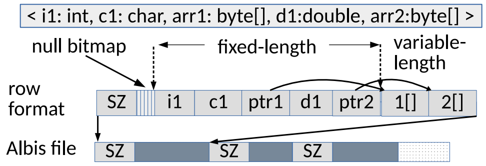


Figure 4: Albis row storage format.

3.1 Row Storage Format

After splitting the table along multiple CGs, each CG can be thought of as a table with its own schema and data. Row data from a column group is stored continuously, one after another, in a file. The Albis row format consists of four sections: a size counter, a null bitmap, a fixed-length and a variable-length section as shown in Figure 4. For a given schema, the number of fields determines the bitmap size in bytes. For example, a 23 columns schema (like TPC-DS `store_sales`) takes 3 bytes for the null bitmap. The fixed-length area is where data for fixed-length columns are stored in situ. A variable-length column data is stored in the variable-length area, and its offset and size is encoded as an 8-byte long and stored in the fixed area. With this setting, for a given schema, Albis calculates the fixed-length section size (that stays fixed, hence the name) by summing up the size of the fixed-type fields and 8×number of variable fields. For example, a schema of `<int, char, byte[], double, byte[]>` (as shown in the figure) takes one byte for bitmap, and 29 (= 4 + 1 + 8 + 8 + 8) bytes for the fixed segment. The row encoding is then prefixed by the total size of the row, including its variable segment. For a fixed-length schema (contains only fixed-length fields), Albis optimizes the row format by eschewing the size prefix as all rows are of the fixed, same size.

3.2 Writing Row Data

A writer application defines a schema and the column grouping configuration by allocating `AlbisSchema` and `AlbisColumn` objects. In the default case, all columns are stored together in a row-major format. The writer application then allocates an `AlbisWriter` object from the schema object. The writer object is responsible for buffering and formatting row data according to the storage format as described previously. Internally, the writer object manages parallel write streams to multiple CG locations, while counting the size. Once a RG size is reached, the current writers are closed, and a new set of writers in a new RG directory are allocated. Data is written and read in the multiple of *segments*. A segment is a unit of I/O buffering and metadata generation (default: 1 MB). The segment metadata includes the minimum and maximum values (if applicable), distribution

Class	Functions	Action

AlbisFileFormat	reGroup(Schema, Path, Schema, Path)
	reBalance(Path)
		re-groups the schema in the given path location
		re-balances the data in the given path location

AlbisColumn	make(String, Type, ...)	makes a column with a name and type
AlbisColGroup	make(AlbisColumn[])	makes a column group from a given list of columns

AlbisSchema	getReader(Path, Filter[], AlbisColumn[])
	getWriter(Path)
	makeSchema(ColumnGroup[])
		gets a reader for a given location, projection, and filter
		gets a writer to a given location
		builds a schema with a given list of CGs

AlbisWriter	setValue(Int, Value)
	nextRow()
		sets a value (can be null) for a given column index
		marks the current row done, and moves the pointer

AlbisReader	hasMore() and next()
	getValue(Int)
	getBinaryRow()
		implements the Scala Iterator abstraction for rows
		gets the value (can be null) for a given column index
		returns a byte[] with the encoded row

Table 4: Abridged Albis API. Apart from row-by-row, Albis also supports a vector reading interface.

of data (e.g., sorted or not), number of rows, padding information, and offset in the data file, etc. The segment metadata is used for implementing filters.

3.3 Reading Row Data

A reader application first reads the schema from the top-level directory and scans the directory paths to identify row and column groups. The reader then allocates an AlbisReader object from the schema, which internally reads in parallel from all column groups to construct the complete row data. AlbisReader implements the Iterator abstraction where the reader application can check if there are more rows in the reader and extract values. The reader object reads and processes a segment's worth of data from all column groups in parallel, and keeps the row index between them in sync. An AlbisReader object also supports a binary API where row-encoded data can be returned as a byte[] to the application.

Projection: AlbisReader takes a list of AlbisColumns that defines a projection. Internally, projection is implemented simply as re-ordering of the column indexes where certain column indexes are skipped. Naturally, the performance of the projection depends upon the column grouping. In the row-major configuration, Albis cannot avoid reading unwanted data. However, if the projected columns are grouped together, Albis only reads data files from the selected column group, thus skipping unwanted data. As we will show in Section 4.1, the implementation of projection is highly competitive with other formats.

Filtering: Albis implements two levels of filtering. The first-level of filtering happens at the segment granularity. If a filter condition is not met by the metadata, the segment reading is skipped immediately. For example, if a segment metadata contains the max value of 100 for an integer column, and a filter asks for values greater than 500, the segment is skipped. However, if the condition is not specific enough, then the rows are checked one-by-one, and only valid rows satisfying all filter conditions are returned. Currently, Albis supports null checks and ordinal filters (less than, greater than, equal to) with combinations of logical (NOT, AND and OR) operators.

3.4 Data and Schema Evolution in Albis

As described so far, the name and location of a data file plays an important role to support data and schema evolution in Albis. We now describe this in detail:

Adding Rows: Adding another row is trivial. A writer adds another row group in the directory and writes its data out. Appending to an existing row group is also possible on append-only file systems like HadoopFS. However, while adding another row, the writer cannot alter the column grouping configuration.

Deleting Rows: Deleting rows in-place is not supported as the underlying file system (HDFS) is append-only.

Adding Columns: Adding new columns is one of the most frequent operations in analytic. Adding a column at the end of the schema involves creating a column group directory (with associated data and metadata files). The ordering of row data in the newly added column is matched with the existing data, and missing row entries are marked null. Using this strategy, more than one column (as a CG) can be added at a time as well. The old schema file is read, and written again (after deleting the old one) with the updated schema.

Deleting Columns: A column delete operation in Albis falls in one of the two categories. The column(s) to be deleted is (are) either (i) stored as a separate CG; or (ii) stored with other columns. In the first case, the deletion operation is simple. The CG directory is deleted, and the schema is updated as mentioned previously. In the latter case, there are two ways Albis deletes columns. A light-weight deletion operation "marks" the column as deleted and updates the schema. The column is only marked as deleted, but the column is not removed from the schema because the column data is still stored in the storage. In order to skip the marked column data, an `AlbisReader` needs to know the type(s) of the deleted column(s). In contrast, a heavy-weight delete operation emulates a read-modify-write cycle, where the CG is read, modified, and written out again.

Maintenance Operations: Apart from the aforementioned operations, Albis supports two maintenance operations: *re-grouping* and *re-balancing*. Re-grouping is for re-configuring the column grouping. For example, due to the evolution in the workload it might be necessary to split (or merge) a CG into multiple CGs for a faster filter or projection processing. Re-balancing refers to re-distributing the data between RGs. A RG is the unit of processing for Albis tables in a distributed setting. Adding and removing column and row data can lead to a situation where data between row-groups is not balanced. This data imbalance will lead to imbalanced compute jobs. The Re-balancing operation reads the current data and re-balances the data distribution in the row groups. While executing the re-balancing, it is possible to increase the number of row groups to increase the parallelism in the system. Re-grouping can be executed at the same time as well. These operations are slow and we expect them to be executed once-in-a-while. Even though column adding and deleting is one of the frequent operations, a complete re-balancing is only required if the added columns/rows contain highly uneven values.

3.5 Distributed Processing Concerns

How does an RDPS system process input Albis files? RDPS frameworks like Spark/SQL divide work among the workers using the size as a criteria. At a first glance, a segment seems to be a perfect fit for providing equal sized work items for workers. For a static table, segments *can* be used as the quantum of processing. However, as a new column is added, often as a result of distributed processing, it is critical in what order the rows in the new column are written because indexes are implicitly encoded with the data position in a file. For example, imagine a table with two segments in a single row-group. Now, another column is added to this table using two Spark/SQL workers, each processing one segment. As there are no ordering guarantees between tasks, and each task in the data-parallel paradigm gets its own file to write, it is possible that the first task gets the second segment, but the first new column file name. This mix-up destroys the row ordering when enumerating files based on their names. However, if the whole row-group is processed only by a single task, the newly added "single" column file is ensured to have the same ordering as the current row file (including all its segments). Thus, an Albis row-group is the unit of processing for a distributed RDPS system. A single task is responsible for processing, adding and deleting columns and rows within a single row group while maintaining the implicit ordering variant of the data. As previously discussed, if necessary, the data can be re-balanced to increase the number of row-groups, hence, parallelism in the system. The schema file updates are expected to take place on a centralized node like the Spark driver.

Which column grouping to use? The recommended column grouping setting depends upon the workload. Systems like H2O [14], etc., can change the storage format dynamically based upon the workload. We consider this work beyond the current scope. However, we expect that Albis can help in this process by providing meaningful insights about accesses and I/O patterns.

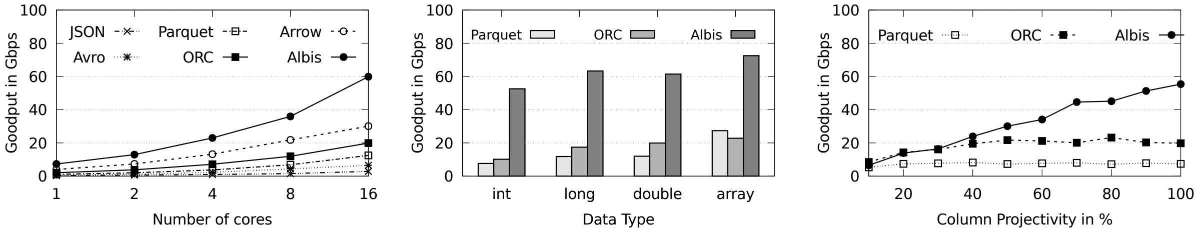
4 Evaluation

Albis is implemented in about 4k lines of Scala/Java code for Java 8. We evaluate the performance of Albis on a 4-node cluster each containing dual Xeon E5-2690 CPUs, 128GB of DDR3 DRAM, 4 enterprise-grade NVMe devices, connected via a 100 Gbps link, running Ubuntu 16.04. All numbers reported here are the average of 3 runs. We attempt to answer three fundamental questions:

- *First, does Albis deliver data access rates close to the modern networking and storage devices?* Using a set of micro-benchmarks over HDFS on 100 Gbps network and NVMe devices we demonstrate that Albis delivers read bandwidths up to 59.9 Gbps, showing a gain of $1.9 - 21.4\times$ over other file formats (Section 4.1). With Apache Crail (instead of HDFS), Albis delivers bandwidth of 85.5 Gbps from NVMe devices.
- *Secondly, does Albis accelerate the performance of data analytic workloads?* To demonstrate the effectiveness of Albis and its API, we have integrated it in Spark/SQL, and demonstrate an up to $3\times$ reduction in query runtimes. The overall TPC-DS runtime is also decreased by 25.4% (Section 4.2).
- *Lastly, what is the cost of design trade-offs of Albis, namely the cost of eschewing compression and increased look-up cost in a distributed system?* In our evaluation, Albis increases the storage cost by a margin of $1.3 - 2.7\times$ (based on the compression choice), but does not increase the load for extra block lookups. In exchange, it delivers performance improvements by a margin of $3.4 - 7.2\times$ (Section 4.3).

4.1 Micro-benchmarks

In this section, we evaluate the performance of Albis, through a series of micro-benchmarks. We focus on the



(a) (b) (c)

Figure 5: (a) Bandwidth vs. core scaling; (b) Effect of data type on performance; (c) Projectivity performance.

read because the write performance of all file formats are bottlenecked by the HDFS write bandwidth ($\sim$20 Gbps).

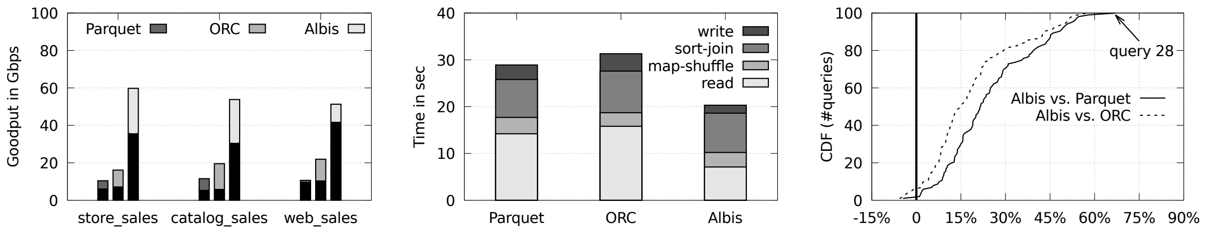
Read performance: We start by revisiting the key experiment from the beginning of the paper. Here, in Figure 5a we show the performance of Albis with respect to other file formats for reading the `store_sales` data. The x-axis shows the number of cores and the y-axis shows the data goodput performance. As shown, in comparison to other data formats, Albis delivers 1.9 (vs. Arrow) – 21.4× (vs. JSON) better read performance for reading the `store_sales` table. The performance gains of Albis can be traced down to its superior instruction utilization (due to its light-weight software stack), and cache profile. Table 5 shows the CPU profile of Albis against Parquet, ORC, and Arrow. As can be seen, Albis takes $1.2-4.1\times$ less instructions, and exhibits $1.5-3.0\times$ fewer cache misses per row. The peak data rate is at 59.9 Gbps, which is within 80% of the HDFS bandwidth. The gap between the HDFS performance and Albis is due to the parsing of schema and materialization of the data. For the sake of brevity, in the following sections we focus our effort on best performing formats, namely Parquet and ORC, for the performance evaluation. Arrow does not have native filter and projection capabilities.

Effect of schema and data types: We now focus our effort to quantify what effect a data type has on the read performance. We choose integers, longs, doubles, and arrays of byte types. For this benchmark, we store 10 billion items of each type. For the array, we randomly generate an array in the range of (1–1024) bytes. Figure 5b shows our results. The key result from this experiment is that Albis's performance is very close to the expected results. The expected result is calculated as what fraction of incoming data is TPC-DS data. As discussed in Section 3.1, each row contains an overhead of the bitmap. For a single column schema that we are testing, it takes 1 byte for the bitmap. Hence, for integers we expect $4/5^{th}$ of the HDFS read performance. In our experiments, the integer performance is 52.6 Gbps which is within 87.8% of the expected performance (59.9 Gbps). Other types also follow the same pattern. The double values are slower to materialize than longs. We are not sure about the cause of this behavior. The byte array schema delivers bandwidth very close to the HDFS read bandwidth as the bitmap overhead is amortized. With arrays, Albis delivers 72.5 Gbps bandwidth. We have only shown the performance of primitive types as higher-level types such as `timestamps, decimal`, or `date` are often encoded into the lower-level primitive types, and their materialization is highly implementation-dependent.

	Parquet	ORC	Arrow	Albis
Instructions/row	6.6K	4.9K	1.9K	1.6K
Cache-misses/row	9.2	4.6	5.1	3.0
Nanosecs/row	105.3	63.9	31.2	20.8

Table 5: Micro-architectual analysis for Parquet, ORC, Arrow, and Albis on a 16-core Xeon machine.

Projection performance: A columnar-format is a natural fit when performing a projection operation. A similar operation in a row-oriented format requires a level of redirection to materialize the values while leaving the unwanted data behind. However, a distinction must be made between a true column-oriented and PAX-alike format (e.g., Parquet). The PAX-encoding does not change the I/O pattern and amount of data read from a file system. It only helps to reduce the amount of work required (i.e., mini-joins) to materialize the projected columns. Albis's efficiency in projection depends upon the column grouping configuration. With a single column group, Albis is essentially a row store. Hence, the complete row data is read in, but only desired columns are materialized. To evaluate the projection performance, we generated a dataset with 100 integer columns and 100 million rows (total size: 40 GB). This dataset is then read in with a variable projectivity, choosing k out of 100 columns for k% projectivity. Figure 5c shows the projectivity (x-axis) and the goodput (y-axis). As shown, Albis (as a row store) always outperforms Parquet and ORC after 30% projectivity. It is only slower than ORC for 10% and 20% projectivity by a margin of 23.5% and 2.7%, respectively. We exercise caution with results as the superiority of row versus column format is a contentious topic, and gains of one over the other come from a variety of



(a)

(b)

(c)

Figure 6: Albis performance results: (a) read bandwidths (with Spark iterator in dark) of file formats for TPC-DS tables; (b) performance of the EquiJoin on two 32GB data sets; (c) CDF for performance gains for TPC-DS queries.

features that go beyond just micro-benchmarks [12].

Selectivity performance: In a real-world workload, RDPS systems often have predicates on column values. As all file formats maintain metadata about columns, they help the RDPS systems to pre-filter the input rows. However, it must be noted that often, filters are "*hints*" to file formats. A format is not expected strictly to return rows that satisfy the filters. Parquet, ORC, and Albis all maintain segment-level metadata that can be used to completely eliminate reading the segment. The performance saving depends upon the segment size. ORC also maintains metadata per 10k rows that allows it to do another level of filtering. In contrast, Albis supports strict filtering of values and hence, it avoids pushing unwanted rows into the processing pipeline. We evaluate selectivity performance on the same 100 integer column table used in the projection. The first column of the table contains integers between 0 and 100. We execute a simple SQL query "*select(*) from table where col0 <= k*", where k varies from 1 to 100, to select k% of input rows. Our results demonstrate similar gains (not shown) as the projection performance. Albis outperforms Parquet and ORC by a margin of $1.6-2.4\times$.

4.2 Workload-level Performance

For workload-level experiments, we have integrated Albis support into Spark/SQL [15] (v2.2) and evaluate its performance for an EquiJoin and the full TPC-DS query set. Naturally, input and output is only one aspect of a workload, and gains solely from a fast format are bounded by the CPU-I/O balance of the workload.

Spark/SQL data ingestion overheads: Integration into Spark/SQL entails converting incoming row data into Spark-specific format (the Iterator[InternalRow] abstraction). We start by quantifying what fraction of performance is lost due to framework-related overheads [54], which, of course, varies with the choice of the SQL framework. In Figure 6a, we show the read bandwidths for the three biggest tables in the TPC-DS dataset for ORC, Parquet, and Albis[3]. In each bar, we also show a dark bar that represents the performance observed at the Spark/SQL level. In general, from one third up to half of the performance can be lost due to framework-related overheads. The table web_sales performs the best with 89.2% of Parquet bandwidth delivered. However, it can be observed the other way around as well because the Parquet bandwidth is so low, hence, further overheads from the framework do not deteriorate it further.

Effect of the Binary API: While measuring the Spark ingestion rate, we also measure the number of live objects that the Java heap manages per second while running the experiment. For Albis we use two modes to materialize Spark's UnsafeRow either using the binary API or not. In our evaluation we find (not shown) that even without using the binary API, Albis (260.4K objs/sec) is better than Parquet (490.5K objs/sec) and ORC (266.4K objs/sec). The use of binary API futher improves Albis's performance by 4.3% to 249.2K objs/sec.

EquiJoin performance: Our first SQL benchmark is an EquiJoin operation, which is implemented as a Sort-Merge join in Spark/SQL. For this experiment, we generate two tables with a <int,byte[]> schema and 32 million rows each. The array size varies between 1 and 2kB. The total data set is around 64GB in two tables. The join operation joins on the int column, and then generates the checksum column for merged byte[] columns, which is written out. Figure 6b shows our results. The figure shows the runtime splits (y-axis) for the 4 stages of the join operation (reading in, mapping to partitions, sorting and joining partitions, and then the final write out) for Parquet, ORC, and Albis. As shown, Albis helps to reduce the read (7.1 sec for Albis) and write (1.7 sec for Albis) stages by more than $2\times$. Naturally, a file format does not improve the performance of the map and join stages, which remain constant for all three file formats. Overall, Albis improves the query run-time by 35.1% and 29.8% over ORC and Parquet, respectively.

TPC-DS performance: Lastly, we run the TPC-DS query set on the three file formats with the scaling factor

[3] Spark/SQL does not support the Arrow format yet (v2.2).

	None	Snappy	Gzip	zlib
Parquet	58.6 GB 12.5 Gbps	44.3 GB 9.4 Gbps	33.8 GB 8.3 Gbps	N/A -
ORC	72.0 GB 19.1 Gbps	47.6 GB 17.8 Gbps	N/A -	36.8 GB 13.0 Gbps
Albis	94.5 GB 59.9 Gbps	N/A -	N/A -	N/A -

Table 6: TPC-DS dataset sizes and performance.

of 100. We choose the factor 100 as it is the largest factor that we can run while keeping the shuffle data in the memory to avoid Spark's shuffle-related overheads. Figure 6c shows our results. On the y-axis, the figure shows the fraction of queries as CDF and on the x-axis it shows percentage performance gains for Albis in comparison to Parquet and ORC formats. There are two main observations here. First, for more than half of the queries, the performance gains are less than 13.8% (ORC) and 21.3% (Parquet). For 6 queries on ORC (only 1 on Parquet), the gains are even negative, however, the loss is small (-5.6%). Second, the last six queries on both file formats see more than a 50% improvement in run-times. The run-time of the query 28, which is the query with most gains, is improved by a margin of 2.3× and 3.0× for ORC and Parquet, respectively. Gains are not uniformly distributed among all queries because they depend upon what fraction of the query time is I/O bounded and what is CPU bounded (including framework related overheads). The run-times of the full TPC-DS suit with all queries is $1,850.1$ sec (Parquet), $1,723.4$ sec (ORC) and $1,379.2$ sec (Albis), representing a gain of 25.4% (over Parquet) and 19.9% (over ORC).

4.3 Efficiency of Albis

The cost of compression: With its sole focus on performance, Albis does not use any compression or encoding to reduce the data set size. This design choice means that Albis file sizes are larger than other file formats. In Table 6, we show the TPC-DS dataset (scale=100) sizes with compression options available on Parquet and ORC. As calculated from the table, due to highly efficient type-specific encoding (e.g. RLE for integers), even uncompressed Parquet and ORC datasets are $23.8 - 37.9\%$ smaller than Albis's. With compression, the gap widens to 64.2%. With the current market prices, the increased space costs 0.5$/GB on NVMe devices. However, the compressed dataset sizes also lead to significant performance loss when reading the dataset (also shown in the table). As we have shown in Section 2, the reading benchmarks are CPU bounded even without compression. Hence, adding additional routines to decompress incoming data only steals cycles from an already saturated CPU. In comparison to compressed bandwidths, Albis delivers $3.4 - 7.2\times$ higher bandwidths. One potential avenue to recover the lost storage efficiency is to leverage advanced hardware-accelerated features like deduplication and block compression further down the storage stack. However, we have not explored this avenue in detail yet.

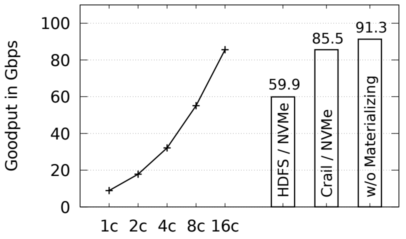


Figure 7: Albis performance on Crail with NVMeF.

Load on the distributed system: One concern with the increased number of files and the storage capacity of data sets is that they increase RPC pressure on the namenode. The number of RPCs to the namenode depends upon the number of files and blocks within a file. With an HDFS block size of 128 MB, the most efficient dataset from TPC-DS takes 271 blocks (33.8 GB with Parquet and gzip). In comparison, Albis's dataset takes 756 blocks. The lookup cost increase for hundreds of blocks is marginal for HDFS. Nonetheless, we are aware of the fact that these factors will change with the scale.

Delivering 100 Gbps bandwidth: For our final experiment, we try to answer the question what it would take to deliver 100 Gbps bandwidth for Albis. Certainly, the first bottleneck is to improve the base storage layer performance. The second factor is to improve the data density. For example, the `store_sales` table on Albis has the data density of 93.9% (out of 100 bytes read from the file system). On top of this, the effective bandwidth on 100 Gbps link is 98.8 Gbps, that gives us the upper bounds for the performance at 92.8 Gbps that we hope to achieve with the Albis `store_sales` table on a 100 Gbps link. To test the peak performance, we port Albis to Apache Crail with its NVMeF tier [8, 52]. Crail is an Apache project that integrates high-performance network (RDMA, DPDK) and storage (NVMeF, SPDK) stacks in the Apache data processing ecosystem. The peak bandwidth of Crail from NVMe devices is 97.8 Gbps [46]. Figure 7 shows our results. In the left half of the figure it shows the scaling performance of Albis on Crail from 1 core performance (8.9 Gbps) to 16 cores (85.5 Gbps). In comparison, the right half of the figure shows the performance of HDFS/NVMe at 59.9 Gbps and Crail/NVMe at 85.5 Gbps. The last bar shows the performance of Albis if the benchmark does not materialize Java object values. In this configuration, Albis on

Crail delivers 91.3 Gbps, which is within 98.4% of the peak expected performance of 92.7 Gbps.

5 Related Work

Storage Formats in Databases: N-ary Storage Model (NSM) stores data records contiguously in a disk page, and uses a record offset table at the end of the page [47]. Decomposition Storage Model (DSM) [23] proposes to split an n-column relation into n sub-relations that can be stored independently on a disk. NSM is considered good for transactions, whereas, DSM is considered suitable for selection and projection-heavy analytical workloads. A series of papers have discussed the effect of NSM and DSM formats on the CPU efficiency and query execution [27, 55, 12]. Naturally, there is no one size that fits all. Ailamaki et al. [13] propose the Partition Attributes Across (PAX) format that combines the benefits of these two for a superior cache performance. The Fractured Mirrors design proposes maintaining both NSM and DSM formats on different copies of data [48]. Jindal et al. propose the Trojan data layout that does workload-driven optimizations for data layouts within replicas [32]. The seminal work from Abadi et al. demonstrates that a column-storage must be augmented by a right query processing strategy with late materialization, batch processing, etc., for performance gains [12]. Various state of the art database systems have been proposed that take advantage of these strategies [51, 19]. In comparison so far, the focus of Albis has been on a *light-weight* file format that can faithfully reflect the performance of the storage and networking hardware.

File Formats in the Cloud: Many parts of the data format research from databases have found its way into commodity, data-parallel computing systems as well. Google has introduced SSTable, an on-disk binary file format to store simple immutable key-value strings [22]. It is one of the first external file formats used in a large-scale table storage system. RCFile [28] is an early attempt to build a columnar store on HDFS. RCFiles do not support schema evolution and have inefficient I/O patterns for MapReduce workloads. To overcome these limitations, Floratou et al. propose the binary columnar-storage CIF format for HDFS [25]. However, in order to maintain data locality, they require a new data placement policy in HDFS. Hadoop-specific column-storage issues like column placement and locality are discussed in detail by [30, 25]. The more popular file formats like Parquet [10] (uses Dremel's column encoding [38]) and ORC [9], etc., are based on the PAX format. Albis's column grouping and row-major storage format match closely with Yahoo's Zebra [4, 39]. However, Zebra does not support filter pushdown or statistics like Albis. Apache CarbonData is an indexed columnar data format for fast analytics on big data platforms [7]. It shares similarities with the Arrow/Parquet project. However, due to its intricate dependencies on Spark, we could not evaluate it independently. Historically, the priorities of these file formats have been I/O efficiency (by trading CPU cycles) and then performance, in that order. However, as we have demonstrated in this paper, the performance of these file formats are in dire need of revision.

High-Performance Hardware: Recently, there has been a lot of interest in integrating high-performance hardware into data processing systems [17, 18]. Often, the potential performance gains from modern hardware are overshadowed by the thick software/CPU stack that is built while holding the decades old I/O assumptions [40, 54]. This pathology manifests itself as "system being CPU-bounded", even for many I/O-bound jobs [20, 43]. A natural response to this situation is to add more resources, which leads to a significant loss in efficiency [37]. In this work, we have shown that by re-evaluating the fundamental assumptions about the nature of I/O and CPU performances, we can build efficient and fast systems - a sentiment echoed by the OS designers as well [45]. Recently, Databricks has also designed its optimized caching format after finding out about the inadequate performance of file formats on NVMe devices [36]. However, details of the format are not public.

6 Conclusion

The availability of high-performance network and storage hardware has fundamentally altered the performance balance between the CPU and I/O devices. Yet, many assumptions about the nature of I/O are still rooted in the hardware of the 1990s. In this paper, we have investigated one manifestation of this situation in the performance of external file formats. Our investigation on 100 Gbps network and NVMe devices reveals that due to the excessive CPU and software involvement in the data access path, none of the file formats delivered performance close to what is possible on modern hardware. Often, CPU cycles are traded for storage efficiency. We have presented Albis, a light-weight, high-performance file format. The key insight in the design of Albis is that by foregoing the assumptions and re-evaluating the CPU-I/O work division in the file format, it is possible to build a high-performance *balanced* system. In the process of designing Albis, we have also presented an extensive evaluation of popular file formats on modern high-performance hardware. We demonstrate that Albis delivers performance gains in the order of $1.9-21.4\times$; superior cache and instruction profile; and its integration in Spark/SQL shows TPC-DS queries acceleration up to a margin of $3\times$. Encouraged by this result, we are exploring applicability of Albis with multiple frameworks.

Abstract

Machine Learning (ML) is an increasingly popular application in the cloud and data-center, inspiring new algorithmic and systems techniques that leverage unique properties of ML applications to improve their distributed performance by orders of magnitude. However, applications built using these techniques tend to be static, unable to elastically adapt to the changing resource availability that is characteristic of multi-tenant environments. Existing distributed frameworks are either inelastic, or offer programming models which are incompatible with the techniques employed by high-performance ML applications.

Motivated by these trends, we present Litz, an elastic framework supporting distributed ML applications. We categorize the wide variety of techniques employed by these applications into three general themes — stateful workers, model scheduling, and relaxed consistency — which are collectively supported by Litz's programming model. Our implementation of Litz's execution system transparently enables elasticity and low-overhead execution.

We implement several popular ML applications using Litz, and show that they can scale in and out quickly to adapt to changing resource availability, as well as how a scheduler can leverage elasticity for faster job completion and more efficient resource allocation. Lastly, we show that Litz enables elasticity without compromising performance, achieving competitive performance with state-of-the-art non-elastic ML frameworks.

1 Introduction

Modern clouds and data-centers are multi-tenant environments in which the set of running jobs and available resources (CPU, memory, etc.) at any given time are constantly changing [5, 45, 27]. At the same time, Machine Learning (ML) is quickly becoming a dominant application among modern distributed computing workloads. It is therefore highly desirable for ML applications executing in such an environment to be *elastic*, being able to opportunistically use additional resources when offered, and gracefully release acquired resources when requested. Elasticity is beneficial for both the individual job and for the cluster as a whole. An elastic job can make use of idle resources to complete within a shorter amount of time, and still make progress when some of its resources are removed. A cluster-wide job scheduler can dynamically re-allocate resources to speed up urgent real-time or interactive jobs, and ensure fairness by preventing jobs from holding highly contested resources for long periods of time.

Recent advancements in algorithmic and systems techniques for distributed ML applications have improved their performance by an order of magnitude or more. New algorithms such as AdaptiveRevision [39], NOMAD [42], and LightLDA [55] can better scale in distributed environments, possessing favorable properties such as staleness tolerance [39, 28], lock-free execution [42, 56], and structure-aware parallelization [20, 55]. Systems and frameworks such as GraphLab [38], Petuum [53], Adam [15], and various parameter servers [36, 28] are able to support and exploit these properties to achieve even higher performance, using techniques such as bounded-staleness consistency models [17], structure-aware scheduling [33], bandwidth management/re-prioritization [50], and network message compression [52, 15].

Although significant work is being done to push the boundaries of distributed ML in terms of performance and scalability, there has not been as much focus on elasticity, thus limiting the resource adaptability of ML applications in real-world computing environments.

General-purpose distributed frameworks such as Hadoop [1] and Spark [57] are well integrated with cloud and data-center environments, and are extensively used for running large-scale data processing jobs. They are designed to support a wide spectrum of conventional tasks—including SQL queries, graph computations, and sorting and counting—which are typically transaction-oriented and rely on deterministic execution. However, their programming models are incompatible with the algorithmic and systems techniques employed by distributed ML applications, abstracting away necessary details such as input data partitioning, computation scheduling, and consistency of shared memory access. As a result, the performance of ML applications built using these frameworks fall short of standalone implementations by two orders of magnitude or more [51].

Consequently, distributed ML applications are often implemented without support from elastic frameworks, resulting in jobs that hold a rigid one-time allocation of cluster resources from start to finish [50, 33, 56, 15]. The lack of an elastic framework, along with a suitable programming model which can support the various distributed ML techniques, is a key roadblock for implementing elastic ML applications.

Although the algorithmic and systems techniques employed by these standalone applications are diverse, they typically arise from only a few fundamental properties of ML that can be collectively supported by an elastic ML framework. This observation exposes an opportunity to design a framework that is able to support a large variety of distributed ML techniques by satisfying a smaller set of more general requirements. We summarize these properties of ML and how they guide the design of an elastic framework below, and further elaborate on them in Sec. 2. parent First, ML computations exhibit a wide variety of memory access patterns. Some mutable state may be accessed when processing each and every entry of a dataset, while other state may only be accessed when processing a single data entry. To improve locality of access, ML applications explicitly co-locate mutable model parameters with immutable dataset entries [55]. Each worker machine in the computation may contain a non-trivial amount of mutable state, which needs to be properly managed under an elastic setting.

Second, ML models contain a wide variety of dependency structures. Some sets of model parameters may safely be updated in parallel, while other sets of parameters must be updated in sequence. Guided by these dependency structures, ML applications carefully schedule their model updates by coordinating tasks across physical worker machines [20]. An elastic ML framework should abstract the physical cluster away from applications while still providing enough flexibility to support this type of task scheduling.

Furthermore, ML algorithms are often iterative-convergent and robust against small errors. Inaccuracies occurring in their execution are automatically corrected during later stages of the algorithm. Distributed ML applications have been able to attain higher performance at no cost to correctness by giving up traditionally desirable properties such as deterministic execution and consistency of memory access [28]. Framework mechanisms for elasticity should not rely on a programming model that restricts this way of exploiting the error-tolerance of ML algorithms.

Thus, to efficiently support ML applications, an elastic ML framework should support **stateful workers**, **model scheduling**, and **relaxed consistency**. It should provide an expressive programming model allowing the application to define a custom scheduling strategy and to specify how the consistency of memory accesses can be relaxed under it. Then, it should correctly execute this strategy within the specified consistency requirements, while gracefully persisting and migrating application state regardless of its placement with respect to input data.

Motivated by the needs and opportunities for elasticity of ML applications, we designed and implemented *Litz*[1], an elastic framework for distributed ML that provides a programming model supporting stateful workers, model scheduling and relaxed consistency.

Litz enables low-overhead elasticity for high-performance ML applications. When physical machines are added to or removed from an active job, state and computation are automatically re-balanced across the new set of available machines without active participation by the application. Litz's programming model can express key distributed ML techniques such as stateful workers, model scheduling and relaxed consistency, allowing high-performance ML applications to be implemented. Furthermore, a cluster job scheduler can leverage Litz's elasticity to achieve faster job completion under priority scheduling, and optimize resource allocation by exploiting inherent resource variability of ML algorithms.

Our main contributions are:

1. **Event-driven Programming Model for ML:** Litz exposes an event-driven programming model that cleanly separates applications from the physical cluster they execute on, enabling stateful workers and allowing the framework to transparently manage application state and computation during elastic events. Computation is decomposed into *micro-tasks* which have shared access to a distributed parameter server.

2. **Task-driven Consistency Model for ML:** Micro-tasks can be scheduled according to dependencies between them, allowing the application to perform model scheduling. Access to the parameter server is controlled by a consistency model in which a micro-task always observes all updates made by its dependencies, while having intentionally weak guarantees between independent micro-tasks.

3. **Optimized Elastic Execution System:** Litz's execution system transparently re-balances workload during scaling events without active participation from the application. It exploits Litz's programming and consistency models to implement optimizations that reduce system overhead, allowing applications using Litz to be as efficient as those using non-elastic execution systems.

The rest of this paper is organized as follows. In Sec. 2, we review ML algorithm properties and opportunities for elasticity, while Sec. 3 and Sec. 4 describes the Litz design and optimizations. In Sec. 5, we evaluate the effectiveness of Litz's optimizations in the distributed elastic setting, as well as its performance versus two other ML frameworks that are specialized to certain ML optimization techniques. Sec. 6 reviews related work, and Sec. 7 concludes the paper with a discussion towards future work.

2 Background

While ML algorithms come in many forms (e.g. matrix factorization, topic models, factorization machines, deep neural networks), nearly all of them share the following commonalities: (1) they possess a loss or objective function $\mathscr{L}(A,\mathscr{D})$, defined over a vector (or matrix) of model parameters A and collection of input data $\mathscr{D}$, and which measures how well the model parameters A fit the data $\mathscr{D}$; (2) their goal is to find a value of A that maximizes (or alternatively, minimizes) the objective $\mathscr{L}(A,\mathscr{D})$, via an *iterative-convergent* procedure that repeatedly executes a set of update equations, which

[1] Meant to evoke the strings of a harp, sounding out as many or as few. Litz is short for "Wurlitzer", a well-known harp maker.

gradually move A towards an optimal value (i.e. hill-climbing). These update equations follow the generic form

$$A^{(t)} = A^{(t-1)} + \Delta(A^{(t-1)}, \mathscr{D}), \qquad (1)$$

where $A^{(t)}$ is the vector (or matrix) of model parameters at iteration t, and $\Delta()$ is a function that computes updates to A using the previous value $A^{(t-1)}$ and the input data $\mathscr{D}$. The remainder of this section provides detailed background on specific properties of ML programs, and then presents two popular ML applications (Multinomial Logistic Regression and Latent Dirichlet Allocation) which we shall use as examples throughout this paper and as the subjects of our evaluation.

2.1 Data-parallelism and Parameter Server

Arising from the iid (independent and identically distributed) assumption on input data, the update function Δ can often be decomposed as

$$\Delta(A, \mathscr{D}) = \sum_{i=1}^{P} \Delta_i(A, \mathscr{D}_i), \qquad (2)$$

where $\mathscr{D}_1, \ldots, \mathscr{D}_P$ partition the input data $\mathscr{D}$ and each Δ_i computes a partial update using $\mathscr{D}_i$ which, when aggregated, form the final update Δ. This allows each update to be calculated in a data-parallel fashion with input data and update calculations distributed across a cluster of workers.

Parameter Server: Eq. 2 shows that the model parameters A are used by the calculations of every partial update Δ_i. In a data-parallel setting it is natural to place the model parameters in a shared location accessible by every machine, known as a *parameter server*. Typically, implementations of this architecture consists of two types of nodes: 1) worker nodes which partition the input data and calculate partial updates and 2) parameter server nodes which partition the model parameters and aggregate/apply the partial updates sent by worker nodes. The parameter server architecture has proven to be a near-essential component of efficient distributed ML and is used in numerous applications and frameworks [50, 18, 36, 28].

Stateful Workers: Even though the model term A appears in the calculations of each partial update, not all of it is necessarily used. In particular, there may be parts of the model which are only used when processing a single partition $\mathscr{D}_i$ of the input data. A large class of examples includes non-parametric models, whose model structures are not fixed but instead depends on the input data itself, typically resulting in model parameters being associated with each entry in the input data. In such applications, it is preferable to co-locate parts of the model on worker nodes with a particular partition of input data so they can be accessed and updated locally rather than across a network. This optimization is especially essential when the input data is large and accesses to such associated model parameters far outnumber accesses to shared model parameters. It also means that workers are *stateful*, and an elastic ML system that supports this optimization needs to preserve worker state during elastic resource re-allocation.

2.2 Error Tolerance & Relaxed Consistency

ML algorithms have several well-established and unique properties, including *error-tolerance*: even if a perturbation or noise ε is added to the model parameters in every iteration, i.e. $A^{(t)} = A^{(t-1)} + \Delta(A^{(t-1)}, \mathscr{D}) + \varepsilon$, the ML algorithm will still converge correctly provided that ε is limited or bounded.

Bounded Staleness Consistency: An important application of error tolerance is bounded staleness consistency models [28, 17, 13], which allow stale model parameters to be used in update computations, i.e. $A^{(t)} = A^{(t-1)} + \Delta(A^{(t-s)}, \mathscr{D})$, where $1 \le s \le k$ for small values of k. ML algorithms that use such consistency models are able to (1) execute in a partially asynchronous manner without sacrificing correctness, thus mitigating the effect of stragglers or slow workers [16, 25]; and (2) reduce the effect of network bottlenecks caused by synchronization by allowing cached parameter values to be used. Stale-Synchronous Parallel (SSP) [28] is such a consistency model, under which a set of distributed workers may read cached values from a shared parameter server as long as their staleness do not exceed a fixed limit.

Staleness-aware ML Algorithms: Beyond simply applying bounded staleness consistency to existing algorithms, the ML community has developed new staleness-aware algorithms [39, 58, 55, 12, 29, 10, 37] which modify each update $\Delta()$ according to the staleness s that it experiences. The modifications usually take the form of a scaling factor $\Delta() \leftarrow c\Delta()$, which are computationally light-weight and do not create new bottlenecks. In the presence of staleness, these algorithms converge up to an order of magnitude faster than their non-staleness-aware counterparts.

2.3 Dependencies and Model Scheduling

Another key property of ML algorithms is the presence of implicit *dependency structures*: supposing A_1 and A_2 are different elements of A, then updating A_1 before A_2 does not necessarily yield the same result as updating A_2 before A_1; whether this happens or not depends on the algebraic form of $\mathscr{L}()$ and $\Delta()$. As a consequence, the convergence rate and thus the running time of ML algorithms can be greatly improved through careful scheduling of parallel model parameter updates.

Dependency-aware ML Algorithms: Like the many existing staleness-aware algorithms that exploit error tolerance, there is a rich set of algorithms that use dependency structures in their models to perform better scheduling of updates [44, 55, 20, 18, 35, 49, 38]. A typical example is to partition the model into subsets, where the parameters inside a subset must be updated sequentially, but multiple subsets can be updated in parallel. Two parameters A_1 and A_2 are placed into the same subset if the strength of their dependency exceeds a threshold $\text{dep}(A_1, A_2) > \varepsilon$. As with staleness-aware algorithms, dependency-aware algorithms converge up to an order of magnitude faster than their non-dependency-aware counterparts.

3 Litz Programming Model and API

The main goal and challenge of designing Litz's programming model is striking a balance between being expressive enough to support the wide variety of proven techniques in distributed ML, while exposing enough structure in the application that the underlying execution system can take control under elastic conditions. Guided by the insights presented in Sec. 2, we describe how Litz's programming model naturally arises from the properties of ML applications, and how it enables an efficient and elastic run-time implementation. For reference, a detailed summary of Litz's API can be found in Table 1.

Input Data Over-Partitioning Across Executors: Eq. 2 shows that the input data and update calculations of ML applications can be partitioned and distributed across a number of workers, but it does not specify any particular partitioning scheme, nor does it require the number of partitions to be equal to the number of physical machines. Instead of directly assigning input data, Litz first distributes it across a set of logical *executors*, which are in turn mapped to physical machines. Elasticity is enabled by allocating more executors than physical machines and migrating excess executors to other machines as they become available. This separation also lets Litz support stateful workers by allowing executor state to be defined and mutated by the application while being treated as a black box by the run-time system.

Micro-Tasks and Parameter Server: Update calculations are decomposed into short-lived (typically shorter than 1 second) units of computation called *micro-tasks*, each of which calculates a partial update using the input data on a single executor. At the end of each micro-task, control is yielded back to the run-time system, exposing frequent opportunities for executors to be migrated. During its execution, a micro-task is granted read/update access to a global parameter server via a key-value interface (`PSGet/PSUpdate` in Table 1) and applies partial updates to model parameters by modifying application state in the executor and/or updating globally-shared values in the parameter server.

Model Scheduling and Relaxed Consistency: Litz enables both model scheduling and relaxed consistency using application-defined dependencies between micro-tasks. If micro-task A is a dependency of micro-task B, then (1) B is executed before A and (2) B observes all updates made by A. This strict ordering and consistency guarantee lets the application perform model scheduling by defining an ordering for when certain updates are calculated and applied. On the other hand, if neither A nor B is a dependency of the other, then they may be executed in any order or in parallel, and may observe none, some, or all of the updates made by the other. This critical piece of non-determinism lets the application exploit relaxed consistency models by allowing the run-time system to cache and use stale values from the parameter server between independent micro-tasks.

Micro-Task Dispatch and Completion: A common way to specify dependencies between tasks is through a directed "dependency" graph in which each vertex corresponds to a micro-task, and an arc from vertex A to vertex B means task A is a dependency of task B. However, due to a potentially large number of micro-tasks, explicitly specifying such a graph up-front may incur significant overhead. Instead, each Litz application defines a *driver* which dynamically dispatches micro-tasks during run-time via the `DispatchTask` method. When a micro-task completes, Litz invokes the `HandleTaskCompletion` method on the driver, which can then dispatch any additional micro-tasks.

Without an explicit dependency graph, Litz needs an alternative way to decide when a micro-task should be able to observe another micro-task's updates. Otherwise, its execution system does not have enough information to know when it is safe for a micro-task to use cached parameter values, thus giving up a significant opportunity for performance optimization. To overcome this issue, Litz uses the sequence of micro-task dispatch and completion events to infer causal relationships between micro-tasks, which can then be used to generate the dependencies needed to implement its cache coherence protocol. According to the following two cases:

1. If micro-task B is dispatched *before* being informed of the completion of micro-task A, then Litz infers that the completion of A *did not cause* the dispatch of B. A *is not* a dependency of B, and B may observe some, all, or none of the updates made by A.
2. If micro-task B is dispatched *after* being informed of the completion of micro-task A, then Litz infers that A *may have caused* the dispatch of B. A *may be* a dependency of B, and B will observe all updates made by A.

This consistency model is similar to Causal Memory [11], in which causally related read/write operations are observed in the same order by all nodes. We discuss how Litz's consistency model and its cache coherence protocol can be implemented efficiently in Sec. 4.

4 Litz Implementation and Optimizations

Litz is implemented in approximately 6500 lines of C++ code using the ZeroMQ [8] library for low latency communication and Boost's Context [2] library for low overhead context-switching between micro-tasks. The run-time system is comprised of a single *master thread* along with a collection of *worker threads* and *server threads*, as shown in Fig. 1. The application's driver exists in the master thread and its executors exist in the worker threads. The key/value pairs comprising the parameter server are distributed across a set of logical *PSshards* stored in the server threads. Additional worker and server threads may join at any time during the computation, and the run-time system can re-distribute its load to make use of them. They may also gracefully leave the computation after signaling to the master thread and allowing their load to be transferred to other threads.

The master thread coordinates the execution of the application. First, it obtains micro-tasks from the driver

Method Name	Part Of	Defined By	Description
`DispatchInitialTasks()`	Driver	Application	Invoked by the framework upon start-up to dispatch the first set of micro-tasks.
`HandleTaskCompletion(result)`	Driver	Application	Invoked by the framework when a micro-task completes so that the driver can dispatch a new set of micro-tasks.
`DispatchTask(executor,args)`	Driver	Framework	Invoked by the application to dispatch a micro-task to the specified executor.
`RunTask(args)`	Executor	Application	Invoked by the framework to perform a micro-task on the executor.
`SignalTaskCompletion(result)`	Executor	Framework	Invoked by the application to indicate the completion of a micro-task.
`PSGet(key)`	Executor	Framework	Returns a specified value in the parameter server.
`PSUpdate(key,update)`	Executor	Framework	Applies an incremental update to a specified value in the parameter server.

Table 1: The programming interface for Litz, an application should define `DispatchInitialTasks` and `HandleTaskCompletion` on the driver, as well as `RunTask` on the executor.

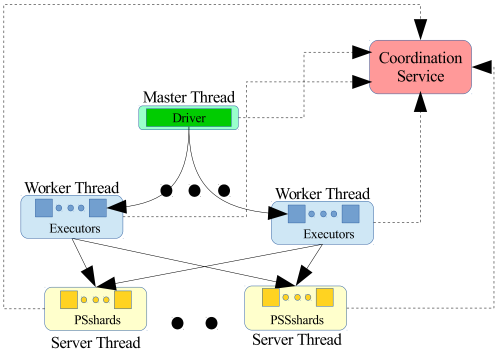

Figure 1: High-level architecture of Litz. The driver in the master thread dispatches micro-tasks to be performed by executors on the worker threads. Executors can read and update the global model parameters distributed across PSshards on the server threads.

by initially invoking `DispatchInitialTasks` and then continuously invoking `HandleTaskCompletion`, sending them to worker threads to be executed. Second, the master thread maintains the dynamic mappings between executors and worker threads, as well as between PSshards and server threads. When worker or server threads join or leave the computation, it initiates load re-distribution by sending commands to move executors between worker threads or PSshards between server threads. Third, the master thread periodically triggers a consistent checkpoint to be taken of the entire application state, and automatically restores it when a failure is detected. Each thread registers with an external coordination service such as ZooKeeper [31] or etcd [4] in order to determine cluster membership and detect failures. In order to transfer and checkpoint the driver and executors, Litz requires the application to provide serialization and de-serialization code. The programming burden on the developer is low since (1) it does not actively participate in elasticity and checkpointing, but simply invoked by the execution system when needed, and (2) third-party libraries can be used to reduce programming overhead [3].

Worker Thread Elasticity: Each worker thread maintains the state of and runs the micro-tasks for a subset of all executors. After any worker threads join the active computation, executors are moved to them from the existing worker threads (scaling out). Similarly, before any worker threads leave the active computation, executors are moved from them to the remaining worker threads (scaling in).When an executor needs to be moved, the worker thread first finishes any of its ongoing micro-tasks for that executor, buffering any other pending micro-tasks for that executor. The worker thread then sends the executor's state and its queue of buffered micro-tasks over the network to the receiving worker thread.

The transfer of the executor's input data is treated differently in the scale-in and scale-out cases. When scaling in, Litz aims to free the requested resources as quickly as possible. The input data is discarded on the originating worker thread to avoid incurring extra network transfer time, and re-loaded on the target worker thread from shared storage. When scaling out, Litz aims to make use of the new worker thread as quickly as possible. The input data is sent directly from the memory of the originating worker thread to avoid incurring extra disk read time on the target worker thread.

Parameter Server Elasticity: Similar to worker threads and executors, each server thread stores and handles the requests and updates for a subset of all PSshards, which are re-distributed before scaling in and after scaling out. However, since requests and updates are continuously being sent to each PSshard and can originate from any executor, their transfer requires a special care. In particular, a worker thread may send requests or updates to a server thread that no longer contains the target PSshard, which can occur if the PSshard has been moved but the worker thread has not yet been notified.

A naïve approach is to stop all micro-tasks on every executor, then perform the transfer, then notify all worker threads of the change, and finally resume execution. This method guarantees that requests and updates are always sent to server threads that contain the target PSshard, but incurs high overhead due to suspending the entire application. Instead, the server threads perform *request and update forwarding*, and executors are never blocked from sending a parameter request or update. When a server thread receives a message for a PSshard it no longer contains, it forwards the message to the server thread it last transferred the PSshard to. Forwarding can occur multiple times until the target PSshard is found, the request/update is performed, and the response is sent back to the originating worker thread. This way, execution of micro-tasks can proceed uninterrupted during parameter server scaling events.

Consistent Checkpoint and Recovery: To achieve fault tolerance, Litz periodically saves a checkpoint of the application to persistent storage, consisting of (1) the state of the driver, (2) the buffered micro-tasks for each executor, (3) the state of each executor, and (4) the key-value pairs stored in each PSshard. Input data is not saved, but is re-loaded from shared storage during recovery. When a failure is detected through the external coordination service, Litz triggers an automatic recovery from the latest checkpoint. The saved driver, executors, buffered micro-tasks, and parameter server values are restored, after which normal execution is resumed.

Parameter Cache Synchronization: The consistency model outlined in Sec. 3 exposes an opportunity for the runtime system to optimize execution by caching and re-using values from the parameter server instead of retrieving them over the network for each access. Specifically, a micro-task A is allowed to use a cached parameter if its value reflects all updates made by all micro-tasks that A depends on. This means that (1) multiple accesses of the same parameter by micro-task A can use the same cached value, and (2) a micro-task B whose dependencies are a subset of A's can use the same cached values that were used by A. By only using the sequence of micro-task dispatch and completion events to infer dependencies, Litz enables both (1) and (2) to be implemented efficiently. In particular, the dependencies of micro-task B are a subset of the dependencies of micro-task A if the total number of micro-tasks that have been completed when B was dispatched is at most the total number of micro-tasks that have been completed when A was dispatched.

To implement this cache coherence protocol, the master thread maintains a single monotonically increasing *version* number that is incremented each time `HandleTaskCompletion` is invoked. Whenever the driver dispatches a micro-task, the master thread tags the micro-task with the version number at that time. After micro-task A retrieves a fresh value from the parameter server, it caches the value and tags it with A's version. When micro-task B wants to access the same parameter, it first checks if its own version is less than or equal to the version of the cached value. If so, then the cached value is used; otherwise a fresh copy of the parameter is retrieved from the parameter server and tagged with B's version. A cache exists on each Litz process running at least one worker thread, so that it can be shared between different worker threads in the same process.

This cache coherence protocol allows Litz to automatically take advantage of parameter caching for applications that use bounded staleness. For example, to implement SSP (Sec. 2.2) with staleness s, all micro-tasks for iteration i are dispatched when the last micro-task for iteration $i-s-1$ is completed. Thus, every micro-task for the same iteration has the same version and share cached parameter values with each other. Since the micro-tasks for iteration i are dispatched before those for iterations between $i-s$ and $i-1$ finish (when $s \geq 1$), the values they retrieve from the parameter server may not reflect all updates made in those prior iterations, allowing staleness in the parameter values being accessed.

Parameter Update Aggregation: Updates for the same parameter value may be generated many times by different micro-tasks. Since the parameter updates in ML applications are incremental and almost always additive, they can be aggregated locally before sending to the parameter server in order to reduce network usage. To facilitate the aggregation of updates, each Litz process contains an *update log* which maps parameter keys to locally aggregated updates. Whenever a micro-task invokes `PSUpdate`, the update is first aggregated with the corresponding entry in the update log, or is inserted into the update log if the corresponding entry does not exist. Therefore, an update sent to the parameter server can be a combination of many updates generated by different micro-tasks on the same Litz process.

In order to maximize the number of updates that are locally aggregated before being sent over the network, the results of micro-tasks are not immediately returned to the master thread after they are completed. Doing this allows the updates from many more micro-tasks to be sent in aggregated form to the server threads, reducing total network usage. The update log is periodically flushed by sending all updates it contains to the server threads to be applied. After each flush, all buffered micro-task results are returned to the master thread, which then informs the driver of their completion. The period of flushing can be carefully tuned, but we find that the simple strategy of flushing only when all micro-tasks on a worker thread are finished works well in practice.

Co-operative Multitasking: Litz employs co-operative multitasking implemented using co-routines [2]. When one task is blocked on an invocation of `PSGet` waiting for a value to be returned from a server thread, the worker thread will switch to executing another micro-task that is not blocked so that useful work is still performed. Each micro-task is executed within a co-routine so that switching between them can be done with low-latency, entirely in user-space. Using co-routines provides the benefit of overlapping communication with computation, while retaining a simple-to-use, synchronous interface for accessing the parameter server from micro-tasks.

5 Evaluation

We start by evaluating Litz's elasticity mechanism and demonstrate its efficacy along several directions. First, with its parameter caching, update aggregation, and co-operative multi-tasking, Litz is able to sustain increasing numbers of executors and micro-tasks with minimal performance impact. Second, a running Litz application is able to efficiently make use of additional nodes allocated to it, accelerating its time to completion. Third, a running Litz application is able to release its nodes on request, quickly freeing them to be allocated to another job.

Next, we discuss how Litz's elasticity can be leveraged by a cluster job scheduler to (1) reduce the completion time of an ML job that yields resources to a higher-priority job, and (2) improve resource allocation by exploiting the inherent decreasing memory usage of many ML algorithms.

Lastly, we evaluate Litz's performance when executing diverse applications which make use of stateful workers, model scheduling, and relaxed consistency. With the multinomial logistic regression (MLR) application, we show that our implementation on Litz is faster than the built-in implementation in Bösen [50], a non-elastic ML system for data-parallel SSP workloads. With the latent Dirichlet allocation (LDA) application, we show that our implementation on Litz is competitive with the built-in implementation in Strads [33], a non-elastic ML system for model scheduling. Furthermore, to evaluate Litz for the special case of deep learning, we implement a deep feed-forward neural network and compare its performance with Tensorflow [9].

ML Applications: MLR and LDA are popular ML applications used for multi-class classification and topic modeling, respectively. The goal of our evaluation is to show that Litz enables elasticity for these applications at little cost to performance when compared with state-of-the-art non-elastic systems. Thus, we closely follow their implementations in Bösen and Strads, using SGD and the SSP relaxed consistency model for MLR, and block-scheduled Gibbs sampling with stateful workers for LDA. For details of these implementations of MLR and LDA, we refer readers to their descriptions in Wei *et al.* [50] and Kim *et al.* [33], respectively.

Cluster Setup: Unless otherwise mentioned, the experiments described in this section are conducted on nodes with the following specifications: 16 cores with 2 hardware threads each (Intel Xeon E5-2698Bv3), 64GiB DDR4-2133 memory, 40GbE NIC (Mellanox MCX314A-BCCT), Ubuntu 16.04 Linux kernel 4.4. The nodes are connected with each other through a 40GbE switch (Cisco Nexus 3264-Q), and access data stored on an NFS cluster connected to the same switch. Each machine runs one Litz process which contains both worker threads and server threads; the master thread is co-located with one of these processes.

Input Datasets: Unless otherwise mentioned, we run MLR on the full ImageNet ILSVRC2012 dataset [43] consisting of 1.2M images labeled using 1000 different object categories. The dataset is pre-processed using the LLC feature extraction algorithm [48], producing 21K features for each image, resulting in a post-processed dataset size of 81GB. We run LDA on a subsample of the ClueWeb12 dataset [19] consisting of 50M English web pages. The dataset is pre-processed by removing stop words and words that rarely occur, resulting in a post-processed dataset with 10B tokens, 2M distinct words, and total size of 88GB.

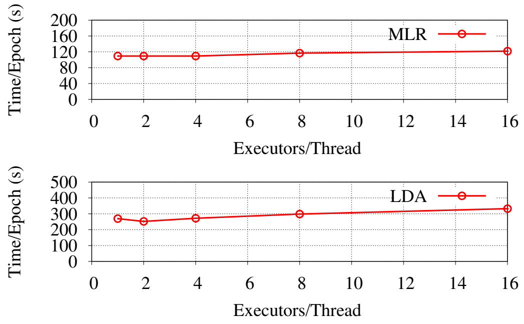

Figure 2: Average time per epoch for MLR and LDA when running with various numbers of executors per worker thread. In both cases the overhead of increasing the number of executors is insignificant. We define one epoch as performing a single pass over all input data.

5.1 Elasticity Experiments

Before discussing elastic scaling, we evaluate Litz's performance characteristics over increasing numbers of executors. The worker threads achieve elasticity by re-distributing executors amongst themselves when their numbers change, and by over-partitioning the application's state and computation across larger numbers of executors, Litz is able to scale out to larger numbers of physical cores and achieve a more balanced work assignment. Thus it is critical for Litz applications to still perform well in such configurations. We run the MLR application on 4 nodes and the LDA application on 12 nodes, varying the number of executors from 1 to 16 per worker thread. Fig. 2 shows how the throughput of each application changes when the number of executors increases. Using a single executor per worker thread as the baseline, the execution time for MLR does not noticeably change when using 4× the number of executors, and gradually increases to 1.11× the baseline when using 16× the number of executors. For LDA, the execution time initially decreases to 0.94× the baseline when using 2× the number of executors, and thereafter gradually increases to 1.23× the baseline when using 16× the number of executors. We believe the overhead introduced by increasing the number of executors is quite an acceptable trade-off for elasticity and can still be reduced with further optimizations.

5.1.1 Elastic Scale Out

As jobs finish in a multi-tenant setting and previously used resources are freed up, additional allocations can be made to a currently running job. It is therefore important for the job to be capable of effectively using the additional resources to speed up its execution. In this section, we evaluate Litz's performance characteristics when scaling a running application out to a larger number of physical nodes. We run experiments scaling MLR jobs from 4 to 8 nodes, and LDA jobs from 12 to 24 nodes. Each node runs both worker threads and server threads, so both executors and PSshards are rebalanced during scaling. The experiments for LDA in

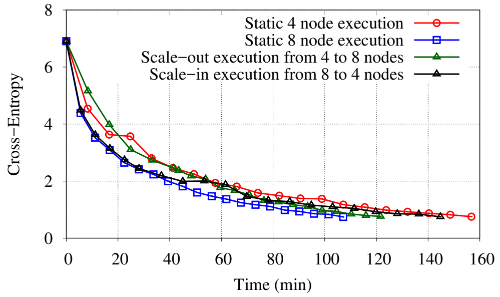

Figure 3: MLR execution on Litz with 4 nodes, with 8 nodes, with an elastic execution that scales out from 4 nodes to 8 nodes, and with an elastic execution that scales in from 8 nodes to 4 nodes. For the scale-out execution, the nodes are added at about 40 minutes into execution. For the scale-in execution, the nodes are removed at about 30 minutes into execution.

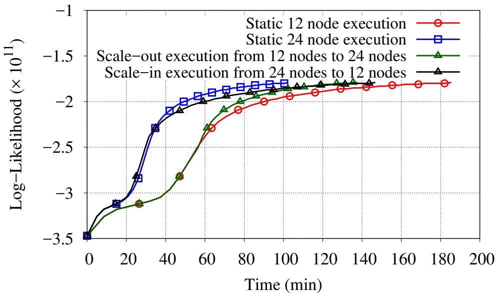

Figure 4: LDA execution on Litz with 12 nodes, with 24 nodes, and with an elastic execution that scales out from 12 nodes to 24 nodes. For the scale-out execution, the nodes are added at about 55 minutes into execution. For the scale-in execution, the nodes are removed at about 33 minutes into execution.

this section were performed using m4.4xlarge instances on AWS EC2, each with 16 vCPUs and 64GiB of memory.

To evaluate the speed-up achieved, we compare our scale-out experiments with static executions of the applications using both the pre-scaling number of nodes and the post-scaling number of nodes. Fig. 3 shows the convergence plots for MLR, 4 new nodes added after ≈40min of execution. The static 4 node execution completes in ≈157min while the scale-out execution completes in ≈122min, resulting in a 22% shorter total run-time. Fig. 4 shows the convergence plots for LDA, 12 new nodes added after ≈55min of execution. The static 12 node execution completes in ≈183min while the scale-out execution completes in ≈134min, resulting in a 27% shorter total run-time.

5.1.2 Ideal Scale Out

Next, we evaluate the amount of room for improvement still achievable over Litz's current scale-out performance. Following a similar construction as Pundir et al. [41], we define and compare with a simple *ideal* scale-out execution time which intuitively measures the total run-time of a job that instantly scales out and adapts to use the additional nodes. For example, consider a job that scales out from 4 to 8 nodes after completing 30% of its iterations, its ideal scale-out execution time is the sum of the time at which the scale-out was triggered and the time it takes a static 8 node execution to run the last 70% of its iterations.

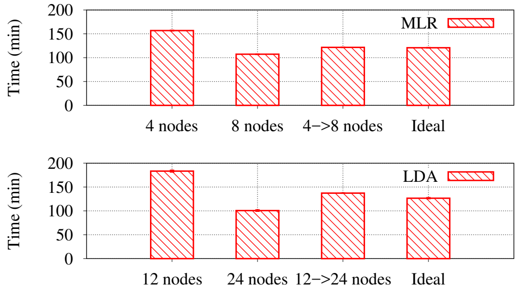

Figure 5: Static, scale-out, and ideal scale-out (See Sec. 5.1.1) execution times for MLR and LDA implemented on Litz. We scale out MLR from 4 nodes to 8 nodes, and LDA from 12 nodes to 24 nodes. Each experiment was performed several times, error bars are omitted due to their negligible size.

Fig. 5 compares the static pre-scaling, static post-scaling, scaling, and ideal execution times for both MLR and LDA. For MLR, the static 8 node execution completes in ≈107min, giving an ideal scale-out execution time of ≈121min. The actual scale-out execution time is ≈122min, indicating a less than 1% difference from the ideal. Similarly for LDA, the static 24 node execution completes in ≈101min, giving an ideal scale-out execution time of ≈127min. The actual scale-out execution time is ≈134min, indicating a 5% difference from the ideal. LDA's higher overhead stems from the large worker state that is inherent to the algorithm, which need to be serialized and sent over the network before the transferred executors can be resumed. We believe this overhead can be reduced further through careful optimization of the serialization process, by minimizing the number of times data is copied in memory and compressing the data sent over the network.

5.1.3 Elastic Scale In

As new and higher-priority jobs are submitted in a multi-tenant environment, the resource allocation for a currently running job may be reduced and given to another job. In this section, we evaluate Litz's scale-in performance based on two key factors. First, we show that Litz applications continue to make progress after scaling in, with performance comparable to the static execution on the fewer nodes. Second, we show that running Litz jobs can release resources with low latency, quickly transferring executors and PSshards away from requested nodes so that they can be used by another job. We measure the time between when the scale-in event is triggered and when the last Litz process running on a requested node exits. This represents the time an external job scheduler needs to wait before all requested resources are free to be used by another job. As with the scale-out experiments, these experiments were run using m4.4xlarge EC2 instances.

We run each experiment at least three times and report the average. Fig. 3 shows the convergence plots for MLR with the scale-in event. We start the job with 8 nodes, and remove 4 nodes ≈ 30 minutes into execution. The convergence plot closely follows the plot of 8-node static execution until the scale-in event, and the plot of 4-node static execution after that. Similarly, Fig. 4 shows the convergence plots for LDA with the scale-in event. We start the job with 24 nodes, and remove nodes ≈ 33 minutes into execution. The convergence plot closely follows the plot of 24-node static execution until the scale-in event, and the plot of 12-node static execution after that.

For MLR, the scale-in event takese 2.5 seconds on average, while for LDA the average is 43s. The low latency for MLR is due to a combination of its stateless workers and Litz's default behavior of discarding input data upon scaling in. As a result, the only state that needs to be transferred are the PSshards residing on the server threads of each requested node, which total ≈ 10MiB when split between 8 nodes. The executors in LDA, on the other hand, are stateful and contain a portion of its model parameters. When distributed across all nodes, each node contains ≈ 4.6GiB of executor state that need to be transferred away. A benchmark of cluster network showed that it can sustain a bandwidth of 2.0Gbps between pairs of machines, meaning that the 4.6GiB of LDA executor state can ideally be transfered within 20s. Nevertheless, the current transfer times are reasonable for an external scheduler to wait for. For comparison, even a pre-emptive environment like the AWS Spot Market gives users a warning time of 120s before forcefully evicting their nodes.

5.2 Elastic Scheduling

Elasticity has many potential applications in both the cloud and data-center. In the cloud, elasticity can be leveraged to take advantage of transient nodes in spot markets [26] and drastically reduce the monetary cost of renting computation resources. In the data-center, a cluster-wide scheduler can optimize resource utilization by adaptively consolidating applications into fewer physical machines [30].

We present two specific instances where the elasticity enabled by Litz can benefit job scheduling. First, when a high-priority job needs to be scheduled, an elastic ML application can avoid preemption by cooperatively releasing resources. Second, the inherent resource variability of many ML applications allow Litz to automatically release memory throughout the lifetime of an ML job, freeing resources to be used by other jobs. Serious design and implementation of such a scheduler and its policies is deserving of thorough investigation, which we leave for future work.

5.2.1 Priority Scheduling

In multi-tenant computing environments, users frequently submit jobs (both ML and non-ML) which can have differing priorities. To meet the stricter SLA requirements of high-priority jobs, a scheduler must sometimes re-allocate some resources used by a lower-priority job. If the lower-priority job is inelastic, then it may be killed or suspended, leaving the rest of its resources under-utilized and delaying its completion time. For long-running jobs such as training ML models, their resources may need to be re-allocated several times during their lifetimes.

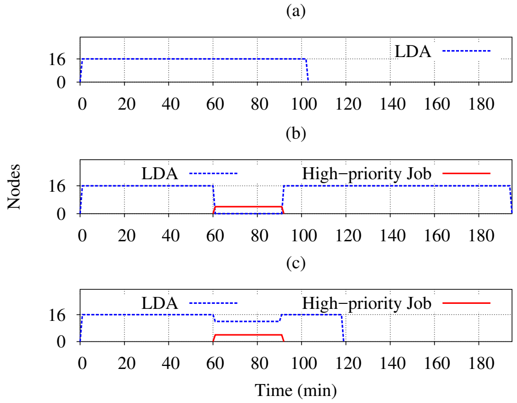

Figure 6: Priority scheduling experiments as described in Sec. 5.2.1. The graphs show the resource allocation over time in the cases of (a) LDA job which is uninterrupted, (b) LDA job which is killed when a higher-priority job is submitted, and (c) LDA job which elastically scales in when a higher-priority job is scheduled. We ran each experiment three times and saw negligible variation between each instance.

However, with the elasticity mechanism enabled by Litz, a long-running ML application can simply scale-in to use a fewer amount of resources, while the higher-priority job uses the released resources. After the higher-priority job completes, it can scale-out again, uninterrupted. We implemented this priority scheduling policy on a cluster of 16 m4.4xlarge nodes, and launched an LDA job on all 16 machines that runs for ≈100min if left uninterrupted (Fig. 6(a)). A higher-priority job is launched 60min into its runtime, requiring 4 nodes for 30min. Without elasticity, the LDA job is killed and re-started after the higher-priority job ends, requiring a total of ≈190min to complete (Fig. 6(b)). However, by leveraging elasticity to scale-in the LDA job, it can continue to run using 12 nodes and completes in ≈120min (Fig. 6(c)). At the same time, waiting for LDA to scale-in only increased the completion time of the high-priority job from 30min to 31min.

5.2.2 ML Resource Variability

The iterative-convergent nature of ML algorithms presents opportunities for resource scheduling not usually found in other computing tasks. One advantage of elasticity in an ML framework is that in addition to scaling in and out based on the directions from a cluster scheduler, an elastic ML framework can leverage resource variability that is inherent in ML applications to autonomously give up resources.

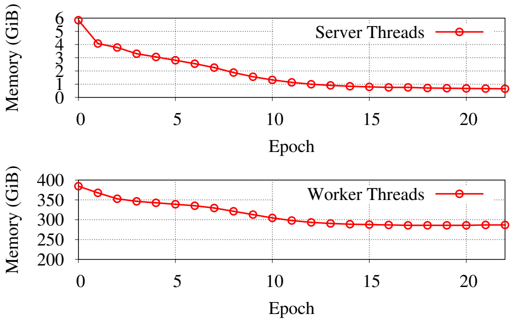

Figure 7: Memory usage on a cluster of 12 m4.4xlarge nodes during runtime of LDA implemented using Litz, broken down by server threads and worker threads. During the first 10 epochs, memory usage of server threads decrease by 5GiB, while memory usage of worker threads decrease by 70GiB.

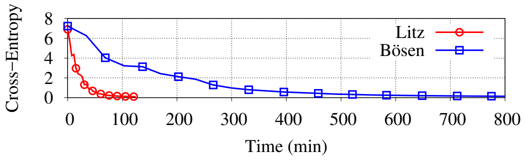

Figure 8: Multinomial Logistic Regression (MLR) running on 8 nodes using 25% of the ImageNet ILSVRC2012 dataset. Litz achieves convergence about 8× faster than Bösen.

In particular, many ML algorithms, including LDA, may find their model parameters becoming sparse (ie. mostly zeros) as they approach convergence [33], allowing memory usage to be reduced by using a more memory-efficient storage format (ie. sparse vector). Although LDA running on Strads has a similar decreasing memory usage, the lack of elasticity in Strads does not allow it to leverage this phenomenon for efficient scheduling.

Litz, on the other hand, can detect variability in the resource usage and reduce the number of worker and server threads accordingly. Fig. 7 shows the breakdown of memory usage during LDA. Server threads that store the model start with 6 GiB and drop to around 1 GiB by the 10th epoch, suggesting that the server threads can be reduced by 80%. Similarly, the worker threads start with 370 GiB of memory and reduce to about 300 GiB by the 10th epoch, suggesting that their count can be reduced by 20% and respective resources can be released. This dynamic resource usage of ML jobs, when exposed through an elastic framework like Litz, can inform the policies of a cluster scheduler that allocates resources between many jobs.

5.3 Performance Experiments

We compare our Litz implementations of MLR and LDA with those built-in with the open-source versions of Bösen and Strads, respectively. All three systems along with their applications are written using C++, and to further ensure fairness, we compiled all three using the `-O2 -g` flags and linked with the TCMalloc [21] memory allocator. These settings are the default for both Bösen and Strads.

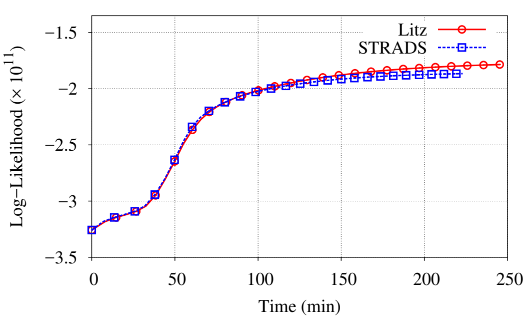

Figure 9: Latent Dirichlet Allocation (LDA) training algorithm running on Strads and Litz with the subsampled ClueWeb12 dataset. Litz completes all 34 epochs roughly 6% slower than Strads, but achieves a better objective value.

MLR Comparison with Bösen: We compare Litz with Bösen running the MLR application on 25% of the ImageNet ILSVRC2012 dataset[2] using 8 nodes. The open-source version of Bösen differs from the system described by Wei *et. al.* [50] in that it does not implement early communication nor update prioritization, but is otherwise the same and fully supports SSP execution. Both MLR instances were configured to use the same SSP staleness bound of 2 as well as the same SGD tuning parameters such as step size and minibatch size. As Fig. 8 shows, our MLR implementation on Litz converges about 8× faster than that on Bösen. Our profiling of Bösen and cursory examination of its code shows that it does not fully utilize CPUs due to lock contention. We believe the wide gap in performance is not due to fundamental architectural reasons, and that Bösen should be able to narrow the gap on such SSP applications given a more optimized implementation.

LDA Comparison with Strads: We next compare Litz with Strads running the LDA application using 12 nodes. The open-source version of Strads is the same implementation used in Kim *et. al.* [33]. Both LDA instances were configured to use the same number of block partitions as well as the same LDA hyper-parameters α and β. We ran each application until 34 epochs have been completed, where an *epoch* is equivalent to a full pass over the input data. As Fig. 9 shows, our LDA implementation on Litz completes all epochs roughly 6% slower than that on Strads. However, it also achieves a better objective value (measured in log-likelihood), resulting in faster convergence than Strads overall. Even though more investigation into the per-epoch convergence difference is needed, we can attribute the throughput difference to the optimizations built into Strads, which employs a ring-topology specifically optimized for the block-partitioned model scheduling strategy used by LDA.

Deep Neural Networks (DNNs): To evaluate Litz with DNNs, we implemented a particular deep learning model called a deep feed-forward network [22], which forms the

[2] With the full dataset, the Bösen baseline does not complete within a reasonable amount of time.

basis of many deep learning applications. We used a network with two hidden layers with ReLU activation and one output layer with Softmax activation. We trained this model using both Litz and TensorFlow [9] on 4 m4.4xlarge EC2 instances, with the CIFAR-10 [34] dataset. This dataset consists of 60K images, which are pre-processed into vectors of ≈98K features, labeled using 10 classes. Both systems used the same data-parallel SGD algorithm, and were configured with the same tuning parameters such as a learning rate of 0.0001 and mini-batch size of 64. The training using Tensorflow progressed at a pace of ≈79s per batch, while the training using Litz progressed 3.4× faster at a pace of ≈23s per batch.

6 Discussion and Related Work

Recently, there has been a growing interest in utilizing *transient* nodes in the cloud spot markets for big-data analytics. The systems developed for this setting try to execute jobs with the performance of *on-demand* nodes at a significantly cheaper cost, using transient nodes. The challenge for these systems is to deal with the bulk revocations efficiently by choosing right fault-tolerance mechanism. For example, SpotOn [47] dynamically determines the fault-tolerance mechanism that best balances the risk of revocation with the overhead of the mechanism. While SpotOn applies these fault-tolerance mechanisms at the systems level—using virtual machines or containers—Flint [46] argues that application-aware approach is preferable and can improve efficiency by adapting the fault-tolerance policy. Flint, which is based on Spark, proposes automated and selective checkpointing policies for RDDs, to bound the time Spark spends recomputing lost in-memory data after a bulk revocation of transient nodes. TR-Spark [54] argues that RDDs—the checkpointing unit in Spark—are too coarse-grained, making Spark unfit to run on transient resources, and takes Flint's approach further by providing fine-grained task-level checkpointing.

Unlike Flint and TR-Spark that adapt a general-purpose Spark framework to achieve cost-effective analytics with transient resources, Proteus [26] adapts a specialized ML framework to achieve significantly faster and cheaper execution, while introducing elasticity optimizations tuned for the setting. Specifically, Proteus stores the ML model on parameter servers that run on reliable on-demand nodes, and makes the workers stateless so that they can be run on transient node, effectively pushing workers' states to parameter servers, along with the model. This is a reasonable approach for the spot market setting where bulk revocations can take offline a large number of workers without notice. Although it works well for applications with small worker state, with an increasing data and model size, the approach may run into performance problems due to the communication overhead between workers and their state stored on the parameter servers. Litz, on the other hand, keeps the worker state in the workers and assumes a cooperative cluster scheduler that will ask the running application to give up nodes and wait for state to be transferred away. This approach results in high performance while still providing elasticity.

7 Conclusion and Future Work

We present the design and implementation of Litz, an evolutionary step in the elastic execution of ML applications in clouds and data-centers. We identify three important classes of distributed ML techniques—stateful workers, model scheduling, and relaxed consistency—and designed Litz's programming model to collectively support each of them. By adopting an event-driven API, Litz is able to control the execution of its applications, transparently migrating their state and computation between physical machines. Litz achieves elasticity—the ability to scale out and in based on changing resource availability—without compromising the state-of-the-art efficiency of non-elastic ML systems.

Furthermore, we describe the inherent dynamic memory usage of ML applications. We show that Litz is able to expose these patterns and significantly decrease its demand for memory across the lifetimes of ML jobs. Resource variability during the runtime of large data-analytics jobs is well known, and many schedulers have been introduced to exploit this variability for an efficient scheduling of jobs [32, 24, 23]. However, no previous work exists that exploit the specific resource usage patterns of ML applications. In future work, we plan to further investigate and identify the resource usage patterns of distributed ML applications, and then leverage their resource variability together with the elasticity of Litz for more efficient scheduling of ML jobs.

Lastly, we identify deep learning and elastic GPU computing as another interesting direction for future work. In particular, how does the relatively low-level event-driven API of Litz fit together with the higher-level symbolic programming models of deep learning frameworks like TensorFlow, MXNet [14], and DyNet [40]? With the current trend towards using compiler techniques to separate deep learning programming and execution [6, 7], we believe that frameworks like Litz will play an important role in the elastic and efficient execution of many future deep learning applications. The answers to these problems deserve thorough investigation.

Putting the “Micro” Back in Microservice

* *Carnegie Mellon University* [†] *Intel Labs*

Abstract

Modern cloud computing environments strive to provide users with fine-grained scheduling and accounting, as well as seamless scalability. The most recent face to this trend is the “serverless” model, in which individual functions, or microservices, are executed on demand. Popular implementations of this model, however, operate at a relatively coarse granularity, occupying resources for minutes at a time and requiring hundreds of milliseconds for a cold launch. In this paper, we describe a novel design for providing “functions as a service” (FaaS) that attempts to be truly *micro*: cold launch times in microseconds that enable even finer-grained resource accounting and support latency-critical applications. Our proposal is to eschew much of the traditional serverless infrastructure in favor of language-based isolation. The result is microsecond-granularity launch latency, and microsecond-scale preemptive scheduling using high-precision timers.

1 Introduction

As the scope and scale of Internet services continues to grow, system designers have sought platforms that simplify scaling and deployment. Services that outgrew self-hosted servers moved to datacenter racks, then eventually to virtualized cloud hosting environments. However, this model only partially delivered two related benefits:

1. Pay for only what you use at very fine granularity
2. Scale up rapidly on demand

The VM approach suffered from relatively coarse granularity: Its atomic compute unit of machines were billed at a minimum of minutes to months. Relatively long startup times often required system designers to keep some spare capacity online to handle load spikes.

These shortcomings led cloud providers to introduce a new model, known as serverless computing, in which the customer provides *only* their code, without having to configure its environment. Such “function as a service” (FaaS) platforms are now available as AWS Lambda [4], Google Cloud Functions [10], Azure Functions [18], and Apache OpenWhisk [5]. These platforms provide a model in which: (1) user code is invoked whenever some event occurs (e.g., an HTTP API request), runs to completion, and nominally stops running (and being billed) after it completes; and (2) there is no state preserved between separate invocations of the user code. Property (2) enables easy auto-scaling of the function as load changes.

Because these services execute within a cloud provider’s infrastructure, they benefit from low-latency access to other cloud services. In fact, acting as an access-control proxy is a recurring microservice pattern: receive an API request from a user, validate it, then access a backend storage service (e.g., S3) using the service’s credentials.

In this paper, we explore a design intended to reduce the tension between two of the desiderata for cloud functions: low latency invocation and low cost. Contemporary invocation techniques exhibit high latency with a large tail; this is unsuitable for many modern distributed systems which involve high-fanout communication, sometimes performing thousands of lookups to handle each user request. Because user-visible response time often depends on the tail latency of the slowest chain of dependent responses [7], shrinking the tail is crucial [11, 24, 16, 12].

Thus we seek to reduce the invocation latency and improve predictability, a goal supported by the impressively low network latencies available in modern datacenters. For example, it now takes $< 20\mu s$ to perform an RPC between two machines in Microsoft Azure’s virtual machines [9]. We believe, however, that fully leveraging this improving network performance will require reducing microservices’ invocation latencies to the point where the network is once again the bottleneck.

We further hypothesize—admittedly without much proof for this chicken-and-egg scenario—that substantially reducing both the latency and cost of running intermittently-used services will enable new classes and scales of applications for cloud functions, and in the remainder of this paper, present a design that achieves this. As Lampson noted, there is power in making systems “fast rather than general or powerful” [14], because fast building blocks can be used more widely.

Of course, a microservice is only as fast as the slowest service it relies on; however, recall that many such services are offered in the same clouds and datacenters as serverless platforms. Decreasing network latencies will push these services to respond faster as well, and new stable storage technologies such as 3D XPoint (projected to offer sub-microsecond reads and writes) will further accelerate this trend by offering lower-latency storage.

In this paper, we propose a restructuring of the serverless model centered around low-latency: *lightweight microservices* run in *shared processes* and are isolated primarily with language-based *compile-time guarantees* and *fine-grained preemption*.

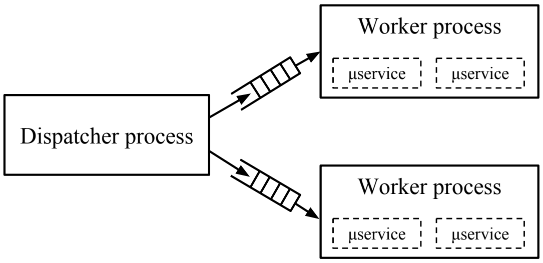

Figure 1: Language-based isolation design. The dispatcher process uses shared in-memory queues to feed requests to the worker processes, each of which runs one user-supplied microservice at a time.

2 Motivation

Our decision to use language-based isolation is based on two experimental findings: (1) Process-level isolation is too slow for microsecond-scale user functions. (2) Commodity CPUs support task preemption at microsecond scale. We conducted our experiments on an Intel® Xeon® E5-2683 v4 server (16 cores, 2.1 GHz) and Linux 4.13.0.[1]

2.1 Process-level isolation is too slow

We use a single-machine experiment to evaluate the invocation overhead of different isolation mechanisms: Microservices run on 14 *worker* CPU cores. Another core runs a *dispatcher* process that launches microservices on the workers. All requests originate at the dispatcher (which in a full serverless platform would forward from a cluster scheduler); it schedules ≤14 microservices at a time, one per worker core, choosing from a pool of 5,000.

To provide a comparison against contemporary system designs, we use two different isolation mechanisms:

1. **Process-based isolation:** Each microservice is a separate process. We expect this approach to exhibit latency at least as low as the container isolation common in contemporary serverless deployments.
2. **Language-based isolation:** Each worker core hosts a single-threaded *worker process* that directly executes different microservices, one at a time. In this approach, shown in Figure 1, a worker process runs a microservice by calling its registered function; we assume that the microservice function can be isolated from the worker process with language-based isolation techniques that we discuss in Section 3. The dispatcher schedules microservices on worker processes by sending them requests on a shared memory queue, which idle worker processes poll.

We use 5,000 copies of a Rust microservice that simply records a timestamp: latency is measured between when the dispatcher invokes a microservice and the time that microservice records. There are two experiment modes:

Microservices		Latency (µs)		Throughput
Resident?	**Isolation**	**Median**	**99%**	**(M invoc/s)**
Warm-start	Process	8.7	27.3	0.29
	Language	1.2	2.0	5.4
Cold-start	Process	2845.8	15976.0	–
	Language	38.7	42.2	–

Table 1: Microservice invocation performance

Warm-start requests. We first model a situation where all of the microservices are already resident on the compute node. In the case of process-based isolation, the dispatcher launches all 5,000 microservices at the beginning of the experiment, but they all block on an IPC call; the dispatcher then invokes each microservice by waking up its process using a UDP datagram. In the case of language-based isolation, the microservices are dynamic libraries preloaded into the worker processes.

Table 1 shows the latency and throughput of the two methods. We find that the process-based isolation approach takes 9 µs and achieves only 300,000 warm microservice invocations per second. In contrast, language-based isolation achieves 1.2 µs latency (with a tail of just 2.0 µs) and over 5 million invocations per second.

Considering that the FaRM distributed computing platform achieved mean TATP transaction commit latencies as low as 19 µs in 2015 [8], a 9 µs microservice invocation delay represents almost 50% overhead for a microservice providing a thin API gateway to such a backend. We therefore conclude that even in the average case, process-based isolation is too slow for microsecond-scale scheduling. Furthermore, IPC overhead limits invocation throughput.

Process-based isolation also has a higher memory footprint: loading the 5,000 trivial microservices consumes 2 GiB of memory with the process-based approach, but only 1.3 GiB with the language-based one. However, this benefit may reduce as microservices' code sizes increase.

Cold-start requests. Achieving ideal wakeup times is possible only when the microservices are already resident, but the tail latency of the serverless platform depends on those requests whose microservices must be loaded before they can be invoked. To assess the difference between process-based and language-based isolation in this context, we run the experiment with the following change: In the former case, the dispatcher now launches a transient microservice process for each request by `fork()/exec()`'ing. In the latter, the dispatcher asks a worker to load a microservice's dynamic library (and unload it afterward). The results in Table 1 reveal an order-of-magnitude slip in the language-based approach's latency; however, this is overshadowed by the three orders of magnitude increase for process-based isolation.

[1] Source code for the benchmarks in this paper is available from https://github.com/efficient/microservices_microbenchmarks.

2.2 Intra-process preemption is fast

In a complete serverless platform, some cluser-level scheduler would route incoming requests to individual worker nodes. Since we run user-provided microservices directly in worker processes, a rogue long-running microservice could thwart such scheduling by unexpectedly consuming the resources of a worker that already had numerous other requests queued. We hypothesize that, in such situations, it is better for tail latency to preempt the long microservice than retarget the waiting jobs to other nodes in real time. (Only the compute node already assigned a request is well positioned to know whether that request is being excessively delayed: whereas other nodes can only tell that the request hasn't yet *completed*, this node alone knows whether it has been *scheduled*.) At our scale, this means a preemption interval up to two orders of magnitude faster than Linux's default 4 ms process scheduling quantum.

Fortunately, we find that high-precision event timers (HPETs) on modern CPUs are sufficient for this task. We measure the granularity and reliability of these timers as follows: We install a signal handler and configure a POSIX timer to trigger it every T μs. Ideally, this handler would always be called exactly T μs after its last invocation; we measure the deviation from T over 65,535 iterations. We find that the variance is smaller than 0.5 μs for $T \geq 3$ μs. This shows that intra-process preemption is fast and reliable enough for our needs.

3 Providing Isolation

Consolidating multiple users' jobs into a single process requires addressing security and isolation. We aim to do it without compromising our ambitious performance goals.

Our guiding philosophy for achieving this is "language-based isolation with defense in depth." We draw inspiration from two recently-published systems whose own demanding performance requirements drove them to perform similar coalescing of traditionally independent components: NetBricks [19] is a network functions runtime for providing programmable network capabilities; it is unique among this class of systems for running third-party network functions in-process rather than in VMs. Tock [15] is an embedded microkernel whose servers ("capsules") form a common compilation unit and communicate using type-safe function calls. As their primary defense against untrusted code, both systems leverage Rust [3], a new type-safe systems programming language.

Rust is a strongly-typed, compiled language that uses a lightweight runtime similar to C. Unlike many other modern systems languages, Rust is an attractive choice for predictable performance because it does not use a garbage collector. It provides strong memory safety guarantees by focusing on "zero-cost abstractions" (i.e., those that can be compiled down to code whose safety is assured without runtime checks). In particular, safe Rust code is guaranteed to be free of null or dangling pointer dereferences, invalid variable values (e.g., casts are checked and unions are tagged), reads from uninitialized memory, mutations of non-`mut` data (roughly the equivalent of C's `const`), and data races, among other misbehaviors [22].

We require each microservice to be written in Rust (although, in the future, it might be possible to support subsets of other languages by compiling them to safe Rust), giving us many aspects of the isolation we need. It is difficult for microservices to crash the worker process, since most segmentation faults are prevented, and runtime errors such as integer overflow generate Rust panics that we can catch. Microservices cannot get references to data that does not belong to them thanks to the variable and pointer initialization rules.

Given our performance goals, there is a crucial isolation aspect that Rust does not provide: there is nothing to stop users from monopolizing the CPU. Our system, however, must be preemptive. We are unaware of existing preemption techniques that work at microsecond scales. Note that coroutine-like cooperative multitasking approaches (such as lightweight threads in Go [2] and Erlang [1]) are not preemptive, so they do not work for us. We briefly discuss our solution to this in the following section; it depends on installing a `SIGALRM` handler and ensuring that trusted code within the process handles the signal.

Our defense-in-depth comes from using lightweight operating-system protections to block access to certain system calls, as well as the proposed mechanisms in Section 6. Some system calls must be blocked to have any defense at all; otherwise, the microservice could create kernel threads (e.g., `fork()`), create competition between threads (e.g., `nice()`), or even terminate the entire worker (e.g., `exit()`). Finally, user functions should not have unmonitored file system access.

We propose to block system calls using Linux's `seccomp()` system call [20]; each worker process should call this during initialization to limit itself to a whitelisted set of system calls. Prior to lockdown, the worker process should install a `SIGSYS` handler for regaining control from any microservice that attempts to violate the policy.

4 Providing Preemption

The system must be able to detect and recover from microservices that, whether maliciously or negligently, attempt to run for longer than permitted. The two parts of this problem are (1) regaining control of the CPU and (2) aborting and cleaning up after the user code.

As proposed in Section 2, regaining control of the CPU happens when a signal (`SIGALRM`) from the kernel transfers control to the worker process's handler.[2] The handler then checks how long the current microservice

[2] For defense in depth, the worker process should be prevented from subsequently modifying this signal-handling configuration.

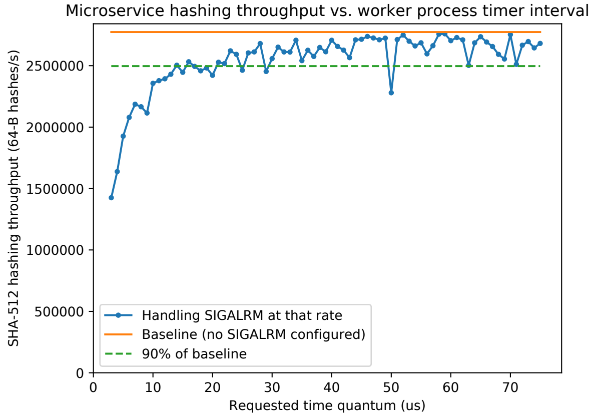

Figure 2: Effect of `SIGALRM` quantum on hashing tput.

has been running and decides whether it should be killed. (We register the handler using the `SA_RESTART` flag to `sigaction()` so that any interrupted blocking syscalls are restarted transparently.) However, there remain three important questions:

For how long should each microservice be allowed to run? Assume that each core executes one user task at a time and that all microservice functions are pre-compiled and resident (warm invocation). We define L to be the desired warm invocation latency, B to be the runtime budget allotted to each microservice, and r_c to be the remaining runtime of the microservice on CPU c. Thus, in the worst case (where all tasks are executing for their entire allotted time) the probability that the incoming microservice will have somewhere to run in time to meet the invocation latency SLO is given by:

$$p(r_{\text{min}} \leq L) = \sum_{c \in C} p(r_c \leq L) = |C| \frac{L}{B} \qquad (1)$$

Given the 14 cores in our setup and imagining we want to keep the 99% tail, $p(r_{\text{min}} \leq L) = 0.99$, to an L of 8 μs, we need to kill tasks running for more than B = 113 μs.

How often should the handler execute (the *quantum*)? We showed in Section 2 that microsecond-scale preemption is *achievable*, but can it be done *efficiently*? To find out, we wrote a microservice that measures the throughput of computing SHA-512 hashes over 64 B of data at a time. We then subjected its worker process to `SIGALRM`s, varying the quantum and observing the resulting hashing throughput. Figure 2 illustrates that by a quantum of about 20 µs, throughput had reached around 90% of baseline. Considering this performance degradation, acceptable we adopt this quantum and prescribe a runtime budget of 113 - 20 = 93 µs so that we can kill over-budget microservices in time to avoid violating our tail latency SLO.

How do we clean up a terminated microservice? We now discuss our mechanism for aborting and cleaning up after a microservice exceeds its runtime budget. POSIX signal handlers receive as an argument a pointer to their *context*, a snapshot of the process's PCB (process control block) at the moment before it received the signal. When the handler returns, the system will transfer control back to the point described by the context, so a naïve way for our worker processes to regain control would be to reset its GPRs (general-purpose registers) to values recorded just before the worker's tight scheduling loop. This approach, however, would not release the microservice's state or memory allocations back to the worker.

One of the few heavyweight components of the Rust runtime is panic handling, reminiscent of C++'s exception handling. The compiler inserts landing pads into each function that call the destructors for the variables in its stack frame: if the program ever panics, the standard library uses these to unwind the stack. We co-opt this functionality by having the `SIGALRM` handler set its context to raise an explicit panic in a fake stack frame just above the real top of the stack.

Section 6 discusses the limitations and security ramifications of this approach.

5 Deployment

We now describe our microservices in the broader context of our full proposed serverless system. We clarify their lifecycle, interactions with the compute nodes, and the trust model for the cloud provider.

Users submit their microservices in the form of Rust source code, allowing the serverless operator to pass the `-Funsafe-code` compilation flag to reject any `unsafe` code. This process need not occur on the compute nodes, provided the deployment server tasked with compilation runs the same version of the Rust compiler.[3] The operator needs to trust the compiler, standard library, and any libraries against which it will permit the microservice to link (since they might contain `unsafe` code), but importantly need not worry about the microservice itself.

We believe that restricting microservices to a specific list of permitted dependencies is reasonable. Any library that contains only safe Rust code could be whitelisted without review. To approximate the size of such a list given the current Rust ecosystem, we turn to a 2017 study [6] by the Tock authors that found just under half of the Rust package manager's top 1000 most-downloaded libraries to be free of unsafe code. They caution that many of those packages have unsafe dependencies, but reviewing a relatively small number of popular libraries would open up the majority of the most popular packages.

If the application compiles (is proven memory-safe) and links (depends only on trusted libraries) successfully, the deployment server produces a shared object file, which the provider then distributes to each compute node on which it might run. Then, in order to ensure that invokers will experience the warm-start latencies discussed in Section 2,

[3] This restriction exists because, as of the latest release (1.23.0) of the compiler, Rust does not have a stable ABI.

those nodes' dispatcher processes should instruct one or more of their workers to preload the dynamic library. If the provider experiences too many active microservices for its available resources, it can unload some libraries; on their next invocation, they will experience higher (cold start) invocation latencies as they synchronously load the dynamic library.

6 Future Work

As noted above, our exploration is preliminary; this section outlines several open questions. These questions fall into two categories: shortcomings in our current implementation and defense-in-depth safeguards against unexpected failures (e.g., compiler bug or the operator allowing use of a buggy or malicious library).

Non-reentrancy. Our use of Rust panics to unwind the stack during preemption can corrupt the internal state of non-reentrant functions (e.g., Rust's dynamic allocator). Possible fixes include blacklisting these functions and delaying preemption until they are finished or replacing the problematic function with a safe one (e.g., a custom memory allocator).

Host process. Our current implementation does not provide isolation between the dispatcher and worker processes. We plan to apply standard OS techniques to reduce the chance of interference by a misbehaving worker. Examples include auditing interactions with the shared memory region to ensure invalid or inconsistent data originating from a worker cannot create an unrecoverable dispatcher error; handling the `SIGCHLD` signal to detect a worker that has somehow crashed; and keeping a recovery log in the dispatcher process so that any user jobs lost to a failed worker process can be reassigned to operational workers.

Further defense in depth with ERIM. ERIM outlines a set of techniques and binary rewriting tools useful for using Intel's Memory Protection Keys to restrict memory access by threads within a process [23]. While preliminary and without source yet available, this appears to be an attractive approach for defense-in-depth both within worker processes and between the workers and the dispatcher.

Library functions. As with system calls, there may exist library functions in Rust (and certainly in libc, which we deny by default) that are unsafe for microservices to access. Because the Rust standard library requires unsafe code, defense-in-depth suggests that a whitelisting-based approach should be employed for access to its functions. Certainly library functions must be masked—for example, our use of Rust's panic handler for preemption means that we must deny microservice code the ability to catch the panic and return to execution. Although we mitigate this possibility by detecting and blacklisting microservices that fail to yield under a SIGALRM, it would be desirable to block such behavior entirely. Possible options include using the dynamic linker to interpose stub implementations or linking against a custom build of the library, or using more in-depth static analysis.

Resource leaks. Safe Rust code provides memory safety, but it cannot prevent memory leaks [21]. For example, destructor invocation is not guaranteed using Rust's default reference counting-based reclamation; therefore, unwinding the stack during preemption is not guaranteed to free all of a microservice's memory or other resources. Potential solutions are interposing on the dynamic allocator to record tracking information (likely proving expensive) or using per-microservice heaps that main worker process can simply deallocate when terminating a microservice. The worker can also deallocate other resources, such as unclosed file descriptors. If these checks end up being too expensive, the worker could execute its cleanup after a certain number of microservices have run or when the load is sufficiently low.

Side channels. Our current approach is vulnerable to side-channel attacks [17, 13]. For example, microservices have access to the memory addresses and timings of dynamic memory allocations, as well as the numbers of opened file descriptors. Although side-channels exist in many systems, the short duration of microservice functions may make mounting such attacks more challenging; nevertheless, standard preventative practices found in the literature should apply.

Despite the security challenges of running microservice as functions, worker processes are still well-isolated from the rest of the system. Worst case, the central dispatcher process can restart a failed worker and automatically ban suspect microservices.

7 Conclusion

In order to permit applications to fully leverage the 10s of μs latencies available from the latest datacenter networks, we propose a novel design for serverless platforms that runs user-submitted microservices within shared processes. This structure is possible because of language-based *compile-time memory safety guarantees* and *microsecond-scale preemption*. Our implementation and experiments demonstrate that these goals of high throughput, low invocation latency, and rapid preemption are achievable on today's commodity systems, while potentially supporting hundreds of thousands of concurrently available microservices on each compute node. We believe that these two building blocks will enable new FaaS platforms that can deliver single-digit microsecond invocation latencies for lightweight, short-lived tasks.

Fast and Concurrent RDF Queries using RDMA-assisted GPU Graph Exploration

Siyuan Wang, Chang Lou, Rong Chen, Haibo Chen
Institute of Parallel and Distributed Systems, Shanghai Jiao Tong University

Abstract

RDF graph has been increasingly used to store and represent information shared over the Web, including social graphs and knowledge bases. With the increasing scale of RDF graphs and the concurrency level of SPARQL queries, current RDF systems are confronted with inefficient concurrent query processing on massive data parallelism, which usually leads to suboptimal response time (latency) as well as throughput.

In this paper, we present Wukong+G, the first graph-based distributed RDF query processing system that efficiently exploits the hybrid parallelism of CPU and GPU. Wukong+G is made fast and concurrent with three key designs. First, Wukong+G utilizes GPU to tame random memory accesses in graph exploration by efficiently mapping data between CPU and GPU for latency hiding, including a set of techniques like query-aware prefetching, pattern-aware pipelining and fine-grained swapping. Second, Wukong+G scales up by introducing a GPU-friendly RDF store to support RDF graphs exceeding GPU memory size, by using techniques like predicate-based grouping, pairwise caching and look-ahead replacing to narrow the gap between host and device memory scale. Third, Wukong+G scales out through a communication layer that decouples the transferring process for query metadata and intermediate results, and leverages both native and GPUDirect RDMA to enable efficient communication on a CPU/GPU cluster.

We have implemented Wukong+G by extending a state-of-the-art distributed RDF store (i.e., Wukong) with distributed GPU support. Evaluation on a 5-node CPU/GPU cluster (10 GPU cards) with RDMA-capable network shows that Wukong+G outperforms Wukong by 2.3X-9.0X in the single heavy query latency and improves latency and throughput by more than one order of magnitude when facing hybrid workloads.

1 Introduction

Resource Description Framework (RDF) is a standard data model for the Semantic Web, recommended by W3C [5]. RDF describes linked data as a set of triples forming a highly connected graph, which powers information retrievable through the query language SPARQL. RDF and SPARQL have been widely used in Google's knowledge graph [22] and many public knowledge bases, such as DBpedia [1], PubChemRDF [38], Wikidata [8], Probase [59], and Bio2RDF [10].

The drastically increasing scale of RDF graphs has posed a grand challenge to fast and concurrent queries over large RDF datasets [17]. Currently, there have been a number of systems built upon relational databases, including both centralized [40, 12, 58] and distributed [48, 44, 23] designs. On the other hand, Trinity.RDF [62] uses graph exploration to reduce the costly join operations in intermediate steps but still requires a final join operation. To further accelerate distributed query processing, Wukong [51] leverages RDMA-based graph exploration to support massively concurrency queries with low latency requirement and adopts full-history pruning to avoid the final join operation.

Essentially, many RDF queries have embarrassing parallelism, especially for *heavy* queries, which usually touch a large portion of the RDF graph on an excessive amount of paths using graph exploration. This poses a significant challenge even for multicore CPUs to handle them efficiently, which usually causes lengthy execution time. For example, the latency differences among seven queries in LUBM [7] is more than 3,000X (0.13ms and 390ms for Q5 and Q7 accordingly). This may cause one heavy query block all other queries, substantially extending the latency of other queries and dramatically impairing the throughput of processing concurrent queries [51]. This problem has also gained increased attention [45].

In this paper, we present Wukong+G[1] with a novel design that exploits a distributed heterogeneous CPU/GPU cluster to accelerate heterogeneous RDF queries based on distributed graph exploration. Unlike CPUs pursuing the minimized execution time for single instructions, GPUs are designed to provide high computational throughput for massive simple control-flow operations with little or no control dependency. Such features expose a design space to distribute hybrid workloads by offloading heavy queries to GPUs. Nevertheless, different from many traditional GPU workloads, RDF graph queries are memory-intensive instead of compute-intensive: there are limited arithmetic operations and most of the processing time is spent on random memory accesses. This unique feature implies that the key of performance optimizations in Wukong+G is on *smart*

memory usage rather than improving the computation algorithm. Wukong+G is made fast and concurrent with the following key designs:

GPU-based query execution (§4.1). To achieve the best performance for massive random accesses demanded by heavy queries, Wukong+G leverages the many-core feature and latency hiding ability of GPUs. Besides making use of hardware advantages, Wukong+G surmounts the limitations of GPU memory size and PCIe (PCI Express) bandwidth by adopting *query-aware prefetching* to mitigate the constraints on graph size, *pattern-aware pipelining* to hide data movement cost, and *fine-grained swapping* to minimize data transfer size.

GPU-friendly RDF store (§4.2). To support desired CPU/GPU co-execution pattern while still enjoying the fast graph exploration, Wukong+G follows a distributed in-memory key/value store and proposes a *predicate-based grouping* to aggregate keys and values with the same predicate individually. Wukong+G further smartly manages GPU memory as a cache of RDF store by supporting *pairwise caching* and *look-ahead replacing*.

Heterogeneous RDMA communication (§4.3). To preserve better communication efficiency in a heterogeneous environment, Wukong+G decouples the transferring process of query metadata and intermediate results for SPARQL queries. Wukong+G uses native RDMA to send metadata like query plan and current step among CPUs, and uses GPUDirect RDMA to send current intermediate results (history table) directly among GPUs. This preserves the performance boost brought by GPUs from potential expensive CPU/GPU data transfer cost.

We have implemented Wukong+G by extending Wukong [51], a state-of-the-art distributed RDF query system to support heterogeneous CPU/GPU processing. To confirm the performance benefit of Wukong+G, we have conducted a set of evaluations on a 5-node CPU/GPU cluster (10 GPU cards) with RDMA-capable network. The experimental results using the LUBM [7] benchmark show that Wukong+G outperforms Wukong by 2.3X-9.0X in the single heavy query latency and improves latency and throughput by more than one order of magnitude when facing hybrid workloads.

2 Background and Motivation

2.1 RDF and SPARQL

An RDF dataset is composed by triples, in the form of $\langle subject, predicate, object \rangle$. To construct a graph (aka RDF graph), each triple can be regarded as a directed edge (*predicate*) connecting two vertices (from *subject* to *object*). In Fig. 1, a simplified sample RDF graph of LUBM dataset [7] includes two professors (Logan and Erik), three students (Marie, Bobby, and Kurt), and two courses (OS and DS).[2] There are also three predicates (teacherOf (to), advisor (ad) and takeCourse (tc)) to link them. Two types of indexes, *predicate* and *type*, are added to accelerate query processing on RDF graph [51].

SPARQL, a W3C recommendation, is a standard query language developed for RDF graphs, which defines queries regarding graph patterns (GP). The principal part of SPARQL queries is as follows:

$$\mathsf{Q} := \mathsf{SELECT\ RD\ WHERE\ GP}$$

where (RD) is the *result description* and GP consists of *triple patterns* (TP). The triple pattern looks like a normal triple except that any *constant* can be replaced by a *variable* (e.g., ?X) to match a subgraph. The result description RD contains a subset of variables in the triple patterns (TP) to define the query results. For example, the query Q_H in Fig. 1 asks for professors (?X), courses (?Y) and students (?Z) such that the professor advises (ad) the student who also takes a course (tc) taught by (to) the professor. After exploring all three TPs in Q_H on the sample graph in Fig. 1, the exact match of RD (?X, ?Y and ?Z) is only a binding of Logan, OS, and Bobby.

Query processing on CPU. There are two representative approaches adopted in state-of-the-art RDF systems, (relational) triple join [40, 58, 12, 23] and graph exploration [62, 51]. A recent study [51] found that graph exploration with full-history pruning can provide low latency and high throughput for concurrent query processing. Therefore, we illustrate this approach to demonstrating the query processing on CPU with the sample RDF graph and SPARQL query (Q_H) in Fig. 1.

As shown in Fig. 2, all triple patterns of the query (Q_H) will be iterated in sequence (❶) to generate the results (*history table*) by exploring the graph, which is stored in an in-memory key/value store. According to the variable (?Y) of the current triple pattern (TP-2), each row of a certain column in the history table (❷) will be combined with the constant (takesCourse) of the triple pattern as

[2] Since the special predicate type (ty) is used to group a set of entities, we follow Wukong [51] to treat every type (e.g., professor (P)) as an index, the same as predicates (e.g., advisor (ad)).

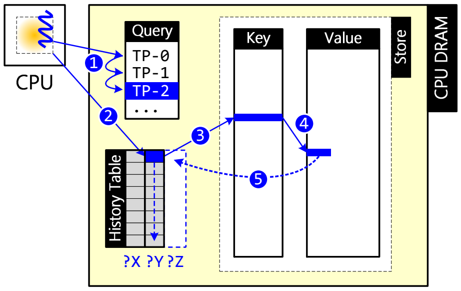

Fig. 2: The execution flow of query processing on CPU.

the key (❸) to retrieve the value (❹). The value will be appended to a new column (?Z) of the history table (❺). Note that an extra triple pattern (TP-0) from an index vertex (teacherOf) will be used to collect all start vertices satisfying a variable (?X) in TP-1.

Full-history pruning. Since processing RDF query by graph exploration needs to traverse the RDF graph, it is crucial to prune infeasible paths for better performance. There are basically two approaches: partial-history pruning [62], by inheriting partial history information (intermediate results) from previous steps of traversing to prune the following traversal paths; and full-history pruning [51], by passing the history information of all previous traversal steps for pruning. Wukong has exploited full-history pruning to prune unnecessary intermediate results precisely and *make all traversal paths completely independent*. Thanks to the fast RDMA-capable network as well as the relative cost-insensitivity of one-sided RDMA operations regarding payload size, full-history pruning is very effective and efficient to handle *concurrent* queries.

Workload heterogeneity. Prior work [62, 23, 51] has observed that there are two distinct types of SPARQL queries: *light* and *heavy*. Light queries (e.g., Q_L in Fig. 1) usually start from a (constant) normal vertex and only explore *a few* paths regardless of the dataset size. In contrast, heavy queries (e.g., Q_H in Fig. 1) usually start from an (type or predicate) index vertex and explore *massive amounts* of paths, which increases along with the growth of dataset size. The top of Fig. 3 demonstrates the number of paths explored by two typical queries (Q5 and Q7) on LUBM-10240 (10 vs. 16,000,000).

The *heterogeneity* in queries can result in tremendous latency differences on state-of-the-art RDF stores [51], even reaching more than 3,000X (0.13ms and 390ms for Q5 and Q7 on LUBM-10240 accordingly).[3] Therefore, the multi-threading mechanism is widely used by prior work [23, 62, 51] to improve the performance of heavy queries. However, such approach is intrinsically restricted by the limited computation resource of CPU. Currently, the maximum number of cores in a commercial CPU processor is usually less than 16. Moreover, the lengthy queries will significantly extend the latency of light queries and impair the throughput of processing concurrent queries. Some CPU systems like Oracle PGX [4] try to address this issue by adopting priority mechanism. However, with no variation of computing power, the sacrifice of user experience for one type of queries is unavoidable.

2.2 Hardware Trends

Hardware heterogeneity. With the prevalence of computational workloads (e.g., machine learning and data mining applications), it is now not uncommon to see server-class machines equipped with GPUs in the modern datacenter. As a landmark difference compared to CPU, the number of GPU cores (threads) can easily exceed two thousand, which far exceeds existing multicore CPU processors. As shown in Fig. 3, in a typical *heterogeneous* (CPU/GPU) machine, CPU and GPU have their private memory (DRAM) connected by PCIe with limited bandwidth (10GB/s). Compared to host memory (CPU DRAM), device memory (GPU DRAM) has much higher bandwidth (288GB/s vs. 68GB/s) but less capacity (12GB vs. 128GB). Generally, GPU is optimized for performing massive, simple and independent operations with intensive accesses on a relatively small memory footprint.

Fast communication: GPUDirect with RDMA. GPUDirect is a family of technologies that is continuously developed by NVIDIA [3]. Currently, it can support various efficient communications, including inter-node, intra-node, and inter-GPU. RDMA (Remote Direct Memory Access) is a networking feature to directly access the memory of a remote machine, which can bypass remote CPU and operating system, and avoid redundant memory copy. Hence, it has unique features like high speed, low latency and low CPU overhead. GPUDirect RDMA has been introduced in NVIDIA Kepler-class GPUs, like Tesla and Quadro series. This technique enables direct data transfer between GPUs by InfiniBand NICs as the name suggests [2].

2.3 Opportunities

Though prior work (e.g., Wukong [51]) has successfully demonstrated the low latency and high throughput of running light queries solely by leveraging graph exploration with full-history pruning, it is still incompetent to handle heavy queries efficiently. This leads to suboptimal performance when facing hybrid workloads comprising both light and heavy queries.

This problem is not due to the design and implementation of existing state-of-the-art systems, which have been heavily optimized by several approaches including multi-threading [62, 23, 51] and work-stealing scheme [51]. We attribute the performance issues mainly to the lim-

[3] Detailed experimental setup and results can be found in §6.

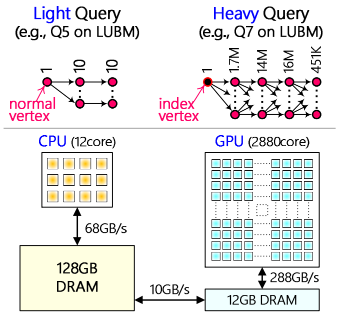

Fig. 3: Motivation of Wukong+G

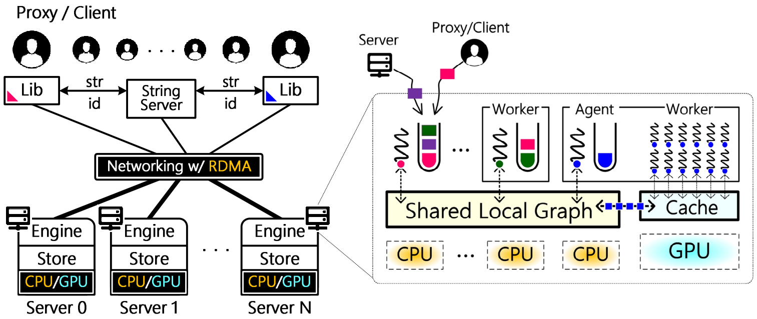

Fig. 4: The architecture overview of Wukong+G.

itation of handling hybrid workloads (light and heavy queries) on the homogeneous hardware (CPU), which can provide neither sufficient computation resources (a few cores) nor efficient data accesses (low bandwidth).

GPU is a good candidate to host heavy queries. First, the graph exploration strategy for query processing heavily relies on traversing massive paths on the graph store, which is a typical memory-intensive workload targeted by GPU's high memory bandwidth. Second, the memory latency hiding capability of GPU is inherently suitable for the random traversal on RDF graph, which is notoriously slow due to poor data locality. Third, every traversal path with the full-history pruning scheme is entirely independent, which can be fully parallelized on thousands of GPU cores.

In summary, the recent trend of hardware heterogeneity (CPU/GPU) opens an opportunity for running different queries on different hardware; namely, *running light queries on CPUs and heavy queries on GPUs*.

3 Wukong+G: An Overview

System architecture. An overview of Wukong+G's architecture is shown in Fig. 4. Wukong+G assumes running on a modern cluster connected with RDMA-capable fast networking, where each machine is equipped with one or more GPU cards. The GPU's device memory is treated as a cache for the large pool of the CPU's host memory. Wukong+G targets various SPARQL queries over a large volume of RDF data; it scales by partitioning the RDF graph into a large number of shards across multiple servers. Wukong+G may duplicate edges to make sure each server contains a self-contained subgraph (e.g., no dangling edges) of the input RDF graph for better locality. Note that there are no replicas of vertices in Wukong+G as no vertex data needs to synchronize. Moreover, Wukong+G also creates index vertices [51] for types and predicates to assist query processing.

Similar to prior work [51], Wukong+G follows a decentralized, shared-nothing, main-memory model on the server side. Each server consists of two separate layers: query engine and graph store. The query engine layer employs a worker-thread model by running N *worker threads* atop N CPU cores and dedicates one CPU core to run an *agent thread*; the agent thread will assist the worker threads on GPU cores to run queries. Each worker/agent thread on CPU has a task queue to continuously handle queries from clients or other servers, one at a time. The graph store layer adopts an RDMA-friendly key/value store over a distributed hash table to support a partitioned global address space. Each server stores a partition of the RDF graph, which is shared by all of worker/agent threads on the same server.

Wukong+G uses a set of dedicated proxies to run the client-side library and collect queries from massive clients. Each proxy parses queries into a set of stored procedures and generates optimal query plans using a cost-based approach. The proxy will further use the *cost* to classify a query into one of two types (light or heavy), and deliver it to a worker or agent thread accordingly.[4]

Basic query processing on GPU. In contrast to the query processing on CPU, which has to perform a triple pattern with massive paths in a verbose loop style (see Fig. 2), Wukong+G can fully parallelize the graph exploration with thousands of GPU cores. The basic approach is to dedicate one CPU core to perform the *control-flow* of the query, and use massive GPU cores to parallelize the *data-flow* of the query. As shown in Fig. 5, the agent thread on CPU core will first read the next triple pattern (❶) of the current query and prepare a cache of RDF datasets on GPU memory (❷). After that, the agent thread will leverage all GPU cores to perform the triple pattern in parallel (❸). Each worker thread on GPU core can independently fetch a row in the history table (❹) and combine it with the constant (takesCourse) of the triple pattern (TP-2) as the key (❺). The value retrieved by the key (❻) will be appended to a new column (?Z) of the history table (❼). While the hybrid design seems intuitive, Wukong+G still faces three challenges to run SPARQL queries on GPUs, which will be addressed by the techniques in §4:

[4] The recent release of Wukong (https://github.com/SJTU-IPADS/wukong) introduced a new cost-based query planner for graph exploration, where the cost estimation is roughly based on the number of paths may be explored. Wukong+G uses a user-defined threshold for the cost to classify queries.

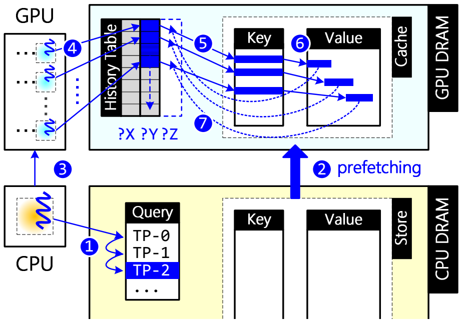

Fig. 5: The execution flow of query processing on CPU/GPU.

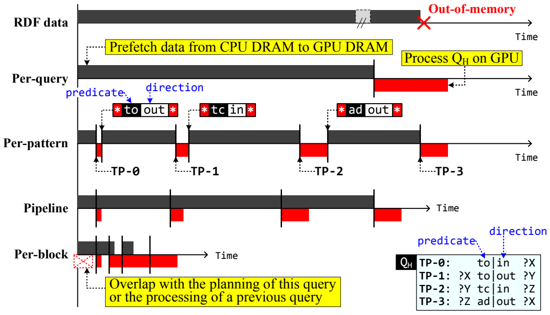

Fig. 6: The timeline of processing sample query (Q_H) on GPU.

C1: Small GPU memory. It is well known that GPU can obtain optimal performance only when the device memory (GPU DRAM) gets everything ready. Prior systems [62, 23, 51] can store an entire RDF graph in the host memory (CPU DRAM) since it is common that server-class machines equip with several hundred GBs of memory. However, this assumption does not apply to GPU since its current memory size usually stays less than 16GB. We should not allow device memory size to limit the upper bound of the supported working sets.

C2: Limited PCIe bandwidth. The memory footprint of SPARQL queries may touch arbitrary triples of the RDF graph. Therefore, the data transfer between CPU and GPU memory during query processing is unavoidable, especially for concurrent query processing. However, GPUs are connected to CPUs by PCIe (PCI Express), which has insufficient memory bandwidth (10GB/s). To avoid the bottleneck of data transfer, we should carefully design mechanisms to predict access patterns and minimize the number, volume and frequency of data swapping.

C3: Cross-GPU communication. With the increasing scale of RDF datasets and the growing number of concurrent queries, it is highly demanding that query processing systems can scale to multiple machines. Prior work [57, 51] has shown the effectiveness and efficiency of the partitioned RDF store and the worker-thread model. However, the intra-/inter-node communication between multiple GPUs has a long path: 1) device-to-host via PCIe; 2) host-to-host via networking; 3) host-to-device via PCIe. We should customize the communication flow for various participants to reduce the latency of network traffic.

4 Design

4.1 Efficient Query Processing on GPU

Facing the challenges like small GPU memory and limited PCIe bandwidth, we propose the following three key techniques to overcome them.

Query-aware prefetching. With the increase of RDF datasets, the limited GPU memory size (less than 16GB) is not enough to host the entire RDF graph. Wukong+G thus treats the GPU memory as a cache of CPU memory, and only ensures the necessary data is retained in GPU memory before running a query. However, it is non-trivial to decide the working set of a query accurately.

As shown in the second timeline of Fig. 6, Wukong+G proposes to just prefetch the triples with the *predicates* involved in a query, which can enormously reduce the memory footprint of a query from the entire RDF graph to the *per-query* scale. This assumption is based on two observations: 1) each query only touches a part of RDF graph; 2) the predicate of a triple pattern is commonly known (i.e., $\langle ?X, predicate, ?Y \rangle$). For example, the sample query (Q_H) only requires three predicates (teacherOf, takesCourse, and advisor), occupying about 3.7GB memory (0.3GB, 2.9GB, and 0.5GB respectively) for LUBM-2560.

Pattern-aware pipelining. For a query with many triple patterns, the total memory footprint of a single query may still exceed the GPU memory size. Fortunately, we further observe that the triple patterns of a query will be executed in sequence. It implies that Wukong+G can further reduce the demand for memory to the *per-pattern* scale. As shown in the third timeline of Fig. 6, Wukong+G can only prefetch the triples with a certain *predicate* that is used by the triple pattern will be immediately executed. Thus, for the sample query (Q_H) on LUBM-2560, the demand for GPU memory will further reduce to 2.9GB, the size of the maximum predicate (takesCourse).

Moreover, since the data prefetching and query processing are split into multiple independent phases, Wukong+G can use a *software pipeline* to create parallelism between the execution of the current triple pattern and the prefetching of the next predicate, as shown in the fourth timeline of Fig. 6. Note that it will also increase the memory footprint to the maximum size of two successive predicates (takesCourse and advisor).

Fine-grained swapping. Although the pattern-aware pipelining can overlap the latency of data prefetching and query processing, it is hard to perfectly hide the I/O cost due to limited bandwidth between system and

Table 1: A summary of optimizations for query processing on GPU. "$X|Y$" indicates XGB memory footprint and YGB data transfer. (†) The numbers are evaluated on 6GB GPU memory.

Granularity	Main Techniques	Q7 (GB) on LUBM-2560
Entire graph	Basic query processing	16.3 | 16.3
Per-query	Query-aware prefetching	5.6 | 5.6
Per-pattern	Pattern-aware pipelining	2.9 | 5.6
Per-block	Fine-grained swapping	2.9 | 0.7†

device memory (e.g., 10GB/s). For example, prefetching 2.9GB triples (takesCourse) requires about 300ms, which is even longer than the whole query latency (100ms). Therefore, Wukong+G adopts a fine-grained swapping scheme to maintain the triples cached in GPU memory. All triples with the same predicate will be further split into multiple fixed-size blocks, and the GPU memory will cache the triples in a best-effort way (§4.2). Consequently, the demand of memory will be further reduced to the *per-block* scale.

Moreover, the data transferring cost will also become the *per-block* scale, and all cached data on GPU memory can be reused by multiple triple patterns of the same query or even multiple queries. As shown in the fifth timeline of Fig. 6, when most triples of the required predicates have been retained in GPU memory, the prefetching cost can be perfectly hidden by query processing. Even for the first required predicate, Wukong+G still can hide the cost by overlapping it with the planning time of this query or the processing time of a previous query.

Table 1 summarizes the granularity of data prefetching on GPU memory, and shows the size of memory footprint and data transfer for a real case (Q7 on LUBM-2560). Note that Q7 is similar to Q_H but requires five predicates. The memory footprint of Q7 with fine-grained swapping is equal to the available GPU memory size (6GB) since Wukong+G only swaps out the triples of predicates on demand.

4.2 GPU-friendly RDF Store

Prior work [62, 51, 64] uses a distributed in-memory key/value store to physically store the RDF graph, which is efficient to support random traversals in graph-exploration scheme. In contrast to the intuitive design [62] that simply uses vertex ID (*vid*) as the key, and the in-/out-edge list (each element is a $[pid, vid]$ pair) as the value, Wukong [51] uses a combination of the vertex ID (*vid*), predicate ID (*pid*) and in/out direction (*d*) as the key (in the form of $[vid, pid, d]$), and the list of neighboring vertex IDs as the value (e.g., $[Logan, to, out] \longmapsto [DS]$ in the left part of Fig. 7).

This design can prominently reduce the graph traversal cost for both local and remote accesses. However, the triples (both key and value) with the same predicate are still sprinkled all over the store. It implies that the cost of prefetching keys and values for a triple pattern is extremely high or even impossible. Therefore, the *key/value store* on CPU memory should be carefully re-organized for heterogeneous CPU/GPU processing by aggregating all triples with the same predicate and direction into a *segment*. Furthermore, the key and value segments should be maintained in a fine-grained way (*block*) and be cached *in pairs*. Finally, the mapping between keys and values should be retained in the *key/value cache* on GPU memory, which uses a separate address space. Wukong+G proposes the following three new techniques to construct a GPU-friendly key/value store, as shown in the right part of Fig. 7.

Predicate-based grouping (CPU memory). Based on the idea of predicate-based decomposition in Wukong, Wukong+G adopts *predicate-based grouping* to exploit the predicate locality of triples and retains the encoding of keys and values. The basic idea is to partition the key space into multiple *segments*, which are identified by the combination of predicate and direction (i.e., $[pid, d]$). To preserve the support of fast graph exploration, Wukong+G still uses the hash function within the segment but changes the parameter from the entire key (i.e., $[vid, pid, d]$) to the vertex ID (*vid*). The number of keys and values in each segment are collected during loading the RDF graph and aligned to an integral multiple of the granularity of data swapping (*block*). To ensure that all values belonged to the triples with the same predicate are stored contiguously, Wukong+G groups such triples and inserts them together. Moreover, Wukong+G uses an indirect mapping to link keys and values, where the link is an *offset* within the value space instead of a direct pointer. As shown in the right part of Fig. 7, the triples required by TP-2 (i.e., $\langle Kurt, tc, DS\rangle$ and $\langle Bobby, tc, OS\rangle$) are aggregated together in both key and value spaces (the purple boxes).

Pairwise caching (GPU memory). To support fine-grained swapping, Wukong+G further splits each segment into multiple fixed-size blocks and stores them into *discontinuous* blocks of the cache on GPU memory, like $[Logan, to, out]$ and $[Erik, to, out]$. Note that the block size for keys and values can be different. Wukong+G follows the design on CPU memory to cache key and value blocks into separate regions on GPU memory, namely key cache and value cache. Wukong+G uses a simple table to map key and value blocks, and the link from key to value becomes the offset within the value block. Unlike the usual cache, the linked key and value blocks must be swapped in and out the (GPU) cache *in pairs*, like $[OS, tc, in]$ and $[Bobby]$ (the purple boxes). Thus, Wukong+G maintains a *bidirectional* mapping between the pair of cached key and value blocks. Moreover, a mapping table of block ID between RDF store (CPU) and cache (GPU) is used to re-translate the link between keys and values,

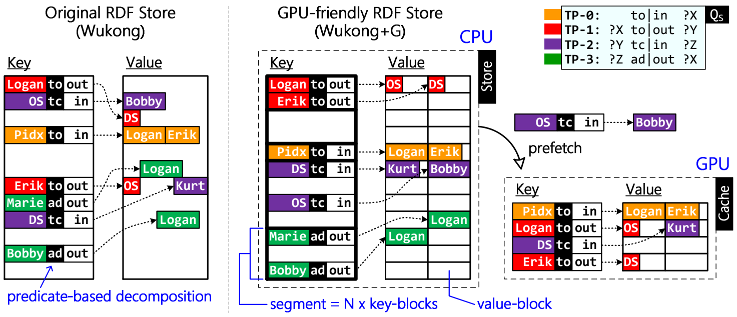

Fig. 7: The structure of GPU-friendly RDF store.

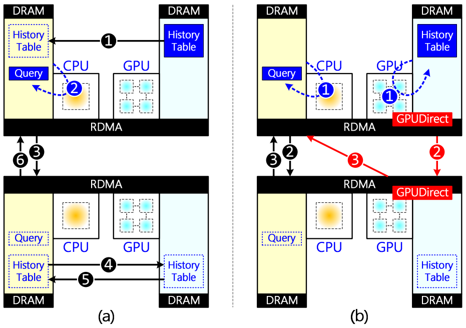

Fig. 8: Communication flow w/o and w/ GPUDirect.

when the pairwise blocks (key and value) are swapped in GPU memory.

Look-ahead replacement policy. The mapping table of block IDs between RDF store and cache records whether the block has been cached. Before running a triple pattern of the query, all of key and value blocks should be prefetched to the GPU memory. For example, the key $[OS, tc, in]$ and value $[Bobby]$ should be loaded into the cache before processing TP-2. Wukong+G proposes a *look-ahead LRU-based replacement policy* to decide where to store prefetched key and value blocks. Specifically, Wukong+G prefers to use free blocks first and then chooses the blocks that will not be used by the following triple patterns of this query (*look-ahead*), with the highest LRU score. The worst choice is the blocks will be used by the following triple patterns, and then the block of the farthest triple pattern will be replaced. Note that the replacement policies for keys and values are the same and there is at most a pair of key/value blocks will be swapped out due to the pairwise caching scheme.

For example, as shown in the right part of Fig. 7, before running the triple pattern TP-2, all key/value blocks of the predicate takeCourse (tc) should be swapped in the cache (the purple boxes). The value block with $[Bobby]$ can be loaded to a free block, while the key block with $[OS, tc, in]$ will replace the cached block with $[Pidx, to, in]$, since it was used by TP-0 with the highest LRU score.

4.3 Distributed Query Processing

Wukong+G splits the RDF graph into multiple disjoint partitions by a differentiated partitioning algorithm [51, 19] [5], and each machine hosts an RDF graph partition and launches many worker threads on CPUs and GPUs to handle concurrent light and heavy queries respectively. The CPU worker threads on different machines will only communicate with each other for (light) query processing, and it is the same to GPU worker threads for (heavy) query processing.

To handle light queries on CPU worker threads, Wukong+G simply follows the procedure (see Fig. 2) that has been successfully demonstrated by Wukong [51]. However, to handle heavy queries on GPU worker threads, the procedure (see Fig. 5) becomes complicated due to the assistance of (CPU) agent thread and the maintenance of (GPU) RDF cache.

Execution mode: fork-join. Prior work [51] proposes two execution modes, *in-place* and *fork-join*, for distributed graph exploration to migrate data and execution respectively. The in-place execution mode synchronously leverages one-sided RDMA `READ` to directly fetch data from remote machines, while the fork-join mode asynchronously splits the following query computation into multiple sub-queries running on remote machines. Wukong+G follows the design on CPU worker threads but only adopts the fork-join mode for query processing on GPU, because the in-place mode is usually inefficient for heavy queries [51] and migrating data from remote CPU memory to local GPU memory is still very costly even with RDMA operations.

In the fork-join mode, the agent thread will split the running query (metadata) with intermediate results (history table) into multiple sub-queries for the following query processing, and dispatch them to the task queue of agent threads on remote machines by leveraging one-sided RDMA `WRITE`. Therefore, multiple heavy queries can be executed on multiple GPUs concurrently in a time-sharing way. However, the current history table is located in GPU memory (see Fig. 8), such that it would be inefficient to fetch and split the table by using a single agent thread on CPU (❶ and ❷ in Fig. 8(a)). Therefore, Wukong+G leverages all GPU cores to partition the history table in fully parallel (❶ in Fig. 8(b)) using a dynamic task scheduling mechanism [47, 18].

Communication flow. To support fork-join execution, the sub-queries will be sent to target machines with their metadata (e.g., query plan and current step) and history table (intermediate results), and the history table will be sent back with final results at the end. As shown in Fig. 8(a), the query metadata will be delivered by one-sided RDMA operations between the CPU memory of

[5] The normal vertex (e.g., Logan) will be assigned to only one machine with all of its edges, while the index vertex (e.g., teacherOf) will be split and replicated to multiple machines with edges linked to normal vertices on the same machine.

Table 2: A collection of synthetic and real-life datasets. #T, #S, #O and #P mean the number of triples, subjects, objects and predicates respectively. (†) The size of datasets in raw NT format.

Dataset	#T	#S	#O	#P	Size†
LUBM-2560	352 M	55 M	41 M	17	58GB
LUBM-10240	1,410 M	222 M	165 M	17	230GB
DBPSB	15 M	0.3 M	5.2 M	14,128	2.8GB
YAGO2	190 M	10.5 M	54.0 M	99	13GB

two machines (❸ and ❻). In contrast, the history table has to go through a long path from local GPU memory to the remote GPU memory, and finally goes back to the local CPU memory. A detailed communication flow for history table (see Fig. 8(a)): 1) from local GPU memory to local CPU memory (❶, Device-to-Host); 2) from local CPU memory to remote CPU memory (❸, Host-to-Host); 3) from remote CPU memory to remote GPU memory (❹, Host-to-Device); 4) from remote GPU memory to remote CPU memory (❺, Device-to-Host); 5) from local CPU memory to remote CPU memory (❻, Host-to-Host).

GPUDirect [3] opens an opportunity for Wukong+G to directly write history table from local GPU memory to remote GPU and CPU memory. Hence, Wukong+G decouples the transferring process of query metadata and history table (❷ and ❷ in Fig. 8(b)), and further shortens the communication flow for history table by leveraging GPUDirect RDMA. It also avoids the contention on agent thread with the metadata transferring. A detailed communication flow for history table (see Fig. 8(b)): 1) from local GPU memory to remote GPU memory (❷, Device-to-Device); 2) from remote GPU memory to local CPU memory (❸, Device-to-Host).

Moreover, to mitigate the pressure on GPU memory when handling multiple heavy queries, Wukong+G choose to send the history table of pending queries from local GPU memory to the buffer on remote CPU memory first via GPUDirect RDMA, and delay the prefetching of history table from CPU memory to GPU memory till handling the query on GPU.

5 Implementation

Wukong+G prototype is implemented in 4,088 lines of C++/CUDA codes atop of the code base of Wukong. This section describes some implementation details.

Multi-GPUs support. Currently, it is not uncommon to equip every CPU socket with a separate GPU card for low communication cost and good locality. To support such multi-GPUs on a single machine, Wukong+G runs a separate server for each GPU card and several co-located CPU cores (usually a socket). All servers comply with the same communication mechanism via GPUDirect-capable RDMA operations, regardless of whether two servers share the same physical machine or not.

Too large intermediate results. In rare cases, the intermediate results may overflow the history buffer on GPU memory. For example, we witness this scenario in YAGO2 benchmark (§6.8) that a heavy query keeps spanning out without any pruning. Wukong+G can horizontally divide the intermediate results into multiple strips by row and only hold a single strip into the history table on GPU memory. The remaining strips will stay in CPU memory and be swapped in GPU memory one-by-one while processing a single triple pattern.

Table 3: The query performance (msec) on a single server.

LUBM-2560		TriAD	Wukong	Wukong+G
H	**Q1** (3.6GB)	851	992	**165**

6 Evaluation

6.1 Experimental Setup

Hardware configuration. All evaluations are conducted on a rack-scale cluster with 10 servers on 5 machines. We run two servers on a single machine. Each server has one 12-core Intel Xeon E5-2650 v4 CPU with 128GB of DRAM, one NVIDIA Tesla K40m GPU with 12GB of DRAM, and one Mellanox ConnectX-3 56Gbps InfiniBand NIC via PCIe 3.0 x8 connected to a Mellanox IS5025 40Gbps IB Switch. Wukong+G only provides a one-to-one mapping between the work and agent threads on different servers [51], which mitigates the scalability issue of RDMA networks with reliable transports [31] and simplifies the implementation of the task queue. In all experiments, we reserve two cores on each CPU to generate requests for all servers to avoid the impact of networking between clients and servers as done in prior work [54, 56, 57, 20, 51].

Benchmarks. Our benchmarks include one synthetic and two real-life datasets, as shown in Table 2. The synthetic dataset is the Lehigh University Benchmark (LUBM) [7]. We generate 5 datasets with different sizes (up to LUBM-10240) and use the query set published in Atre et al. [13], which are widely used by many distributed RDF systems [36, 62, 23, 51]. The real-life datasets include the DBpedia's SPARQL Benchmark (DBPSB) [1] and YAGO2 [9, 30]. For DBPSB, we use the query set recommended by its official site. For YAGO2, we collect our query set from both H_2RDF+ [43] and RDF-3X [42] to make sure the test covers both light and heavy queries.

Comparing targets. We compare our system against two state-of-the-art distributed RDF query systems, TriAD [23] (RDF relational store) and Wukong [51] (RDF graph stores). Note that TriAD does not sup-

Table 4: The query performance (msec) on 10 servers.

LUBM-10240		TriAD	Wukong	Wukong+G
H	**Q1** (14.25GB)	3,400	480	**211**
	Q2 (9.74GB)	880	66	**12**
	Q3 (14.25GB)	2,835	171	**19**
	Q7 (22.58GB)	10,806	390	**100**
	Geo. M	3,094	215	**47**
L	**Q4**	3.08	**0.44**	0.46
	Q5	1.84	**0.13**	0.17
	Q6	65.20	**0.70**	0.71
	Geo. M	7.04	**0.34**	0.38

port concurrent query processing, so we only compare to it in the single query performance. As done in prior work [62, 23, 51], the string server is enabled for all systems to save memory usage, reduce network bandwidth, and boost string matching.

6.2 Single Query Performance

We first study the performance of Wukong+G for a single query using the LUBM dataset. Table 3 shows the optimal performance of different systems on a single server with LUBM-2560. For Wukong+G, there is no data swapping during single query experiment since the current memory footprint of all queries on LUBM-2560 (the numbers in brackets) is smaller than the GPU memory (12GB). The query-aware prefetching reduces the memory footprint to the per-query granularity (see Table 1).

Although Wukong and TriAD have enabled multi-threading (10 worker threads), Wukong+G can still significantly outperform such pure CPU systems for heavy queries (Q1-Q3, Q7) by up to 8.3X and 21.9X (from 4.5X and 5.2X) due to wisely leveraging hardware advantages. The improvement of average (geometric mean) latency reaches 5.9X and 8.5X. For the light queries (Q4-Q6), Wukong+G inherits the prominent performance of Wukong by leveraging graph exploration and outperforms TriAD by up to 32.7X.

We further compare Wukong+G with Wukong and TriAD (multi-threading enabled) on 10 servers using LUBM-10240 in Table 4. For heavy queries, Wukong+G still outperforms the average (geometric mean) latency of Wukong by 4.6X (ranging from 2.3X to 9.0X), thanks to the heterogeneous RDMA communication for preserving the good performance of GPU at scale. Further, using up all CPU worker threads to accelerate a single query is not practical for concurrent query processing since it will result in throughput collapse. For light queries, Wukong+G incurs about 12% performance overhead (geometric mean) compared to Wukong due to adjusting the layout of key/value store on CPU memory for predicate-based grouping. Wukong+G is still one order of magnitude faster than TriAD due to the in-place execution with one-sided RDMA `READ` [51].

Table 5: The contribution of (cumulative) optimizations to the query latency (msec) evaluated on 3GB GPU memory.

LUBM-2560	Per-query	Per-parttern	Per-block	Pipeline
Q1 (3.6GB)	x	743	313	295
Q2 (2.4GB)	284	283	32	31
Q3 (3.6GB)	x	309	62	63
Q7 (5.6GB)	x	893	622	610

6.3 Factor Analysis of Improvement

To study the impact of each technique and how they affect the query performance, we iteratively enable each optimization and collect the average latency by repeatedly running the same query on a single server with 3GB GPU memory for LUBM-2560. As shown in Table 5, even using query-aware prefetching (per-query), the memory footprints of query Q1, Q3 and Q7 still exceed available GPU memory (see Table 3). Hence, they can not run until enabling pattern-aware prefetching (per-pattern). The effectiveness of fine-grained swapping (per-block) varies on different queries. It is quite effective on Q2 and Q3 (8.8X and 5.0X) since all triples required by triple patterns can almost be stored in 3GB GPU memory. Note that Q3 returns an empty history table (intermediate results) half-way and reduces the practical runtime memory footprint to 2.5GB. For Q1 and Q7, although the relative large memory footprint (3.6GB and 5.6GB), incurs massive data swapping (1.5GB by 187 time and 5.1GB by 734 times), the cache sharing with fine-grained mechanism can still notably reduce the query latency by 2.4X and 1.4X. Moreover, pipeline does not work on Q2 and Q3 without data prefetching time. The improvement for Q1 and Q7 is still limited since the prefetching and execution time for each triple pattern are quite imbalanced. For example, 88% of blocks are swapped at two triple patterns for Q7.

Table 6: A comparison of query performance (msec) w/o and w/ GPUDirect RDMA (GDR) on 10 servers with LUBM-10240.

LUBM-10240	Q1	Q2	Q3	Q7
Wukong+G w/o GDR	222 (53.4)	13	22	103 (26.1)
Wukong+G w/ GDR	211 (40.1)	13	22	98 (21.3)

6.4 GPUDirect RDMA

To shorten communication flow and avoid redundant memory copy for history table (intermediate results) of queries, Wukong+G leverages GPUDirect RDMA (GDR) to write history table directly from local GPU memory to remote GPU and CPU memory (§4.3). To study the impact of leveraging GPUDirect RDMA, we enforce Wukong+G to purely use native RDMA for both query metadata and history table (i.e., Wukong+G w/o GDR). As shown in Table 6, the performance of Q2 and Q3 is non-sensitive to GPUDirect RDMA because of no data transfer among GPUs. For Q1, leveraging GPUDirect RDMA can reduce about 30% communication cost (53.4ms vs. 40.1ms), since the query need to send about 487MB intermediate results by about 990 times RDMA operations. For queries with relatively large intermediate results or many triple patterns, there are more rooms for the overall performance improvement.

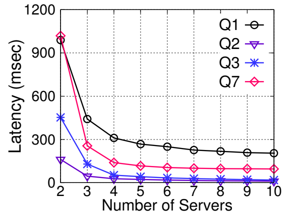

Fig. 9: The latency with the increase of servers.

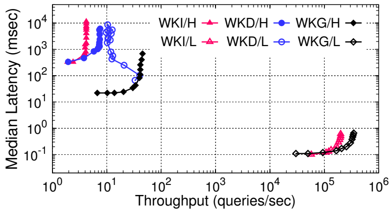

Fig. 10: The performance of hybrid workload on 10 servers with LUBM-10240.

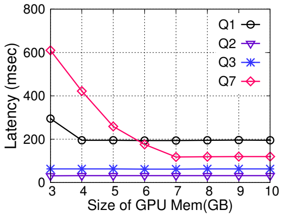

Fig. 11: The latency with the increase of GPU memory.

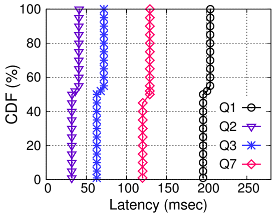

Fig. 12: The CDF of latency for mixed heavy workload.

6.5 Scalability

We evaluate the scalability of Wukong+G with the increase of servers. Since the latency of light queries of Wukong+G mainly inherits from Wukong, We only report the experimental results of heavy queries handled by GPUs. As shown in Fig. 9, the speedup of heavy queries ranges from 4.8X to 23.8X. As the number of servers increases from 2 to 10, a good horizontal scalability is shown. After a detailed analysis of the experimental results, we reveal that there are two different factors improving the performance at different stages. In the first stage (from 2 to 4 servers), the increase of total GPU memory provides the main contribution to the performance gains, ranging from 3.2X to 8.5X, by reducing memory swapping cost. In the second stage (from 4 to 10 servers), since Wukong+G stops launching expensive *memory swapping* operations when enough GPU memory is available, the main performance benefits come from using more GPUs, ranging from 1.5X to 2.8X.

Discussion. With the further increase of servers, the single query latency may not further decrease due to fewer workload per server and more communication cost. It implies that it is not worth making all resources (GPUs) participate in a single query processing, especially for a large-scale cluster (e.g., 100 servers). Therefore, Wukong+G will limit the participants of a single query and can still scale well in term of throughput by handling more concurrent queries simultaneously on different servers.

6.6 Performance of Hybrid Workloads

One principal aim of Wukong+G is to handle concurrent hybrid (light and heavy) queries in an efficient and scalable way. Prior work [51] briefly studied the performance of Wukong with a mixed workload, which consists of 6 classes of light queries (Q4-Q6 and A1-A3[6]). The light query in each class has a similar behavior except that the start point is randomly selected from the same type of vertices (e.g., Univ0, Univ1, etc.). The distribution of query classes follows the reciprocal of their average latency. Therefore, we first extend original mixed workload by adding 4 classes of heavy queries (Q1-Q3, Q7), and then allow all clients to freely send light and heavy queries[7] according to the distribution of query classes.

We compare Wukong+G (WKG) with two different settings of Wukong: Default (WKD) and Isolation (WKI). Wukong/Default (WKD) allows all worker threads to handle hybrid queries, while Wukong/Isolation (WKI) reserves half of the worker threads to handle heavy queries. Each server runs two emulated clients on dedicated cores to send requests. Wukong launches 10 worker threads, while Wukong+G launches 9 worker threads and an agent thread. The multi-threading for heavy queries is configured to 5. We run the hybrid workload over LUBM-10240 on 10 servers for 300 seconds (10s warmup) and report the throughput and median (50^{th} percentile) latency for light and heavy queries separately over that period in Fig. 10.

For heavy queries, Wukong+G improves throughput and latency by over one order of magnitude compared to Wukong (WKD and WKI). The throughput of WKD is notably better (about 80%) than that of WKI, since it can use all worker threads to handle heavy queries. For light queries, Wukong+G performs up to 345K queries per second with median latency of 0.6ms by 9 worker threads. The latency can be halved with a small 10% impact in throughput. As expected, WKI can provide about half of the throughput (199K queries/s) with a similar latency since only half of the worker threads (5) are used to handle light queries. However, the throughput and latency of WKD for light queries are thoroughly impacted by the processing of heavy queries.

6.7 RDF Cache on GPU

To study the influence of GPU cache for the performance of heavy queries on Wukong+G, we first evaluate the single query latency using LUBM-2560 on a single server with the GPU memory sizes varying from 3GB to 10GB. We repeatedly send one kind of heavy queries until the cache on GPU memory is warmed up, and illustrate the average latency of heavy queries in Fig. 11. Since the memory footprint of Q2 (2.4GB) is always smaller than the GPU memory, the latency is stable, and there is no data swapping. For Q3, although the memory footprint

[6] Three additional queries (A1, A2, and A3) are from the official LUBM website (#1, #3, and #5).

[7] In prior experiment [51], only up to one client is used to continually send heavy queries (i.e., Q1).

Table 7: The latency (msec) of queries on DBPSB and YAGO2

DBPSB	D1	D2	D3	D4	D5	Geo. M
Wukong	1.28	0.15	0.25	4.25	1.08	0.74
Wukong+G	0.53	0.16	0.26	0.99	0.52	0.41

YAGO2	Y1	Y2	Y3	Y4	Geo. M
Wukong	0.10	0.13	4685	752	14.6
Wukong+G	0.11	0.15	1856	398	10.5

of the query is about 3.6GB, the latency is still stable since the history table becomes empty after the first two triple patterns due to contradictory conditions, where the rest predicate segment (about 1.1GB) will never be loaded. For Q1 and Q7, the latency decreases with the increase of GPU memory due to the decrease of data swapping size. However, the break point of Q7 is later than that of Q1 since it has a relatively larger memory footprint (5.6GB vs. 3.6GB).

To show the effectiveness of sharing GPU cache by multiple heavy queries, We further evaluate the performance of a mixture of four heavy queries using LUBM-2560 on a single server with 10GB GPU memory. As shown in Fig. 12, the geometric mean of 50^{th} (median) and 99^{th} percentile latency is just 84.5 and 93.8 milliseconds respectively, under the peak throughput. Compared to the single query latency (see Table 3), the performance degradation is just 3% and 14%, thanks to our fine-grained swapping and look-ahead replacing. During the experiment, the number and volume of blocks swapped in per second are about 96 and 750MB.

6.8 Other Workloads

We further compare the performance of Wukong+G with Wukong on two real-life datasets, DBPSB [1] and YAGO2 [9]. As shown in Table 7, for light queries (D2, D3, Y1, and Y2), Wukong+G can provide a close performance to Wukong due to following the same execution mode and a similar in-memory store. For heavy queries (D1, D4, D5, Y3, and Y4), Wukong+G can notably outperform Wukong by up to 4.3X (from 1.9X).

7 Related Work

Wukong+G is inspired by and departs from prior RDF query processing systems [40, 58, 41, 12, 50, 13, 65, 60, 14, 61, 62, 23, 51, 32, 64], but differs from them in exploiting a distributed heterogeneous CPU/GPU cluster to accelerate heterogeneous RDF queries.

Several prior systems [11, 12] have leveraged column-oriented databases [53] and vertical partitioning for RDF dataset, which group all triples with the same predicate into a single two-column table. The predicate-based grouping in Wukong+G is driven by a similar observation. However, Wukong+G still randomly (hash-based) assign keys within the segment to preserve fast RDMA-based graph exploration, which plays a vital role for running light queries efficiently on CPU.

Using prefetching and pipelining mechanisms are not new, which have been exploited in many graph-parallel systems [49, 35] and GPU-accelerated systems [37] to hide the latency of memory accesses. Wukong+G employs a SPARQL-specific prefetching scheme and enables such techniques on multiple concurrent jobs (heavy queries) that share a single cache on the GPU memory.

There has been a lot of work [25, 24, 39, 26, 29, 27, 55, 46, 28] focusing on exploiting the unique features of GPUs to accelerate database operations. Mega-KV [63] is an in-memory key/value store that uses GPUs to accelerate index operations by only saving indexes on the GPU memory to ease device memory pressure. CoGaDB [15, 16] uses a column-oriented caching mechanism on GPU memory to accelerate OLAP workload. SABER [34] is a hybrid high-performance relational stream processing engine for CPUs and GPUs. Wukong+G is inspired by prior work, while the differences in workloads result in different design choices. To our knowledge, none of the above systems exploit distributed heterogeneous (CPU/GPU) environment, let alone using RDMA as well as GPUDirect features.

To reduce communication overhead between multiple GPUs, NVIDIA continuously puts forward GPUDirect technology [3], including GPUDirect RDMA and GPUDirect Async (under development [6]). They enable direct cross-device data transfer on data plane and control plane, respectively. Researchers have also investigated how to provide network [33, 21] and file system abstractions [52] based on such hardware features. Our design currently focuses on using GPUs to deal with heavy queries for RDF graphs. The above efforts provide opportunities to build a more flexible and efficient RDF query system through better abstractions.

8 Conclusions

The trend of hardware heterogeneity (CPU/GPU) opens new opportunities to rethink the design of query processing systems facing hybrid workloads. This paper describes Wukong+G, a graph-based distributed RDF query system that supports heterogeneous CPU/GPU processing for hybrid workloads with both light and heavy queries. We have shown that Wukong+G achieves low query latency and high overall throughput in the single query performance and hybrid workloads.

Abstract

The fast access to data and high parallel processing in high-performance computing instigates an urgent demand on the I/O improvement of the NVMe storage within datacenters. However, unsatisfactory performance of the former NVMe virtualization demonstrates that NVMe storage devices are often underutilized within cloud computing platforms. NVMe virtualization with high performance and device sharing has captured the attention of researchers. This paper introduces MDev-NVMe, a new virtualization implementation for NVMe storage device with: (1) full NVMe storage virtualization running native NVMe driver in guest, and (2) a mediated pass-through mechanism with an active polling mode which can achieve both high throughput, low latency performance and a good device scalability. This paper subsequently evaluates MDev-NVMe on Intel OPTANE and P3600 NVMe SSD by comparison with the mainstream virtualization mechanisms using application-level I/O benchmarks. With polling, MDev-NVMe can demonstrate a 142% improvement over native (interrupt-driven) throughput and over 2.5 × the *Virtio* throughput with only 70% native average latency and 31% *Virtio* average latency with a reliable scalability. Finally, the advantages of MDev-NVMe and the importance of polling are discussed, offering evidence that MDev-NVMe is a superior virtualization choice with high performance and promising levels of maintenance.

1 Introduction

NVM Express (NVMe) [21] is an inherently parallel, high-performing interface and command set designed for non-volatile memory based storage. NVMe devices have been designed from a logical device interface where storage media is attached via a PCIe bus [26]. NVMe SSDs can deliver I/O operations with a very high throughput performance on the low latency, making them the superior storage choices for data-intensive datacenters to obtain high performance computing in cloud services [2, 5]. Currently, NVMe SSDs are also used to accelerate I/O missions between system storage and other PCIe devices, such as GPUs on graphics cards [7]. However, because of imbalanced requirements of applications in high performance platforms, NVMe devices are often underutilized in terms of I/O performance [19, 22, 17]. NVMe devices in datacenters require solutions to achieve high performance and sharing capabilities [31].

I/O virtualization [13, 24] is a key component of cloud computing, which not only optimizes utilization of physical resources, but also simplifies storage management, providing a simple and consistent interface to complex functions. Typical cases of NVMe virtualization include VM boot disk and server side caching of VM data. With respect to NVMe devices, limited PCIe slots make NVMe virtualization essential in datacenters with high density so that the benefits of NVMe devices can be shared among the VMs.

Recently, NVMe virtualization [33, 28, 3] has become widely studied by computer scientists and researchers. Keeriyadath [16] summarizes three of the NVMe virtualization approaches; implementing SCSI to NVMe translation layer on the hypervisor (blind mode), pure virtual NVMe stack by distributing I/O queues amongst hosted VMs (Virtual Mode), and SR-IOV [11] based NVMe controllers per virtual functions (physical mode). Modern virtualization solutions for NVMe Storage such as *Virtio* [23], Userspace NVMe driver in QEMU [34] and Storage Performance Development Kit (SPDK) [15] are implemented in the userspace of the Linux system. However, these mechanisms have their respective shortcomings: the performance of VMs with *Virtio* and Userspace NVMe driver in QEMU are considered poor compared with native drivers. At the same time SPDK must collaborate with “Hugepage” memory which adds further pressure to the memory resources of the host server.

Observing that mediated pass-through [30] has been gradually recognized as an effective solution for I/O virtualization [12, 27], concurrently the Linux kernel has introduced a mediated device framework which supports such usage since 4.10 [25]. Therefore, it is proposed that implementing an effective NVMe virtualization using mediated pass-through is an appropriate methodology. The detail of MDev-NVMe design is that a full virtualization is proposed which enables VMs running with a native driver, and a MDev-NVMe module with device emulation, admin queue emulation, and also with I/O queue shadow. To improve the VM performance, an active polling mode for queue handling is proposed. As a result, this design is then built for the experiments on Fio [4] benchmarks by undertaking comparison experiments between mainstream NVMe virtualization solutions. The proposed design can achieve up to 142% improvement of througerhput with 70% average latency over native performance, and also performs well regarding scalability and flexibility. Also, the experiments are performed on different I/O blocksizes and provide suggestions on selecting appropriate blocksizes for NVMe virtualization. At last, the discussion of optimization on active polling is undertaken in the final section, which also provides suggestions on the future design of virtualization and high-performance storage.

In summary, this paper makes the following contributions:

(1) We introduce a full NVMe virtualization solution MDev-NVMe with mediated pass-through that runs the native NVMe driver in each guest.

(2) We demonstrate details of emulation of Admin queues and shadow of I/O queues in the mediated pass-through which can pass-through performance-critical resources accesses in NVMe storage.

(3) We design an active polling for shadow SQ and CQs and host CQs in NVMe to achieve better performance over native devices.

(4) We do further comparison evaluations of overall performance on throughput, average latency, QoS between MDev-NVMe and other virtualization mechanisms. We analyse the influence of blocksizes on performance and give suggestions for NVMe virtualization to choose blocksizes in different I/O scenarios.

(5) We discuss both MDev-NVMe's performance and maintenance advantages over former virtualization And we discuss the active polling optimization in virtualization and give suggestions on polling support in the design of virtualization and storage hardware.

The rest of this paper is organized as follows. A background of NVMe storage protocol and the motivation on NVMe virtualization are provided §2. The design is demonstrated and implementation details of MDev-NVMe are detailed in §3. The results of the comparison evaluations between MDev-NVMe and other mechanisms are located within §4. There is a discussion on polling in §5. §6 details related developments, and finally the conclusion is located in §7.

2 Background and Motivation

2.1 NVMe Storage Protocol

For a long time, SATA (Serial ATA) has been used as the interface for traditional storage devices such as Hard Disk Drives (HDD) and a number of Solid State Drives(SSD). Despite the fact that SATA is enough for a rotational storage, the SATA interface cannot meet the requirement of modern storage devices. This is because of the requirement to provide a much higher I/O throughput due to the limitation of Advance Host Controller Interface (AHCI) architecture design in SATA interface. To resolve the I/O performance bottleneck, the NVMe protocol was designed and developed with a PCIe interface instead of SATA [21]. Generally, to accelerate the I/O speed of SSD, NVMe protocol optimized command issues between the host system and the storage devices, compared with the traditional ATA AHCI protocol. Concurrently, it includes support for parallel operations by supporting up to 64K commands within a single I/O queue to the device [21].

Here are some basic definitions in NVMe protocols. NVMe defines two main types of commands: **Admin Commands** and **I/O Commands**. In I/O operations, commands are placed by the host software into the **Submission Queue (SQ)**, and completion information received from SSD hardware is then placed into an associated **Completion Queue (CQ)** by the controller. NVMe separately designs SQ and CQ pairs for any Admin and I/O commands respectively. The host system maintains only one Admin SQ and its associated Admin CQ for the purpose of storage management and command control, while the host can maintain a maximum of 64K I/O SQs or CQs. The depth of the Admin SQ or CQ is 4K, where the Admin Queue can store at most 4096 entries, while the depth of I/O Queues is 64K. SQ and CQ should work in pairs, and normally one SQ utilizes on one CQ or multiple SQs utilize the same CQ to meet the requirements of high performances in multithread I/O processing. A SQ or CQ is a ring buffer and it is a memory area which is shared with the device that can be accessed by Direct Memory Access (DMA). Moreover, a doorbell is a register of the NVMe device controller to record the head or tail pointer of the ring buffer (SQ or CQ).

A specific command in a NVMe IO request contains concrete read/write messages and an address pointing to the DMA buffer if the IO request is a DMA operation. Once the request is stored in a SQ, the host writes the doorbell and kicks (transfers) the request into the NVMe device so that the device can fetch I/O operations. After an IO request has been completed, the device will subsequently write the success or failure status of the request into a CQ and the device then generates an interrupt request into the host. After the host receives the interrupt and processes the completion entries, it writes to the doorbell to release the completion entries.

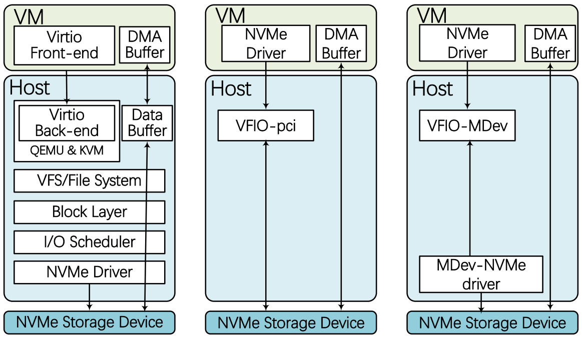
2.2 Motivation

High-performance cloud computing applications have raised great demands on the I/O performance of modern datacenters. The I/O virtualization is widely deployed in datacenter servers to support the heavy data transmission and storage tasks within cloud computing workloads. The virtualization for the new high-performance storage devices NVMe is a concentration point of I/O virtualization in cloud computing. This is because the NVMe devices can demonstrate great performance advantages over the traditional devices on the native host servers. There have been a number of previous successful NVMe virtualization solutions including VM boot disk and server side caching of VM data, both of which prove that NVMe is well suited for exploitation in various virtualization. To ensure all the VMs in cloud computing servers share the benefits of NVMe devices from the basic I/O virtualization has become essential in virtualization research for NVMe. The NVMe devices in VMs provides some basic requirements for the virtualization mechanisms:

High Throughput: The throughput performance of NVMe storage is the most important performance feature due to the requirements for both quick data access and parallel processing of cloud computing services. The virtualization mechanism needs to ensure the high performance of the NVMe devices in VMs, so the throughput-intensive services can work increasingly efficiently.

Low Latency: From previous research, the unloaded read latency of NVMe SSD storage is 20-100μs [9]. Storage virtualization mechanisms usually cause latency overhead in VMs because the high frequency of I/O operations will bring large numbers of context switches. To satisfy latency-sensitive applications in cloud computing services, NVMe virtualization should suffer a low latency overhead.

Device Sharing: Modern high-performance datecenter servers often support large numbers of VMs for separate cloud computing services. The limited NVMe storage devices should be shared by different VMs which can show great scalability. With device sharing, different VMs can work with high-performing NVMe without interference between each other, and the statuses of different VMs need to be managed by the hypervisor. Also, supporting VM live migration [32] is also an important requirement on the virtualization mechanism, which greatly relies on device sharing features. Also, the tail latency in VMs shows the QoS of device sharing among different VMs.



(a) Virtio (b) VFIO (c) MDev-NVMe

Figure 1: NVMe virtualization comparisons.

The comparisons between *Virtio* and *VFIO* and our design are displayed in Fig. 1. The previous NVMe storage virtualization *Virtio* and *Virtual Function I/O (VFIO)* [29] both have their shortcomings: *Virtio* uses the original *virtio-blk* [20] driver and it has no specific optimization for NVMe. Consequently, *Virtio* suffers readily apparent overhead from software layers which originate from guest OS to the NVMe devices, including the Virtual File System (VFS), block layer and I/O scheduler. Whereas in *Virtio*, the throughput and latency in VMs can only meet 50% of the native performance.

On the other hand, *VFIO* method can use direct pass-through [1, 10] to assign the entire NVMe device to a single VM, therefore *VFIO* can not meet the requirements of device sharing despite its near-native performance on both latency and throughput. Also, with direct pass-through, the information of virtual NVMe can not be managed by the hypervisor so it cannot support migration.

As shown in Fig. 1(c), the mediated pass-through virtualization is a full virtualization mechanism which combines both the advantages of the two former mechanisms, and it requires no modification to guest OS kernel and these guests can use the raw NVMe drivers. A “VFIO-MDev” interface is implemented for each individual VM to cooperate with QEMU [6] to support device sharing between multi VMs, which “VFIO-MDev” can emulate all the PCIe device features for each guest NVMe devices. In order to guarantee a near-native I/O performance in mediated pass-through, the direct concept of the proposed MDev-NVMe is to optimize *VFIO* by modifying the raw NVMe driver into the MDev-NVMe driver in Linux kernel, so that it can pass-through basic units of I/O operations as many as possible. As a result, all the statuses of physical and virtual queues can be managed by the MDev-NVMe module, and any file system on the host kernel is unnecessary, which helps reduce the software stack overhead. In general, a mediate pass-through is a superior choice which can meet all the essential goals of NVMe virtualization.

3 Design and Implementation

Cloud applications demand on high performance NVMe storage devices in modern datacenters. To meet both low latency and high throughput performance goals and support a sharing policy on NVMe devices, we design a mediated pass through virtualization mechanism: MDev-NVMe.

3.1 Architecture

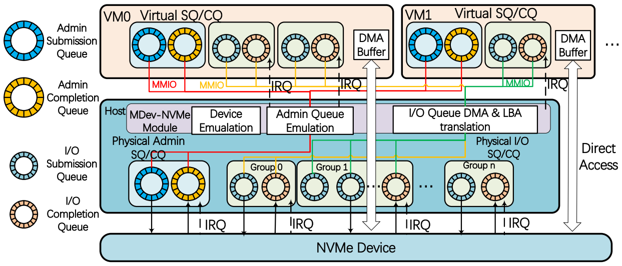


Figure 2: Architecture of MDev-NVMe.

The mediated pass-through virtualization is a full virtualization mechanism which combines both advantages of the two former mechanisms *Virtio* and *VFIO*. At the same time, it requires no modification to the guest OS kernel so the guest kernel can use the raw NVMe drivers. From the aspect of the architecture, *Virtio* provides a full device emulation with the *virtio-blk* front end driver which suffers an apparent performance overhead from software layers. And *VFIO* passes through the entire device to one VM with no sharing features. Therefore, the mediated pass-through selectively emulates or pass-throughs basic I/O units of the NVMe I/O operations. To accelerate the I/O operations and reduce the unnecessary frequent "vm-exit", we pass through I/O SQs and CQs with a queue shadow instead of I/O queue emulation. The access of DMA buffers in NVMe devices can be dealt similar to other PCIe devices.

The brief introduction of the architecture is shown in Fig. 2. From the architecture, we offer a full virtualization method, so all guests require no modification to raw NVMe drivers and can utilize all the basic NVMe commands. The MDev-NVMe is a kernel module within the Linux host system which offers three important functions: the basic PCI device emulation, Admin queue emulation and I/O queue shadow with DMA & LBA translation. Also, in MDev-NVMe, the DMA buffer in NVMe devices can be accessed by VMs as normal PCIe devices, which is similar to direct pass-through. All the guests cooperate with these three important functions.

Device Emulation: MDev-NVMe allows that all the guests need no modification to the native NVMe driver in kernels, so each guest can access a virtual NVMe device with the PCIe bus. So the MDev-NVMe module should emulate all the features of the NVMe devices for each VMs. The details of PCIe device emulation based on"VFIO-MDev" which is similar with the original "VFIO-pci": we emulated PCI registers such as BAR and other PCI configurations, and emulated NVMe registers and logic of guest device. The emulated interrupts contain INTx, MSI, and MSI-X.

Admin Queue Emulation: In NVMe protocol, there is only one pair of Admin SQ and CQ, while there can be up to 65535 pairs of I/O SQs and CQs. When different VMs generates I/O SQ and CQ at the same time, the only pair of Admin SQ and CQ in the host kernel should be able to handle the sharing and scheduling between the VMs. So we need device emulation for the Admin Queue so that all the guests can manage their NVMe I/O operations in the emulated pair of Admin Queue, and MDev-NVMe will finally parse the virtual Admin commands into physical Admin commands.

I/O Queue Shadow: Since there can be up to 64K I/O queues in a NVMe device instead of only one pair, I/O queues do not require device emulations. In our architecture, all the guest I/O commands in virtual queues can be passed through into the shadowed physical queues with the DMA & LBA translation. The guest I/O commands are directly executed by the device as the same as host commands after command translations, which can apparently reduce the overhead through emulation.

DMA Buffer Access: Similar to other PCIe devices, the host DMA engine can directly manage the memory addresses of the DMA buffer in guest NVMe storage devices, just like the *VFIO* pass-through. The DMA feature is necessary at any time that the CPU cannot maintain the rate of data transfer required, or when the CPU needs to perform work while waiting for a relatively slow I/O data transfer. The frequent I/O operations on NVMe storage devices cause a high rate of data transfer, and MDev-NVMe can overcome the CPU overhead of frequent "vm-exit" when accessing device memory.

3.2 Queue Handling

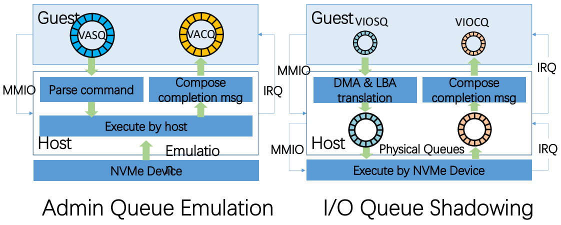

Figure 3: A brief introduction to queue handling.

We separately design queue handling mechanism for Admin Queues and I/O Queues, as shown in Fig. 3.

When more than one virtual machine runs on the host, they all maintain one pair of virtual Admin SQ and CQ in their guest OS as native. Therefore, the only physical pair of Admin SQ and CQ must be shared among the virtual machines. Concretely, MDev-NVMe usually examines the virtual Admin Queue to check the commands. If the guest Admin commands wants to create guest I/O queues, the MDev-NVMe module can directly create corresponding physical I/O queues in the host kernel. If guest Admin commands only want to check and manage the information of the I/O status and device information without attaining the concrete features and parameters of the NVMe devices. The MDev-NVMe module can directly write or update information from the NVMe doorbell register with Memory-Mapped I/O (MMIO) operation. The majority of the Admin queue operations are accomplished in the initialization process of virtual machines, so the Admin queue emulation will not become the bottleneck location of the NVMe I/O performance.

Compared with Admin queues, we use a more convenient pass-through mechanism for guest I/O SQs and CQs, where we make a queue shadow from the guest queues to the host queues. NVMe devices have more than one pair I/O SQs and CQs, so I/O queue shadow is feasible in MDev-NVMe virtualization. In host kernel, I/O queues are separately bound with physical cores of the server and interrupts of the submission and completion of each I/O commands from queues are trapped by the corresponding cores to accelerate I/O operation. To improve performance in MDev-NVMe VMs, we can also bind the guest I/O queues with the host CPU resources by shadowing guest I/O queues and host I/O queues by providing a simple DMA & LBA translation, which is introduced in the §3.3. Once the guest writes or updates an I/O command, the MDev-NVMe module will directly writes translated commands into shadowed physical queues and updates the device doorbell register with MMIO. When a guest I/O operation completes in the corresponding physical queue, the device will generate an interrupt into the host kernel, and also our MDev-NVMe module generates an interrupt into the guest kernel after checking the DMA & LBA translator. With queue shadowing, the handling of interrupts of the guest virtual queues is actually the handling of interrupts of shadowed physical queues, where we make full use of the bound CPUs (by physical queues) to accelerate the interrupt handling.

3.3 DMA & LBA translation

As we demonstrated in the architecture figure in §3.1, a guest I/O queue are shadowed with a corresponding physical I/O queue in a DMA & LBA translator to achieve resource partitioning and better I/O performance. After translation, a virtual I/O queue id are bound with a physical I/O queue id, and the translation result will be stored in a translation table which is maintained in the host kernel. The translation process is based on the Intel Extension Page Table (EPT) support for memory translation, so that we can maintain a translation table cache when multiple VMs create large numbers of virtual I/O queues and the limited physical queues must be shared.

The DMA & LBA translation are based on the static partition strategy, where all VMs are assigned with part of the continuous space of the NVMe device at the initialization process. Specifically, the translation unit in an I/O command is the data pointer which points to a DMA buffer. The address is a Guest Physical Address (GPA). The MDev-NVMe module use *vfio_pin_pages* to translate the GPA to HPA (Host Physical Address) and pin the DMA buffer in host memory. Specifically, the *vfio_pin_pages* can ensure the isolation of the guest memory between different virtual machines. Since all the translations are under control of the translator in MDev-NVMe module, a malicious VM cannot access the physical I/O queues which is not assigned to itself and can not access the I/O queues in other VMs either. The command buffer is also protected by the EPT, which helps to ensure the security of DMA buffers of different VMs. Another important unit of the I/O operation is the Start Logical Block Address (SLBA). Since our MDev-NVMe virtualization takes a static partition mechanism, the SLBA in guest I/O command can be modified and subsequently copied into the host I/O queue by applying a space area offset, which are also managed by MDev-NVMe module in host kernel.

3.4 2-Way Polling Mode

With the mediated pass-through mechanism, the NVMe devices can achieve a performance better than *Virtio*. However, the performance in VMs still show an obvious gap compared with the native platform in experiment observation. The I/O bottleneck results from frequent submissions and completions of guest I/O commands, so we discuss the detailed origin of overhead in Fig. 4.

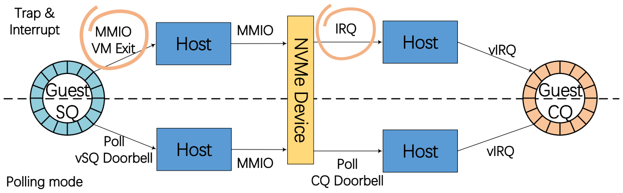

Figure 4: A guest I/O operation process in two modes.

Fig. 4 shows entire processes of a guest NVMe I/O command operation in "non-polling" or "polling" mode. Generally, the submission latency from the host kernel to the physical NVMe device is inappreciable, which is less than 10 μs in our observations from experiments. However, the guest I/O commands suffers seriously from two part overhead: (1) when the guest I/O commands are translated and submitted to the corresponding physical queues through an MMIO operation it will result in a "vm-exit", (2) when handling interrupts generated by physical device when updating a doorbell register with a completion of physical I/O queue.

To overcome the two-part overhead, a direct idea is to change the trap of interrupts into an active polling mechanism in the 2-way overhead. First, the shadowed doorbell of guest SQ or CQ can be stored in host memory area so that MDev-NVMe can directly manage all the guest I/O operations and update the NVMe queue status. With polling, we polls guests to write into the shadow doorbells instead of generating an MMIO into the host. Also, we disables interrupt integration of host CQs into guests and adopts polling new completion entries from the host CQs. As a result, the shadow SQ tail doorbell, the shadow CQ head doorbell, and the host CQ are all stored in the host memory, and they can be directly fetched and immediately updated by the polling threads.

Now in our MDev-NVMe, we use 3 threads for individually polling the shadow SQ tail doorbells, the shadow CQ head doorbells, and the host CQs so that we can get even better performance of I/O queue handling than native platform in the host kernel, which is shown in §4, while using 1 thread with round-robin polling of multiple queues cannot provide corresponding performance. The threads will bring 100% usage of 3 cores on the host server. And the polling threads can be shared between VMs.

4 Experiments

To demonstrate the I/O performance of virtual machines of our mediated pass-through virtualization mechanism, we run fio [4] I/O benchmark experiments in Linux virtual machines based on the comparison between different virtualization mechanisms, including *Virtio*, famz userspace driver, SPDK *vhost-scsi*, and SPDK *vhost-blk*. The performance of MDev-NVMe and the other 4 mechanisms are compared and normalized with the native performance on the physical devices. For Throughput performance, MDev-NVMe shows the best bandwidth performance among all the virtualization mechanisms and can provide up to 1.5× native performance. For Latency performance, MDev-NVMe presents the lowest average latency, and can give a bounded maximum latency with a reliable QoS performance. Also, the tail latency performance of MDev-NVMe is also outstanding among all the comparison experiments. In the meanwhile, our MDev-NVMe scales well without a visible performance drop.

4.1 Configuration

The evaluation concentrates on achieving the I/O performance of NVMe Storage devices and demonstrating the advantages and disadvantages of different virtualization methods, including *Virtio*, Famz userspace driver, SPDK *vhost-scsi*, and SPDK *vhost-blk*. Experiments on different concrete NVMe SSD products show different results and give us more insights. Nowadays, the most advanced NVMe Storage Device is based on Intel OPTANE Technology with 3D XPoint Memory media. The OPTANE SSD has an amazing performance which can support up to 550K IOPS in 4K random read and 500k IOPS in 4K random write with a 10μs latency. So we first build our experiment environment on the OPTANE SSD DC P4800X 375G NVMe SSD, and the server hardware platform includes 2 Intel Xeon CPU E5-2699 v3 with 18 CPU cores (2.3GHz), 64GB system memory. Besides, we also do the same experiments on a more commonly used NVMe SSD: INTEL SSD DC P3600 400G, running on the server which includes 2 Intel Xeon CPU E5-2680 v4 with 14 CPU cores (28 threads) (2.4GHz), 64GB system memory.

We run 64bit Ubuntu 16.04 with a 4.10.0 kernel with our MDev-NVMe kernel module in the host server, and 64bit Debian 9.0 with a 4.10.0 kernel in the guests. Each virtual machine is allocated with 4 VCPUs and 8GB system memory. To get the best I/O performance in comparison experiments, we set up 1-VM case which the single virtual machine can get the entire volume. To discuss the scalability of MDev-NVMe sharing, we partition the NVMe SSD with 4 60G area into 4 individual VMs.

We use the flexible I/O tester (FIO) [4] as our application evaluation benchmark. FIO is a typical I/O benchmark with different parameters to demonstrate the IO performance, and it is widely used in research and industries. Specifically, we take **libaio** as the fio engine and we run 5 groups of test scripts in Table 1, including the random read or write with "iodepth=1", the random read or write with "iodepth=32", and the 70% random read and 30% random write. The FIO test doesn't use any file system and chooses "O_DIRECT" parameter for Direct I/O experiments.

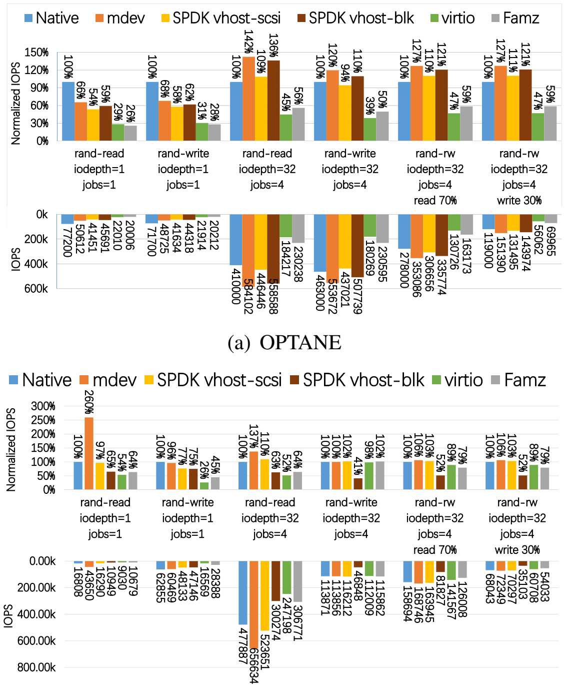
Table 1: Fio test cases

Test case	Description
rand-read-qd1	4K random read, iodepth=1, numjobs=1
rand-write-qd1	4K random write, iodepth=1, numjobs=1
rand-read-qd32	4K random write, iodepth=32, numjobs=4
rand-write-qd32	4K random write, iodepth=32, numjobs=4
rand-rw-qd32 read 70%	4K random read, iodepth=32, numjobs=4
rand-rw-qd32 write 30%	4K random write, iodepth=32, numjobs=4

4.2 Throughput Performance

We first concentrate on the throughput performance of I/O operations on OPTANE and P3600. The basic throughput benchmark concentrates on the 4K page random read and write. Fig. 5(a) and Fig. 5(b) are the corresponding IOPS results on the OPTANE and P3600 NVMe SSDs. The results in these figures contain two parts: the upper part is the normalized performance results based on the native performance baseline, and the bottom part is the original benchmark IOPS results. On OPTANE, the MDev-NVMe mechanism shows the best throughput performance with or without I/O multi-queue optimization(“iodepth=1” or “iodepth=32”) over all the other virtualization mechanisms. With the active polling for I/O queues, MDev-NVMe can make full use of multi-queue features in 4K random read and write I/O benchmarks with “iodepth=32”, where MDev-NVMe shows up to 142% performance over native results. Since the SPDK *vhost-scsi* and SPDK *vhost-blk* mechanisms utilize similar idea of polling, they can also achieve better performance than native results. On P3600 NVMe SSDs, MDev-NVMe show the best performance although the advantages are not as obvious as the OPTANE experiments. Moreover, the throughput performance of 4K random write with multi-queue optimization presents an apparent gap compared with the 4K random read with multi-queue optimization, as we shown in the bottom part of Fig. 5(b).

In this group of experiments, different virtualization mechanisms show well-matched performance expect SPDK *vhost-blk*, which shows that SPDK *vhost-blk* optimization does not works efficiently on P3600.



(a) OPTANE

(b) P3600

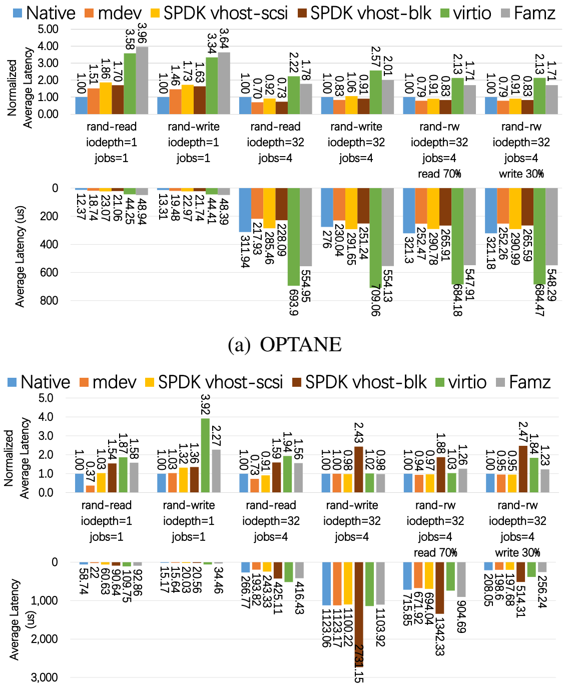
Figure 5: Throughput performance of IOPS.

4.3 Latency Performance

We also focus on the latency of I/O operations in virtual machines based on different NVMe virtualization mechanisms. We particularly discussed the average latency, max latency and the tail latency on different virtualization mechanisms in our latency experiments. Specifically, the latency measured in our fio experiments contains both submission latency and completion latency.

4.3.1 Average Latency

Firstly, the average of latency performance in benchmarks are demonstrated in Fig. 6(a) and Fig. 6(b). Also the upper part is the normalized performance results based on the native performance baseline, and the bottom part is the original latency results. The average latency performance can show the average operation overhead of each I/O commands in NVMe devices through the software stack of virtualization.



(a) OPTANE

(b) P3600

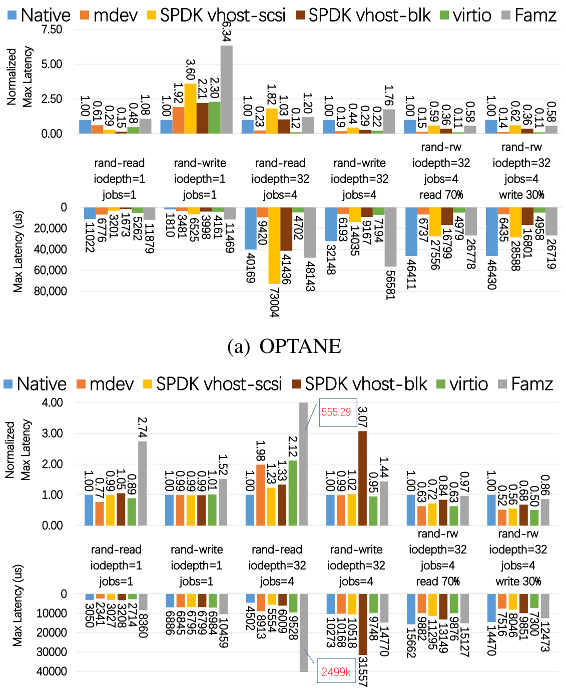
Figure 6: Average latency performance.

As we talked in the former section, the mediated pass-through takes advantage of the *VFIO* pass-through mechanisms and it overcomes the block layer and Backend software stack. When there is no multi-queue optimization [8, 18], all the virtualization mechanism shows no apparent advantage over the native latency performance. The MDev-NVMe, SPDK *vhost-scsi* and SPDK *vhost-blk* can show 2× latency performance over the *Virtio* and Famz userspace driver, and the original latency intervals between native performance and MDev-NVMe is nearly 10 μs, which is at the level of the latency from the host to physical NVMe devices. In multi-queue experiments where “iodepth=32”, the native latency increase to 322 μs which is about 30× the result with “iodepth=1”. However, in multi-queue benchmarks, Mdev-NVMe show the best performance and can achieve only 81% of the native performance. MDev-NVMe shows over 2.5× advantages over *Virtio* and Famz drivers, and the advantages over SPDK *vhost-scsi* and SPDK *vhost-blk* are not far but obvious. On P3600, MDev-NVMe can show great results on all the test cases, except the random write with "iodepth=32" benchmark where all the virtualization performance results are similar. Similar to the throughput benchmarks, SPDK *vhost-blk* does not show the optimization results as those on OPTANE.

In general, MDev-NVMe can achieve the best average latency performance, so our mediated pass-through mechanism has overcome utmost software layer I/O overhead.

4.3.2 QoS

To talk about the QoS performance of the NVMe devices in virtual machines, we concentrate on the maximum latency and tail latency performance in different benchmark test cases.

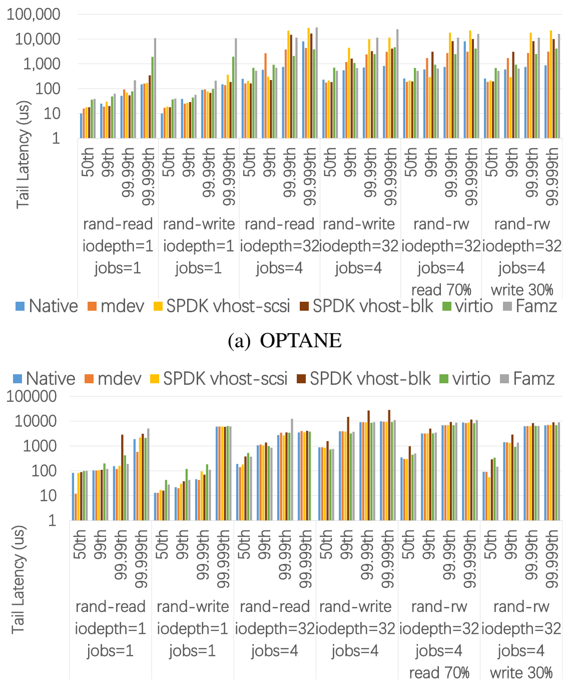


(a) OPTANE

(b) P3600

Figure 7: Maximum Latency performance.

Firstly, the max of latency performance in benchmarks is demonstrated in Fig. 7(a) and Fig. 7(b). For Qos performance, our MDev-NVMe shows well-matched performance of the maximum latency with *Virtio* on both OPTANE and P3600. Also, the normalized maximum latency performance of MDev-NVMe can be less than 1, showing the latency performance can be bound in a very low level. In this part of experiments, SPDK *vhost-scsi* and SPDK *vhost-blk* can not offer a well-matched performance with *Virtio* and MDev-NVMe on both Optane and P3600. Specially, Famz userspace NVMe driver cannot bound its maximum latency in an acceptable level because in Fig. 7(b), the maximum latency of random read with "iodepth=32" is 2499k μs. Also, SPDK *vhost-blk* present a straggler QoS performance on P3600 when doing the random write with "iodepth=32" benchmarks.



(a) OPTANE

(b) P3600

Figure 8: Tail Latency performance.

And we also present the tail latency performance in Fig. 8(a) and Fig. 8(b) with a logarithmic scale coordinate of the latency results. From the figures, MDev-NVMe can bind the 50th and 99th latency performance in similar level. We also compare 99th, 99.99th and 99.999th tail latency in different virtualization mechanisms. MDev-NVMe has the smallest intervals between 99th, 99.99th and 99.999th latency compared with other virtualization mechanisms. In general, MDev-NVMe can provide a promising QoS performance of NVMe virtualization.

4.4 Scalability

Our mediated pass-through mechanism can provide device sharing over a NVMe SSD on the initialization process of virtual machines with a static partition of the device. We design an experiment by separately running 1 VM, 2VMs, and 4VMs and evaluating the virtual NVMe I/O performance to discuss the scalability. In our experiment, each VM manages a 60G continuous storage area by the unmodified guest driver. Fig. 9 presents the relative scalability performance results of MDev-NVMe on the P3600 NVMe device with the scripts in Table 1, and each result is the sum of all throughput in all VMs. As we talked about in the former section, the random write performance is not well-matched with the random read performance. When increasing VMs in the benchmark with "iodepth=1", the performance of 4K random read can increase by the numbers of VMs because the NVMe read performances are not fully exerted when there is no multi-queue optimization [8, 18]. In the other test cases, since the I/O queue resource has been fully used, the I/O performance stays in a stable status when VMs increase from 1 to 4. Since the basic units of NVMe I/O operation are the SQs and CQs, and the performance in VMs is strictly connected with the number of queues assigned for them. As a result, when the number of VMs increases, the assignment of limited I/O queues becomes the bottleneck of scalability. When the queue depth is small, setting up more VMs can utilize make better use of queue resource. When the queue depth is large, MDev-NVME can guarantee that multi VMs can work together without performance obvious drop. So we can conclude that MDev-NVME can ensure a promising scalability.

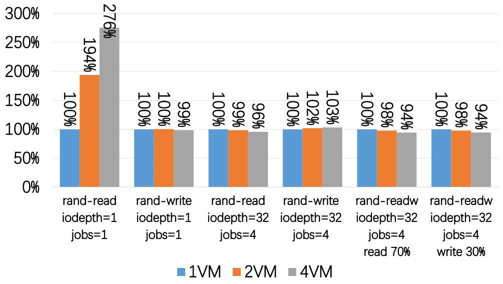


Figure 9: IOPS performance of multi VMs on P3600.

4.5 Influence of I/O Blocksize

The former experiments are based on the 4K random read or write benchmarks, which are concentrated points of test cases on different storage devices. Moreover, the I/O blocksize can explicitly influence the performance of devices wherever on the native devices or in virtual machines. As a result, we want to take the blocksize parameter of I/O performance into consideration to give a law of performance varying with different blocksizes, and we can also give more suggestions for different NVMe virtualization mechanisms to make a right choice of blocksizes in different I/O scenarios.

We run the fio test cases with multi-thread optimization ("iodepth=32") which are the last four test cases presented in Table 1. We chose 10 groups of blocksize parameters in each group of random read of write experiments on OPTANE (512B, 1K, 2K, 4K, 8K, 16K, 64K, 512K, 1M, 4M). The results of the influence of blocksizes on bandwidths are presented in Fig. 10(a), 10(b) ,and 10(c). We only chose the native, MDev-NVMe, and SPDK *vhost-blk* experiments as a comparison since MDev-NVMe and SPDK *vhost-blk* show the best 4K I/O performance based on our prior experiments on OPTANE. In Fig. 10, the variation trends of the influence of blocksizes on bandwidths in the three sub figures basically agree with each other. When the blocksizes are smaller than 4K, the throughput performance improve with the blocksize parameter and the high throughput performance are not fully exerted. These is because the NVMe I/O queues can be 64K large at most and when the blocksize is too small and the device is not fully occupied, resulting in a I/O queue resource waste. Also the throughput performance can be continuously improved with the growing blocksize on native devices, but the performance results of MDev-NVMe and SPDK shows apparent declines when the blocksize is larger than 512K. The reason for this performance drop is that when the I/O blocksize is too large, then transmission of an I/O block may be automatically separated by the hypervisor and these separations bring an appreciable overhead. A single I/O command of such a large block needs cooperation of several I/O queues and the scheduling of queues will become a performance bottleneck.

Also, we demonstrate the average latency performance of native, MDev-NVMe, and SPDK *vhost-blk* experiments in Fig. 11(a), 11(b), and 11(c). We use the a logarithmic scale coordinate to present the average latency experiment results in the three sub figures from Fig. 11. The variation trends of the influence of blocksizes on average latency performance in the three sub figures agree with each other as well as the throughput performance results. The average latency slightly decreases from 512B to 4K and then progressively increases from 4K to 4M. The MDev-NVME and SPDK can all bind their average latency performance in the same order of magnitude as the native performance. When the blocksize $\leq$ 16K, the average latency performance is in the level of several hundred μs. When the blocksize is chosen as 64K, 512K, 1M and 4M, the average latency performance increases exponentially by the magnitude. The main reason for this unacceptable latency are mainly resulted by the I/O block separations and the overhead waiting for all queue competitions.

In general, the throughput performance is good when blocksizes is bigger than 4K while the average latency performance will become unacceptable when the blocksize is bigger than 64K. Our MDev-NVMe can provide a stable and excellent performance of both throughput and latency when choosing blocksizes as 4K, 8K, and 16K, and the performance is better than SPDK and native performance. To support more optional blocksize with the high performance, we would give a more efficient I/O queue scheduling in our future works.

5 Discussions

In this section we discuss the advantages of MDev-NVMe over other viruralization mechanisms, the overhead issues, and the importance of active polling in virtualization.

Advantages of MDev-NVMe: As we demonstrated in §4, MDev-NVMe presents outstanding performance on throughput, average latency, and QoS. Furthermore, the data from the experiments suggests the performance in VMs can be even better than a native device. In our comparison experiment, MDev-NVMe can achieve over 2.5× throughput performance of Virtio and Famz, and achieve less than 31% average latency of *Virtio* and Famz. SPDK *vhost-scsi* and *vhost-blk* can provide a promising performance, slightly inferior to MDev-NVMe. However, SPDK needs Hugepage memory and additionally the setting up of a SPDK *vhost* device on the NVMe device, so it may restrict the flexibility of physical NVMe devices. Our MDev-NVMe is implemented as a kernel module, offering more convenience for cloud administrators and users with its better maintenance than SPDK, and MDev-NVMe brings no memory overhead.

Overhead issues: The shadow of guest I/O queues to physical queues is determined by the MDev-NVMe module. The scheduling of I/O queues is based on a simple FIFO policy. When aggressive I/O tasks in VMs are competing for the limited physical queues it can increase the scheduling overhead in the host and will lead to some problems in the balancing of requests. Here, a increasingly complicated scheduling algorithm is implemented or a queue resource ballooning methodology could be used in future work to overcome the potential overhead in heavy I/O workloads. To overcome the I/O performance bottleneck results from the high frequency vm-exit of guest I/O commands, an additional CPU resource is used for polling in order to accelerate the interrupt operations. A polling thread aggressively utilizes the CPU resource of a single core, which transfers overhead to the host server when running large numbers of VMs. However, the proposed system ensures no CPU resource overhead to VMs since all the guests use native NVMe drivers which are not aware of the polling threads. Moreover, polling can significantly reduce CPU usage in the VM because it avoids "vm-exit".

Importance of polling: The main agreement of MDev-NVMe and SPDK is that the virtualization mechanisms take active polling instead of interrupts handling. The traditional virtualization mechanisms are often based on the trap and emulations. The trap of the "vm-exit" needs additional context switches between VMs and the host kernel. The NVMe protocol is an inherently parallel and high-performing interface and command set. Therefore, when we would like to make full use of the I/O queue resource, the large numbers of interrupts bring an appreciable overhead for guests. Now, assigning exclusive CPU computing resources to handle the high frequency of interrupts can directly help to achieve high performance of I/O operations in VMs. Taking polling is the most direct and obvious idea to assign the exclusive CPU resource for queue handling.

Despite the high utilization of polling CPU may generate limited CPU computing resource waste to the host servers, polling is still necessary when the I/O workloads are aggressive in achieving extremely high performance.

For example, when shopping seasons such as "Black Friday" arrive, the servers of e-commerce companies will face great pressure of database accesses and parallel processing. Subsequently, the storage device throughput and latency performance is directly connected with the respective companies profits, losses and their customers satisfaction. Supporting polling in the virtualization mechanism is essential to take full advantage of the benefits of NVMe devices to meet the requirements on I/O performance in datacenters. Moreover, NVMe virtualization should support adaptive polling, which allows such datacenter administrators to decide when to choose a mild policy for I/O acceleration in VMs, to reduce expenses and support an increasing number of VMs. Therefore the provision of an adaptive polling mode and increasingly optimized polling algorithms is part of our focus for future work. It is also expected that the high performance I/O device hardware will be designed with a number of components to actively support or cooperate with the polling algorithm in the near future.

6 Related Work

Some research concentrates on NVMe virtualization, including the para-virtualization abstraction *Virtio*, a userspace NVMe driver in Qemu, and the Storage Performance Development Kit (SPDK).

VMware virtual NVMe device: After vSphere 6.5, VMware adds an NVMe controller for NVMe devices in its virtualization solution. The biggest benefit of using an NVMe interface over the traditional SCSI is that it can significantly reduce the amount of overhead, as well as reducing the IO latency for VM workloads.

Virtio for NVMe: *Virtio* is an abstraction for a set of common emulated devices in a para-virtualized hypervisor, which allows the hypervisor to export a common set of emulated devices and make them available through the costumed API. Briefly, *Virtio* is easy in the implementation of storage device virtualization. *Virtio* inevitably increases the I/O path which indicates that guest I/O request goes through both guest and host I/O path. Data replication between guest and host can also have an impact on performance.

Userspace NVMe Driver in QEMU: Fam Zheng [34] implements a NVMe driver with *VFIO* as the driver of NVMe device to cooperate with the modified userspace NVMe driver in Qemu. Compared with the *VFIO* method, this userspace driver emulates several software layer, that is the BlockBackend, Block layer, and Qcow2 layers in Qemu. This userspace NVMe driver takes advantages of *VFIO*, enabling NVMe device to gain more I/O software layer features at the cost of device sharing capability and this virtualization mechanism brings apparent latency to the VMs.

SPDK: The Storage Performance Development Kit (SPDK) is a user-mode application which aims at providing a high performance and scalable I/O application interfaces for different storage devices. It integrates all of the necessary drivers into userspace and operates with an enforced polling mode to achieve high I/O performances by taking advantage of DPDK [14]. Specifically, SPDK application extends "SPDK vhost" to present *Virtio* storage controllers to QEMU-based VMs with *vhost-scsi* and *vhost-blk* [20] interfaces.

7 Conclusion

Within this paper, there is introduction of a new virtualization implementation for NVMe storage device MDev-NVMe. The MDev-NVMe is a full NVMe storage virtualization mechanism where all the VMs can run native NVMe driver. The proposed solution takes a mediated pass-through as the main implementation containing the Admin queue emulations and I/O queues shadowing on the basis of Device emulation for all PCI configurations. To achieve the most outstanding performance of the NVMe device among mainstream NVMe virtualization mechanisms, it is proposed that an active polling mode is implemented, which can achieve both high throughput, low latency performance and a reliable device scalability on both Intel OPTANE and P3600 NVMe SSD. With the MDev-NVMe module, the physical device can be partitioned to support device sharing, and each VM can own a full-fledged NVMe device which can directly access the physical performance-critical resources without interference with other VMs. The large numbers of Fio benchmark experiments provides evidence for the great performance of MDev-NVMe, which is better than native performance and other existing virtualization mechanisms. There is also focus and consideration into the influence of blocksize on the I/O performance to provide more suggestions to different I/O applications. Finally, we focus on the high performance of MDev-NVMe by analysis of the performance comparisons between different mechanisms, raising a discussion about polling. Therefore recommendations are provided for the optimization on polling support from both aspects for the design of storage hardware and also, virtualization. In the future, further research on the support for polling will be conducted as well as the optimization of the polling algorithm for MDev-NVMe.

Abstract

From small mobile devices to large-scale storage arrays, flash memory-based storage systems have gained a lot of popularity in recent years. However, the uncoordinated use of resources by competing tasks in the flash translation layer (FTL) makes it difficult to guarantee predictable performance.

In this paper, we present *AutoSSD*, an autonomic SSD architecture that self-manages FTL tasks to maintain a high-level of QoS performance. In AutoSSD, each FTL task is given an illusion of a dedicated flash memory subsystem, allowing tasks to be implemented oblivious to others and making it easy to integrate new tasks to handle future flash memory quirks. Furthermore, each task is allocated a share that represents its relative importance, and its utilization is enforced by a simple and effective scheduling scheme that limits the number of outstanding flash memory requests for each task. The shares are dynamically adjusted through feedback control by monitoring key system states and reacting to their changes to coordinate the progress of FTL tasks.

We demonstrate the effectiveness of AutoSSD by holistically considering multiple facets of SSD internal management, and by evaluating it across diverse workloads. Compared to state-of-the-art techniques, our design reduces the average response time by up to 18.0%, the 3 nines (99.9%) QoS by up to 67.2%, and the 6 nines (99.9999%) QoS by up to 76.6% for QoS-sensitive small reads.

1 Introduction

Flash memory-based storage systems have become popular across a wide range of applications from mobile systems to enterprise data storages. Flash memory's small size, resistance to shock and vibration, and low power consumption make it the *de facto* storage medium in mobile devices. On the other hand, flash memory's low latency and collectively massive parallelism make flash storage suitable for high-performance storage for mission-critical applications. As multi-level cell technology [5] and 3D stacking [38] continue to lower the cost per GB, flash storage will not only remain competitive in the data storage market, but also will enable the emergence of new applications in this *Age of Big Data*.

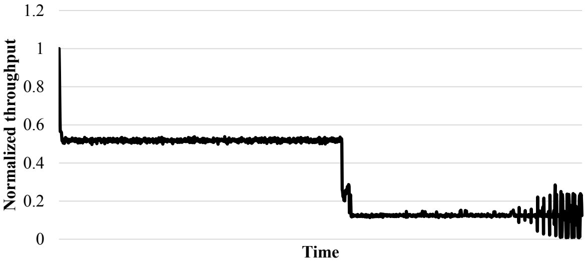

Figure 1: Performance drop and variation under 4KB random writes.

Large-scale deployments and user experiences, however, reveal that despite its low latency and massive parallelism, flash storage exhibits high performance instabilities and variations [9, 17]. Garbage collection (GC) has been pointed out as the main source of the problem [9, 25, 28, 29, 45], and Figure 1 illustrates this case. It shows the performance degradation of our SSD model under small random writes, and it closely resembles measured results from commercial SSDs [2,23]. Initially, the SSD's performance is good because all the resources of the flash memory subsystem can be used to service host requests. But as the flash memory blocks are consumed by host writes, GC needs to reclaim space by compacting data spread across blocks and erasing unused blocks. Consequently, host and GC compete for resources, and the host performance inevitably suffers.

However, garbage collection is a necessary evil for the flash storage. Simply putting off space reclamation or treating GC as a low priority task will lead to larger performance degradations, as host writes will eventually block and wait for GC to reclaim space. Instead, garbage collection must be judiciously scheduled with host requests to ensure that there is enough free space for future requests, while meeting the performance demands of current requests. This principle of harmonious coexistence, in fact, extends to every internal management task. Map caching [15] that selectively keeps mapping data in memory generates flash memory traffic on cache misses, but this is a mandatory step for locating host data. Read scrubbing [16] that preventively migrates data before its corruption also creates traffic when blocks are repeatedly read, but failure to perform its duty on time can lead to data loss. As more tasks with unique responsibilities are added to the system, it becomes increasingly difficult to design a system that meets its performance and reliability requirements [13].

In this paper, we present an autonomic SSD architecture called AutoSSD that self-manages its management tasks to maintain a high-level of QoS performance. In our design, each task is given a virtualized view of the flash memory subsystem by hiding the details of flash memory request scheduling. Each task is allocated a share that represents the amount of progress it can make, and a simple yet effective scheduling scheme enforces resource arbitration according to the allotted shares. The shares are dynamically and automatically adjusted through feedback control by monitoring key system states and reacting to their changes. This achieves predictable performance by maintaining a stable system. We show that for small read requests, AutoSSD reduces the average response time by up to 18.0%, the 3 nines (99.9%) QoS by up to 67.2%, and the 6 nines (99.9999%) QoS by up to 76.6% compared to state-of-the-art techniques. Our contributions are as follows:

- We present AutoSSD, an autonomic SSD architecture that dynamically manages internal housekeeping tasks to maintain a stable system state. (§ 3)
- We holistically consider multiple facets of SSD internal management, including not only garbage collection and host request handling, but also mapping management and read scrubbing. (§ 4)
- We evaluate our design and compare it to the state-of-the-art techniques across diverse workloads, analyze causes for long tail latencies, and demonstrate the advantages of dynamic management. (§ 5)

The remainder of this paper is organized as follows. § 2 gives a background on understanding why flash storages exhibit performance unpredictability. § 3 presents the overall architecture of AutoSSD and explains our design choices. § 4 describes the evaluation methodology and the SSD model that implements various FTL tasks, and § 5 presents the experimental results under both synthetic and real I/O workloads. § 6 discusses our design in relation to prior work, and finally § 7 concludes.

2 Background

For flash memory to be used as storage, several of its limitations need to be addressed. First, it does not allow in-place updates, mandating a mapping table between the logical and the physical address space. Second, the granularities of the two state-modifying operations—program and erase—are different in size, making it necessary to perform garbage collection (GC) that copies valid data to another location for reclaiming space. These internal management schemes, collectively known as the flash translation layer (FTL) [11], hide the limitations of flash memory and provide an illusion of a traditional block storage interface.

The role of the FTL has become increasingly important as hiding the error-prone nature of flash memory can be challenging when relying solely on hardware techniques such as error correction code (ECC) and RAID-like parity schemes. Data stored in the flash array may become corrupt in a wide variety of ways. Bits in a cell may be disturbed when neighboring cells are accessed [12, 41, 44], and the electrons in the floating gate that represent data may gradually leak over time [6, 35, 44]. Sudden power loss can increase bit error rates beyond the error correction capabilities [44, 47], and error rates increase as flash memory blocks wear out [6, 12, 19]. As flash memory becomes less reliable in favor of high-density [13], more sophisticated FTL algorithms are needed to complement existing reliability enhancement techniques.

Even though modern flash storages are equipped with sophisticated FTLs and powerful controllers, meeting performance requirements have three main challenges. First, as new quirks of flash memory are introduced, more FTL tasks are added to hide the limitations, thereby increasing the complexity of the system. Furthermore, existing FTL algorithms need to be fine-tuned for every new generation of flash memory, making it difficult to design a system that universally meets performance requirements. Second, multiple FTL tasks generate sequences of flash memory requests that contend for the resources of the shared flash memory subsystem. This resource contention creates queueing delays that increase response times and causes long-tail latencies. Lastly, depending on the state of the flash storage, the importance of FTL tasks dynamically changes. For example, if the flash storage runs out of free blocks for writing host data, host request handling stalls and waits for garbage collection to reclaim free space. On the other hand, with sufficient free blocks, there is no incentive prioritizing garbage collection over host request handling.

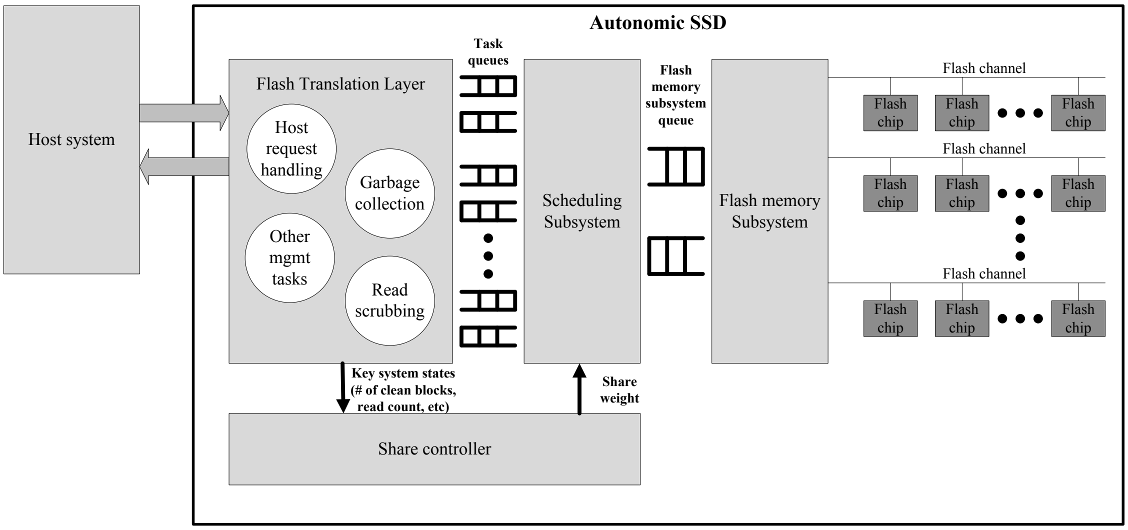

Figure 2: Overall architecture of AutoSSD and its components.

3 AutoSSD Architecture

In this section, we describe the overall architecture and design of the autonomic SSD (AutoSSD) as shown in Figure 3. In our model, all FTL tasks run concurrently, with each designed and implemented specifically for its job. Each task independently interfaces the scheduling subsystem, and the scheduler arbitrates the resources in the flash memory subsystem according to the assigned share. The share controller monitors key system states and determines the appropriate share for each FTL task. AutoSSD is agnostic to the specifics of the FTL algorithms (i.e., mapping scheme and GC victim selection), and the following subsections focus on the overall architecture and design that enable the self-management of the flash storage.

3.1 Virtualization of the Flash Memory Subsystem

The architecture of AutoSSD allows each task to be independent of others by virtualizing the flash memory subsystem. Each FTL task is given a pair of request and response queues to send and receive flash memory requests and responses, respectively. This interface provides an illusion of a dedicated (yet slower) flash memory subsystem and allows an FTL task to generate flash memory requests oblivious of others (whether idle or active) or the requests they generate (intensity or which resources they are using). Details of the flash memory subsystem are completely abstracted by the scheduling subsystem, and only the back-pressure of the queue limits each task from generating more flash memory requests.

This virtualization not only effectively frees each task from having to worry about others, but also makes it easy to add a new FTL task to address any future flash memory quirks. While background operations such as garbage collection, read scrubbing, and wear leveling have similar flash memory workload patterns (reads and programs, and then erases), the objective of each task is distinctly different. Garbage collection reclaims space for writes, read scrubbing preventively relocates data to ensure data integrity, and wear leveling swaps contents of data to even out the damage done on flash memory cells. Our design allows seamless integration of new tasks without having to modify existing ones and reoptimize the system.

3.2 Scheduling for Share Enforcement

The scheduling subsystem interfaces with each FTL task and arbitrates the resources of the flash memory subsystem. The scheduler needs to be efficient with low overhead as it manages concurrency (tens and hundreds of flash memory requests) and parallelism (tens and hundreds of flash memory chips) at a small timescale.

In AutoSSD, we consider these unique domain characteristics and arbitrate the flash memory subsystem resource through *debit scheduling*. The debit scheduler tracks and limits the number of outstanding requests per task across all resources, and is based on the request windowing technique [14, 20, 34] from the disk scheduling domain. If the number of outstanding requests for a task, which we call debit, is under the limit, its requests are eligible to be issued; if it's not, the request cannot be issued until one or more of requests from that task completes. The debt limit is proportional to the share set by the share controller, allowing a task with a higher share to potentially utilize more resources simultaneously. The sum of all tasks' debt limit represents the total amount of

	Task A	Task B
Debit	1 → 2	3
Debt limit	5	3

	Task A	Task B
Debit	2	2 → 3
Debt limit	5	3

(a) Task A's request issued to Chip 2.

(b) Task B's request issued to Chip 0.

Figure 3: Two debit scheduling examples. In the scenario of Figure 3a, no more requests can be sent to Chip 0, and Task B is at its maximum debit. The only eligible scheduling is issuing Task A's request to Chip 2. In the scenario of Figure 3b, while Task A is still under the debt limit, its request cannot be issued to a chip with a full queue. On the other hand, a request from Task B can be issued as Chip 3's operation for Task B completes.

parallelism, and is set to the total number of requests that can be queued in the flash memory controller.

Figure 3 illustrates two scenarios of the debit scheduling. In both scenarios, the debt limit is set to 5 requests for Task A, and 3 for Task B. In Figure 3a, no more requests can be sent to Chip 0 as its queue is full, and Task B's requests cannot be scheduled as it is at its debt limit. Under this circumstance, Task A's request to Chip 2 is scheduled, increasing its debit value from 1 to 2. In Figure 3b, the active operation at Chip 3 for Task B completes, allowing Task B's request to be scheduled. Though Task B's request to Chip 1 is not at the head of the queue, it is scheduled out-of-order as there is no dependence between the requests to Chip 0 and Chip 1. Task A, although below the debt limit, cannot have its requests issued until Chip 0 finishes a queued operation, or until a new request to another chip arrives. Though not illustrated in these scenarios, when multiple tasks under the limit compete for the same resource, one is chosen with skewed randomness favoring a task with a smaller debit to debt limit ratio. Randomness is added to probabilistically avoid starvation.

Debit scheduling only tracks the number of outstanding requests, yet exhibits interesting properties. First, it can make scheduling decisions without complex computations and bookkeeping. This allows the debit scheduler to scale with increasing number of resources. Second, although it does not explicitly track *time*, it implicitly favors short latency operations as they have a faster turn-around-time. In scheduling disciplines such as weighted round robin [26] and weighted fair queueing (WFQ) [10], the latency of operations must be known or estimated to achieve some degree of fairness. Debit scheduling, however, approximates fairness in the time-domain only by tracking the number of outstanding requests. Lastly, the scheduler is in fact not work-conserving. The total debt limit can be scaled up to approximate a work-conserving scheduler, but the share-based resource reservation of the debit scheduler allows high responsiveness, as observed in the resource reservation protocol for Ozone [36].

3.3 Feedback Control of Share

The share controller determines the appropriate share for the scheduling subsystem by observing key system states. States such as the number of free blocks and the maximum read count reflect the stability of the flash storage. This is critical for the overall performance and reliability of the system, as failure to keep these states at a stable level can lead to an unbounded increase in response time or even data loss.

For example, if the flash storage runs out of free blocks, not only do host writes block, but also all other tasks that use flash memory programs stall: activities such as making mapping data durable and writing periodic checkpoints also depend on the garbage collection to reclaim free space. Even worse, a poorly constructed FTL may become deadlocked if GC is unable to obtain a free block to write the valid data from its victim. On the other hand, if a read count for a block exceeds its recommended limit, accumulated read disturbances can lead to data loss if the number of errors is beyond the error correction capabilities. In order to prevent falling into these adverse system conditions, the share controller monitors the system states and adjusts shares to control the rate of progress for individual FTL tasks, so that the system is maintained within stable levels.

AutoSSD uses feedback to adaptively determine the shares for the internal FTL tasks. While the values of key system states must be maintained at an adequate level, the shares of internal tasks must not be set too high such that they severely degrade the host performance. Once a task becomes active, it initially is allocated a small share. If this fails to maintain the current level of the system state, the share is gradually increased to counteract the momentum. The following control function is used to achieve this behavior:

$$S_A[t] = P_A \cdot e_A[t] + I_A \cdot S_A[t-1] \tag{1}$$

Where $S_A[t]$ is the share for task A at time t, $S_A[t-1]$ is the previous share for task A, P_A and I_A are two non-negative coefficients for task A, and $e_A[t]$ is the error value for task A at time t. The error value function for GC is defined as follows:

$$e_{GC}[t] = \max(0, target_{freeblk} - num_{freeblk}[t]) \tag{2}$$

With $target_{freeblk}$ set to the GC activation threshold, the share for GC S_{GC} starts out small. If the number of free blocks $num_{freeblk}[t]$ falls far below $target_{freeblk}$, the error function $e_{GC}[t]$ augmented by P_{GC} ramps up the GC share S_{GC}. After the number of free blocks $num_{freeblk}[t]$ exceeds the threshold $target_{freeblk}$, the share S_{GC} slowly decays given $I_{GC} < 1$.

Addition to the GC share control, the error value function for read scrubbing (RS) is defined as follows:

$$e_{RS}[t] = \max(0, \max_{i \in blk}(readcnt_i[t]) - target_{readcnt}) \tag{3}$$

Where $\max\limits_{i \in blk}(readcnt_i[t])$ is the maximum read count across all blocks in the system at time t, and $target_{readcnt}$ is the RS activation threshold.

In our design, the share for internal management schemes starts out small, anticipating host request arrivals and using the minimum amount of resources to perform its task. If the system state does not recover, the error (the difference between the desired and the actual system state values) accumulates, increasing the share over time.

It is important to note that the progress rate for a task depends not only on the share, but also on the workload, algorithm, and system state. For example, the number of valid data in the victim block, the location of the mapping data associated with the valid data, and the access patterns at the flash memory subsystem all affect the rate of progress for GC. A task's progress rate is, in fact, non-linear to the share under real-world workloads, and computationally solving for the optimal share involves large overhead, if not impossible. As a result, the two coefficients P and I for FTL tasks are empirically hand-tuned in this work.

Table 1: System configuration.

Parameter	Value	Parameter	Value
# of channels	4	Read latency	50μs
# of chips/channel	4	Program latency	500μs
# of planes/chip	2	Erase latency	5ms
# of blocks/plane	1024	Data transfer rate	400MB/s
# of pages/block	512	Physical capacity	256GB
Page size	16KB	Logical capacity	200GB

4 Evaluation Methodology and Modeling

We model a flash storage system on top of the DiskSim environment [1] by enhancing its SSD extension [3]. In this section, we describe the various components and configuration of the SSD, and the workload and test settings used for the evaluation.

4.1 Flash Memory Subsystem

Flash memory controller is based on Ozone [36] that fully utilizes flash memory subsystem's channel and chip parallelism. There can be at most four requests queued to each chip in the controller. Increasing this queue depth does not significantly increase intra-chip parallelism, as cached operations of flash memory have diminishing benefits as the channel bandwidth increases. Instead, a smaller queue depth is chosen to increase the responsiveness of the system.

Table 1 summarizes the default flash storage configuration used in our experiments. Of the 256GB of physical space, 200GB is addressable by the host system, giving an over-provisioning factor of 28%.

4.2 Flash Translation Layer

We implement core FTL tasks and features that are essential for storage functions, yet cause performance variations. Garbage collection reclaims space, but it degrades the performance of the system under host random writes. Read scrubbing that preventively relocates data creates background traffic on read-dominant workloads. Mapping table lookup is necessary to locate host data, but it increases response time on map cache misses.

Mapping. We implement an FTL with map caching [15] and a mapping granularity of 4KB. The entire mapping table is backed in flash, and mapping data, also maintained at the 4KB granularity, is selectively read into memory and written out to flash during runtime. The LRU policy is used to evict mapping data, and if the victim contains any dirty mapping entries, the 4KB mapping data is written to flash. By default, we use 128MB of memory to cache the mapping table. The second-level mapping that tracks the locations of the 4KB mapping

Table 2: Trace workload characteristics.

Workload	Duration (hrs)	Number of I/Os (Millions)		Average request size(KB)		Inter-arrival time (ms)	
		Write	Read	Write	Read	Average	Median
DAP-DS	23.5	0.1	1.3	7.2	31.5	56.9	31.6
DAP-PS	23.5	0.5	0.6	96.7	62.1	79.9	1.7
DTRS	23.0	5.8	12.0	31.9	21.8	4.6	1.5
LM-TBE	23.0	9.2	34.7	61.9	53.2	1.9	0.8
MSN-CFS	5.9	1.1	3.2	12.9	8.9	4.9	2.0
MSN-BEFS	5.9	9.2	18.9	11.6	10.7	0.8	0.3
RAD-AS	15.3	2.0	0.2	9.9	11.0	24.9	0.8
RAD-BE	17.0	4.3	1.0	13.0	106.2	11.7	2.6

data is always kept in memory as it is accessed more frequently and orders of magnitude smaller than the first-level mapping table.

Host request handling. Upon receiving a request, the host request handler looks up the second-level mapping to locate the mapping data that translates the host logical address to the flash memory physical address. If the mapping data is present in memory (hit), the host request handler references the mapping data and generates flash memory requests to service the host request. If it is a miss, a flash memory read request to fetch the mapping data is generated, and the host request waits until the mapping data is fetched. Host requests are processed in a non-blocking manner; if a request is waiting for the mapping data, other requests may be serviced out-of-order. In our model, if the host write request is smaller than the physical flash memory page size, multiple host writes are aggregated to fill the page to improve storage space utilization. We also take into consideration of the mapping table access overhead and processing delays. Mapping table lookup delay is set to be uniformly distributed between 0.5μs and 1μs, and the flash memory request generation delay for the host task is between 1μs and 2μs.

Garbage collection. The garbage collection (GC) task runs concurrently and independently from the host request handler and generates its own flash memory requests. Victim blocks are selected based on cost-benefit [40]. Once a victim block is selected, valid pages are read and programmed to a new location. Mapping data is updated as valid data is copied, and this process may generate additional requests (both reads and programs) for mapping management. Once all the valid pages have been successfully copied, the old block is erased and marked free. GC becomes active when the number of free blocks drops below a threshold, and stops once the number of free blocks exceeds another threshold, similar to the segment cleaning policy used for the log-structured file system [40]. In our experiments, the two threshold values for GC activation and deactivation are set to 128 and 256 free blocks, respectively. The garbage collection task also has a request generation delay, set to be uniformly distributed between 1μs and 3μs.

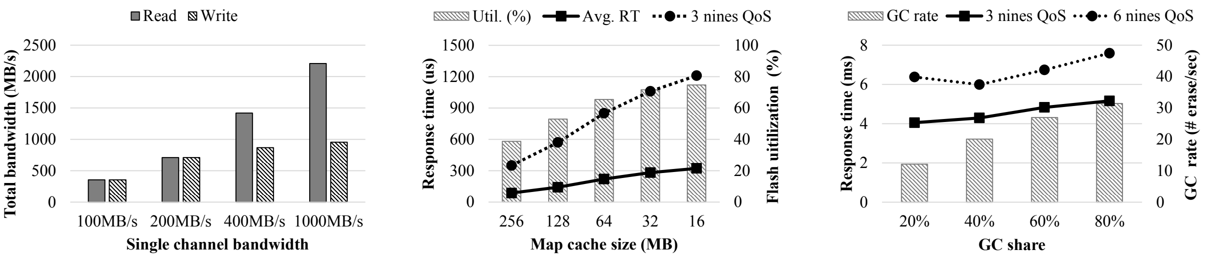
Read scrubbing. The read scrubbing (RS) task also runs as its own stand-alone task. Victims are selected greedily based on the read count of a block: the block with the most number of reads is chosen. Other than that, the process of copying valid data is identical to that of the garbage collection task. RS becomes active when the maximum read count of the system goes beyond a threshold, and stops once it falls below another threshold. The default threshold values for the activation and deactivation are set to 100,000 and 80,000 reads, respectively. Like the garbage collection task, the request generation delay (modeling the processing overhead of read scrubbing) is uniformly distributed between 1μs and 3μs.

4.3 Workload and Test Settings

We use both synthetic workloads and real-world I/O traces from Microsoft production servers [27] to evaluate the autonomic SSD architecture. Synthetic workloads of 128KB sequential accesses, 4KB random reads, and 4KB random read/writes are used to verify that our model behaves expectedly according to the system parameters.

From the original traces, the logical address of each host request is modified to fit into the 200GB range, and all the accesses are aligned to 4KB boundaries. All the traces are run for their full duration, with some lasting up to 24 hours and replaying up to 44 million I/Os. The trace workload characteristics are summarized in Table 2.

Prior to each experiment, the entire physical space is randomly written to emulate a pre-conditioned state so that the storage would fall under the steady state performance described in SNIA's SSS-PTS [2]. Furthermore, each block's read count is initialized with a non-negative random value less than the read scrubbing threshold to emulate past read activities.



(a) 128KB sequential accesses.

(b) 4KB random reads.

(c) 4KB random reads/writes.

Figure 4: Performance under synthetic workloads. Figure 4a shows the total bandwidth under 128KB sequential accesses with respect to changes in the channel bandwidth. Figure 4b shows the performance (average response time and 3 nines QoS) and the utilization of the flash memory subsystem with respect to changes in the size of the in-memory map cache. Figure 4c shows the performance (3 nines and 6 nines QoS) and the GC progress rate with respect to the GC share.

5 Experiment Results

This section presents experimental results under the configuration and workload settings described in the previous section. The main performance metric we report is the system response time seen at the I/O device driver. We first validate our SSD model using synthetic workloads, and then present experimental results with I/O traces. We replayed the I/O traces with the original request dispatch times, and with the dispatch times scaled down to increase the workload intensity.

5.1 Micro-benchmark Results

Figure 4 illustrates the performance of the autonomic SSD architecture (AutoSSD) with debit scheduling under four micro-benchmarks. Figure 4a plots the total bandwidth under 128KB sequential reads and 128KB sequential writes as we increase the channel bandwidth. As the channel bandwidth increases, the flash memory operation latency becomes the performance bottleneck. Write performance saturates early as the program latency cannot be hidden with data transfers. At 1000MB/s channel bandwidth, the read operation latency also becomes the bottleneck, unable to further extract bandwidth from the configured four channels. Traffic from GC and mapping management has a negligible effect for large sequential accesses, and RS task was disabled for this run to measure maximum raw bandwidth.

In Figure 4b, we vary the in-memory map cache size and measure the response times of 4KB random read requests when issued at 100K I/Os per second (IOPS). As expected, the response time is the smallest when the entire map is in memory, as it does not generate map read requests once the cache is filled after cold-start misses. However, as the map cache becomes smaller, the response time for host reads increases not only because it probabilistically stalls waiting for map reads from flash memory, but also due to increased flash memory traffic, which causes larger queueing delays.

Lastly, we demonstrate that the debit scheduling mechanism exerts control over FTL tasks in Figure 4c. In this scenario, 4KB random read/write requests are issued at 20K IOPS with a 1-to-9 read/write ratio. Both the response time of host read requests and GC task's progress (in terms of the number of erases per second while active) are measured at fixed GC shares from 20% to 80%. As shown by the bar graph, more blocks are erased as the share for GC increases. Furthermore, with more GC share, the overall host performance suffers, as evident by the increase in the 3 nines QoS. Deceptively, however, assigning not enough share to GC will result in worse tail latency as shown by the 6 nines QoS. GC needs to produce sufficient number of free blocks for the host to consume, and failure to do so will cause the host to block.

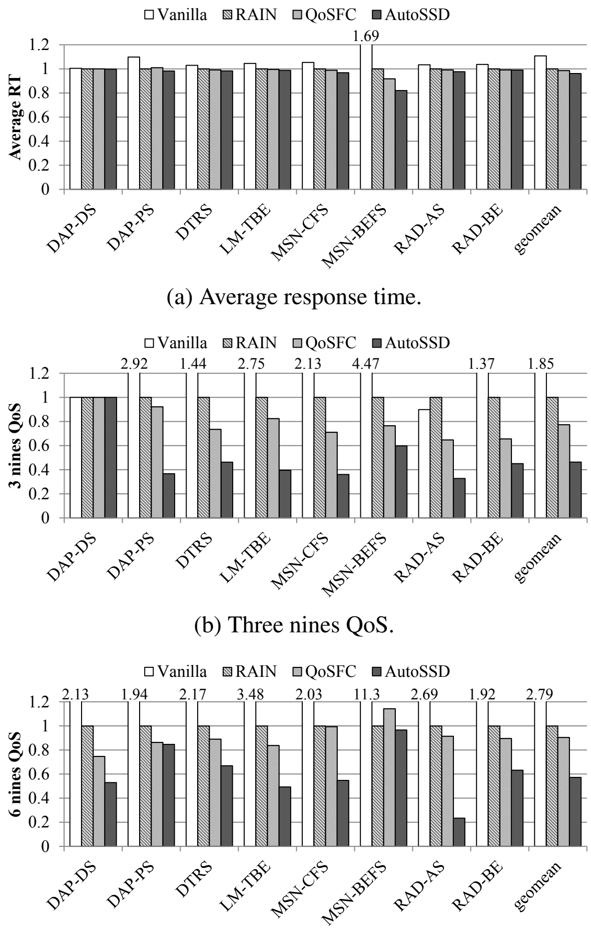
5.2 I/O Trace Results

Using I/O traces, we evaluate the performance of AutoSSD and compare it to following three systems:

Vanilla represents a design without virtualization and coordination, and all tasks dispatch requests to the controller through a single pair of request/response queue.

RAIN [45] uses parity to reconstruct data when accessing the chip is blocked by background tasks. Resources are arbitrated through fixed priority scheduling, with host requests having the highest priority. This technique requires an additional physical capacity to store parity data.

QoSFC [28] schedules using weighted fair queueing (WFQ) and represents a work-conserving system that does not reserve resources. It maintains virtual time as a measure of progress for each FTL task at each flash memory resource.



(a) Average response time.

(b) Three nines QoS.

(c) Six nines QoS.

Figure 5: Comparison of Vanilla, RAIN, QoSFC, and AutoSSD under eight different traces. Results are normalized to the performance of RAIN. AutoSSD reduces the average response time by up to 18.0% under MSN-BEFS (by 3.8% on average), the 3 nines QoS by up to 67.2% under RAD-AS (by 53.6% on average). and the 6 nines QoS by up to 76.6% under RAD-AS (by 42.7% on average).

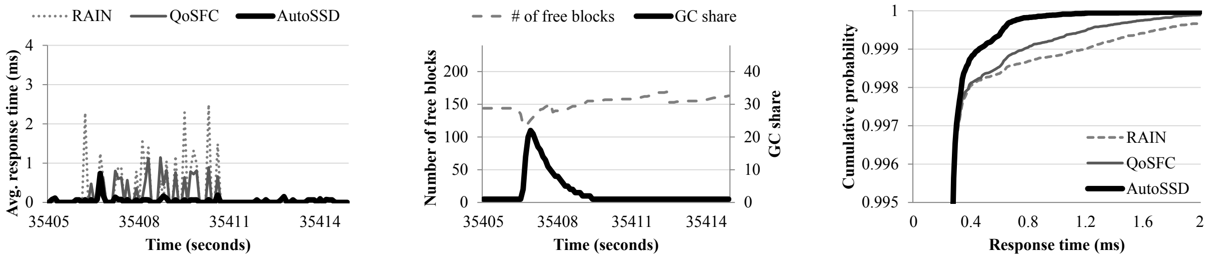
As the focus of this paper is response time characteristics, we only measure the performance of QoS-sensitive small reads (no larger than 64KB) in terms of the average response time, the 3 nines (99.9%) QoS figure, and the 6 nines (99.9999%).

Figure 5 compares the performance of the four systems under eight different traces. Compared to RAIN, AutoSSD reduces the average response time by up to 18.0% under MSN-BEFS as shown in Figure 5a. For the 3 nines QoS, AutoSSD shows improvements across most workloads, reducing it by 53.6% on average and as much as by 67.2% under RAD-AS (see Figure 5b). For the 6 nines QoS, AutoSSD shows much greater improvements, reducing it as much as by 76.6% under RAD-AS (see Figure 5c). Without coordination among FTL tasks, the Vanilla performance suffers, especially for the long tail latencies. In terms of the 6 nines, AutoSSD performs well under bursty workloads such as RAD-AS and LM-TBE (large difference between average and median inter-arrival times in Table 2). This is because AutoSSD limits the progress of internal FTL tasks depending on the state of the system, making resources available for the host in a non-work-conserving manner. This is in contrast to the scheduling disciplines used by the other systems: Vanilla uses FIFO scheduling; RAIN, priority scheduling; and QoSFC, weighted fair queueing.

To better understand the overall results in Figure 5, we microscopically examine the performance under RAD-AS in Figure 6 and LM-TBE in Figure 7. Figure 6a shows the average response time of three systems—RAIN, QoSFC, and AutoSSD—during a 10-second window, approximately 10 hours into RAD-AS. GC is active during this window for all the three systems, and both RAIN and QoSFC exhibit large spikes in response time. On the other hand, AutoSSD is better able to bound the performance degradation caused by an active garbage collection. Figure 6b shows the number of free blocks and the GC share during that window for AutoSSD. The sawtooth behavior for the number of free blocks is due to host requests consuming blocks, and GC gradually reclaiming space. GC share is reactively increased when the number of free blocks becomes low, thereby increasing the rate at which GC produces free blocks. If the number of free blocks exceeds the GC activation threshold, the share decays gradually to allow other tasks to use more resources. In effect, AutoSSD improves the overall response time as shown in Figure 6c.

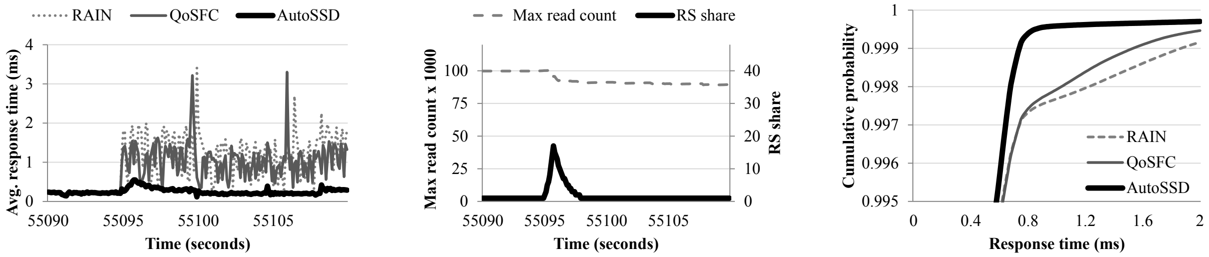
For LM-TBE, Figure 7a shows the average response time of the three systems during a 20-second window, approximately 15 hours into the workload. Here we observe read scrubbing (RS) becoming active due to the read-dominant characteristics of LM-TBE. We observe that both RAIN and QoSFC show large spikes in response time that lasts longer than the perturbation caused by GC for RAD-AS (cf. Figure 6a). While GC is incentivized to select a block with less valid data, RS is likely to pick a block with a lot of valid data that are frequently read but not frequently updated: this causes the performance degradation induced by RS to last longer than that by GC. AutoSSD limits this effect, while still decreasing the maximum read count in the system by dynamically adjusting the share of RS, as shown in Figure 7b. Figure 7c shows the response time CDF of the three systems.

Figure 8 illustrates the delay causes for the flash memory requests generated by the host request handling task under MSN-BEFS. Note that this is different from the response time of host requests: this shows the average wait time that a flash memory request (for servicing the host) experiences, broken down by different causes. Category



(a) Average response time under `RAD-AS`. (b) Change in GC share under `RAD-AS`. (c) Response time CDF under `RAD-AS`.

Figure 6: Comparison of RAIN, QoSFC, and AutoSSD under `RAD-AS`. Figure 6a shows the average response time sampled at 100ms in the selected 10-second window. Figure 6b shows the number of free blocks and the GC share of AutoSSD for the same 10-second window. Figure 6c plots the response time CDF for the entire duration.



(a) Average response time under `LM-TBE`. (b) Change in RS share under `LM-TBE`. (c) Response time CDF under `LM-TBE`.

Figure 7: Comparison of RAIN, QoSFC, and AutoSSD under `LM-TBE`. Figure 7a shows the average response time sampled at 100ms in the selected 20-second window. Figure 7b shows the maximum read count and the RS share of AutoSSD for the same 20-second window. Figure 7c plots the response time CDF for the entire duration.

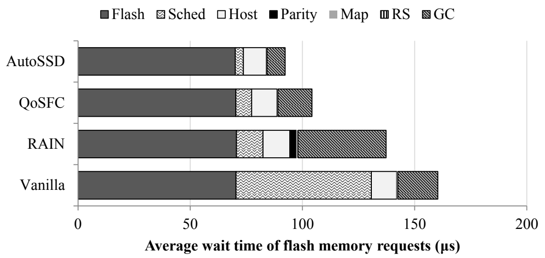


Figure 8: Breakdown of wait time experienced by flash memory requests under `MSN-BEFS`.

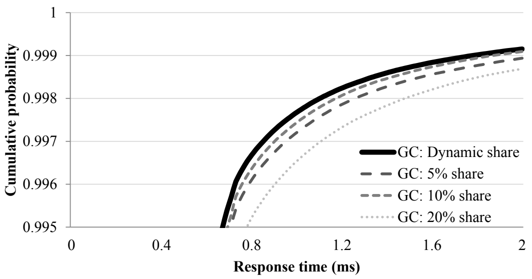

Figure 9: Comparison of AutoSSD with static shares and dynamic share under `MSN-BEFS`.

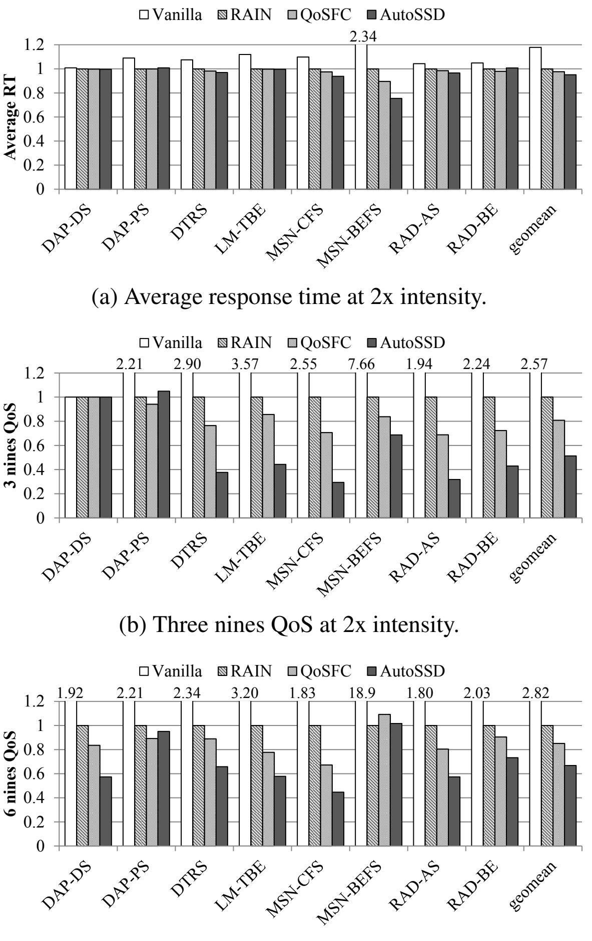
`Flash` represents flash memory latency, combining both flash array access latency and data transfers. `Sched` is the time spent waiting to be scheduled, either waiting in the queue because the target queue is full, or waiting because the scheduler limits the progress in a non-work-conserving manner (the case for AutoSSD). The large `Sched` wait time for Vanilla is caused by uncoordinated sharing of resources, while that for AutoSSD is small as the scheduler reserves resources for host requests. The remaining five categories are delays experienced due to resource blocking. Most noticeably, the wait time caused by GC in RAIN is higher than the other systems. When RAIN generates alternate flash memory requests to reconstruct data through parity, these additional requests can, in turn, be blocked again at another resource. In ttFlash [45], this problem is overcome by statically limiting the number of active GC to one per parity group. This technique is not used in our evaluation as a fixed cap on the number of allowed GC can quickly deplete free blocks, especially for high-intensity small random write workloads.

Next, we examine the effectiveness of the dynamic share assignment over the static ones. Figure 9 shows the response time CDF of AutoSSD under `MSN-BEFS` with static shares of 5%, 10%, and 20% for GC, along with the share controlled dynamically. As illustrated by the gray lines, decreasing the GC share from 20% to 10% improves the overall performance. However, when further reducing the GC share to 5%, we observe that the curve for 5% dwindles as it approaches higher QoS and performs worse than the 10% curve. This indicates that while a lower GC share achieves better performance at lower QoS levels, a higher GC share is desirable to reduce long-tail latencies as it generates free blocks at a higher rate, preventing the number of free blocks from becoming critically low. This observation is in accordance with the performance under synthetic workload in Figure 4c. Using feedback control to adjust the GC share dynamically shows better performance over all the static values, as it can adapt to an appropriate share value by reacting to the changes in the system state.



(a) Average response time at 2x intensity.

(b) Three nines QoS at 2x intensity.

(c) Six nines QoS at 2x intensity.

Figure 10: Comparison of Vanilla, RAIN, QoSFC, and AutoSSD under eight different traces at 2x intensity. Results are normalized to the performance of RAIN at 2x intensity. AutoSSD reduces the average response time by up to 24.6% under MSN-BEFS (by 4.9% on average), the 3 nines QoS by up to 70.6% under MSN-CFS (by 48.6% on average). and the 6 nines QoS by up to 55.3% under MSN-CFS (by 33.2% on average).

5.3 I/O Trace Results at Higher Intensity

In this subsection, we present experimental results with higher request intensities. Here, the request dispatch times are reduced in half, but other parameters such as the access type and the target address remain unchanged. This experiment is intended to examine the performance of the four systems—Vanilla, RAIN, QoSFC, and AutoSSD—under a more stressful scenario.

Figure 10 compares the performance in the new setting. AutoSSD reduces the average response time by up to 24.6% under MSN-BEFS (see Figure 10a), the 3 nines QoS figure by 48.6% on average and as much as 70.6% under MSN-CFS (see Figure 10b), and the 6 nines QoS figure by as much as 55.3% under MSN-CFS (see Figure 10c). With workload intensity increased, the overall improvement in long tail latency decreases due to a smaller wiggle room for AutoSSD to manage FTL tasks. This is especially true for high-intensity workloads such as MSN-BEFS: with host requests arriving back-to-back (cf. halve the inter-arrival time in Table 2), debit scheduling has little advantage over other scheduling schemes. However, AutoSSD nevertheless outperforms prior techniques across the diverse set of workloads. Workloads such as RAD-AS and LM-TBE that showed the most reduction in long tail latency under the original intensity (cf. Figure 5c) still exhibit performance improvements with AutoSSD in the 6 nines, even with increased workload intensity.

We examine DTRS more closely in Figure 11. Figure 11a shows the average response time of the three systems—RAIN, QoSFC, and AutoSSD—during a 20-second window, approximately 2 hours into the workload. GC is active during this window for all the three systems, and AutoSSD is better able to bound the performance degradation caused by an active garbage collection, while both RAIN and QoSFC exhibit large spikes in response time. Figure 11b shows the number of free blocks and the GC share during that window for AutoSSD. Similar to the results in the previous section, the share for GC reactively increases at a lower number of blocks, and decays once the number of free blocks reaches a stable region. Again, the number of free blocks shows a sawtooth behavior, and the ridges of GC share curve matches the valleys of the free block curve. Figure 11c plots the response time CDF of the three systems, demonstrating the effectiveness of our dynamic management.

6 Discussion and Related Work

There are several studies on real-time performance guarantees of flash storage, but they depend on RTOS support [7], specific mapping schemes [8, 39, 46], a number of reserve blocks [8, 39], and flash operation latencies [46]. These tight couplings make it difficult to extend performance guarantees when system requirements

Figure 11: Comparison of the RAIN, QoSFC, and AutoSSD under DTRS running at 2x intensity. Figure 11a shows the average response time sampled at 100ms in the selected 20-second window. Figure 11b shows the number of free blocks and the GC share of AutoSSD for the same 20-second window. Figure 11c plots the response time CDF for the entire duration.

and flash memory technology change. On the other hand, our architecture is FTL implementation-agnostic, allowing it to be used across a wide range of flash devices and applications.

Some techniques focus on when to perform GC (based on threshold [31], slack [22], or host idleness [25, 37]). These approaches complement our design that focuses on the fine-grained scheduling and dynamic management of multiple FTL tasks running concurrently. By incorporating workload prediction techniques to our design, we can extend AutoSSD to increase the share on background tasks when host idleness is expected, and decrease it when host requests are anticipated.

Exploiting redundancy to reduce performance variation has been studied in a number of prior art. Harmonia [30] and Storage engine [42] duplicate data across multiples SSDs, placing one in read mode and the other in write mode to eliminate GC's impact on read performance. ttFlash [45] uses multiple flash memory chips to reconstruct data through a RAID-like parity scheme. Relying on redundancy effectively reduces the storage utilization, but otherwise complements our design of dynamic management of various FTL tasks.

Performance isolation aims to reduce performance variation caused by multiple hosts through partitioning resources (vFlash [43], FlashBlox [18]), improving GC efficiency by grouping data from the same source (Multistreamed [24], OPS isolation [29]), and penalizing noisy neighbors (WA-BC [21]). These performance isolation techniques are complementary to our approach of fine-grained scheduling and dynamic management of concurrent FTL tasks.

The design of the autonomic SSD architecture borrows ideas from prior work on shared disk-based storage systems such as Façade [33], PARDA [14], and Maestro [34]. These systems aim to meet performance requirements of multiple clients by throttling request rates and dynamically adjusting the bound through a feedback control. However, while these disk-based systems deal with fair sharing of disk resources among multiple hosts, we address the interplay between the foreground (host I/O) and the background work (garbage collection and other management schemes).

Aqueduct [32] and Duet [4] address the performance impact of background tasks such as backup and data migration in disk-based storage systems. However, background tasks in flash storage are triggered at a much smaller timescale, and SSDs uniquely create scenarios where the foreground task depends on the background task, necessitating a different approach.

7 Conclusion

In this paper, we presented the design of an autonomic SSD architecture that self-manages concurrent FTL tasks in the flash storage. By judiciously coordinating the use of resources in the flash memory subsystem, the autonomic SSD manages the progress of concurrent FTL tasks and maintains the internal system states of the storage at a stable level. This self-management prevents the SSD from falling into a critical condition that causes long tail latency. In effect, AutoSSD reduces the average response time by up to 18.0%, the 3 nines (99.9%) QoS by up to 67.2%, and the 6 nines (99.9999%) QoS by up to 76.6% for QoS-sensitive small reads.

Acknowledgment

We thank the anonymous reviewers for their constructive and insightful comments, and also thank Jaejin Lee, Jongmoo Choi, Hyeonsang Eom, and Eunji Lee for reviewing the early stages of this work. This work was supported in part by SK Hynix and the National Research Foundation of Korea under the PF Class Heterogeneous High Performance Computer Development (NRF-2016M3C4A7952587). Geriatrix: Aging what you see and what you don't see

A file system aging approach for modern storage systems

Saurabh Kadekodi[1] Vaishnavh Nagarajan[1] Gregory R. Ganger[1] Garth A. Gibson[1,2]

Abstract

File system performance on modern primary storage devices (Flash-based SSDs) is greatly affected by aging of the free space, much more so than were mechanical disk drives. We introduce *Geriatrix*, a simple-to-use profile driven file system aging tool that induces target levels of fragmentation in both allocated files (what you see) and remaining free space (what you don't see), unlike previous approaches that focus on just the former. This paper describes and evaluates the effectiveness of Geriatrix, showing that it recreates both fragmentation effects better than previous approaches. Using Geriatrix, we show that measurements presented in many recent file systems papers are higher than should be expected, by up to 30% on mechanical (HDD) and up to 80% on Flash (SSD) disks. Worse, in some cases, the performance rank ordering of file system designs being compared are different from the published results.

Geriatrix will be released as open source software with eight built-in aging profiles, in the hopes that it can address the need created by the increased performance impact of file system aging in modern SSD-based storage.

1 Introduction

The performance of a file system (FS) usually deteriorates over time. As FSs experience heavy churn, techniques such as write-back caching to expedite writes [38, 31, 14], data prefetching to assist reads [8, 35] and self-balancing data structures to contain search times [10] may pay for faster normal path performance now with more complex and fragmented on-device images as the system ages. An important factor affecting aged FS performance is poor FS layout [43, 42].

Naturally, therefore, FS benchmarking should consider the effects of aging. But, despite it being an important issue known for over twenty years [44], most research and benchmarks still ignore aging. For example, 65% (13 of 20) recent FS papers we examined (Table 1) neither mention aging nor include it in their evaluations. Unsurprisingly, our experiments confirm that aging continues to be a critical factor for FS performance.

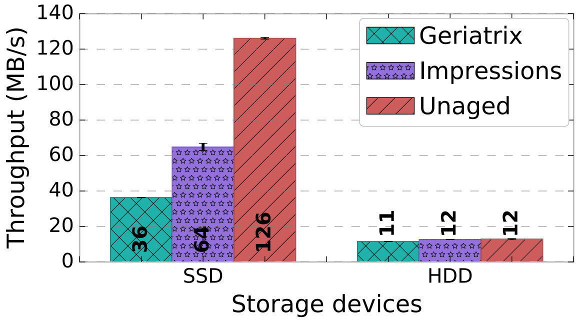

Figure 1: Aging impact on Ext4 atop SSD and HDD. The three bars for each device represent the FS freshly formatted (unaged), aged with Geriatrix, and aged with Impressions [2]. Although relatively small differences are seen with the HDD, aging has a big impact on FS performance on the SSD. Although their file fragmentation levels are similar, the higher free space fragmentation produced by Geriatrix induces larger throughput reductions than for Impressions. The experimental setup is detailed in Section 6.

While aging's overall importance has not waned, the particular aspects that have the most impact have changed over time, making previous aging approaches... stale. Previous general purpose aging approaches, from the work of Smith and Seltzer [44] to the state-of-the-art *Impressions* [2] tool, focus on achieving representative levels of file fragmentation. Such fragmentation exists when sequential blocks of a file or related metadata / files are scattered among logical block addresses (LBAs) of underlying storage. For FSs atop HDDs, with time-consuming mechanical positioning costs for accessing scattered LBAs, these file fragmentation effects are of most concern. For the Flash-based SSDs that now dominate primary and performance-tier deployments, these effects are less significant, due to LBA remapping and absence of mechanical positioning.

This paper introduces *Geriatrix*, a new FS aging tool for modern storage. In addition to file fragmentation, Geriatrix aggressively induces free space fragmentation and thereby even ages any underlying device remapping structures. As a result, it can recreate the much more significant aging effects seen with SSDs in real systems [36]. As one example, Figure 1 compares three instances of an Ext4 FS: Unaged, aged by Impressions, and aged by Geriatrix. On the HDD, fairly minor performance differences are observed for this particular benchmark, since the workload involves small files and relatively little access locality. On the SSD, however, large differences can be seen, and the Geriatrix-aged FS produces much greater aging effects.

Additional evaluation and experiments, later in the paper, confirm that these greater Geriatrix-induced effects are consistent and correctly representative. In addition, we recreated experiments from recent papers, showing both, that the reported performance fails to represent realistic expectations **and** that the rank ordering of configurations compared is sometimes changed. Figure 2 shows one such re-evaluation, in which we observe both effects.

Geriatrix uses a sophisticated profile-driven approach that ages a FS according to a reference (old) FS. This paper describes how Geriatrix extracts information from a profile and exercises the FS to recreate its fragmentation properties. With both theoretical analysis and experimental comparison to real FS images used as profiles, we show that Geriatrix faithfully reproduces both file and free space fragmentation.

Geriatrix is being released as an open source tool, together with eight built-in aging profiles and a repository of aged images of popular FSs. We hope that its availability will help increase the use of aging in FS benchmarking.

This paper makes three primary contributions. First, it exposes the impact of free space fragmentation and device aging for FSs on SSDs and the failure of existing aging approaches to recreate them. Second, it describes a new aging approach, embodied in Geriatrix, and confirms that it does faithfully recreate these aging effects. Third, it provides extensive evidence, including recreating recently published comparisons and showing that results change, of why aging must be part of benchmarking and offers Geriatrix as an open-source tool for doing so.

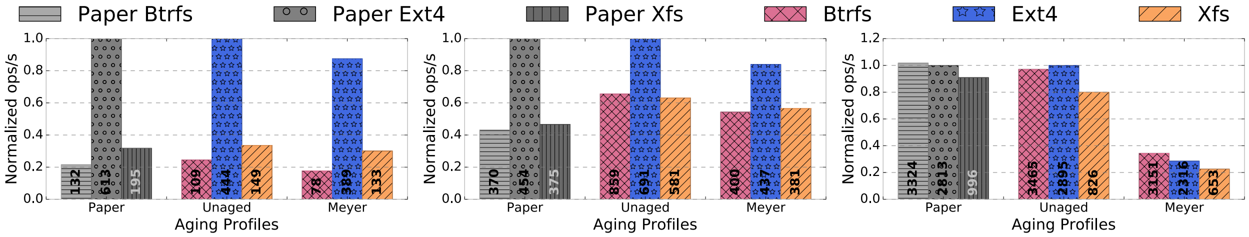
2 Related work

We classify aging tools into three categories: trace replay tools, scripts executing real-world applications and synthetic workload generators.

Trace replay tools are best used with FSs expecting a highly specialized workload. Traces can be captured and replayed at multiple levels - the network level [57], file level [32], FS level [40, 4], system call level [50], VFS level [20] and also at the block level [7]. Low level traces are typically FS specific resulting in loss of usefulness for comparing different FSs. Moreover, long traces are not widely available and are hard to capture. Trace replay tools rank high on reproducibility but do not represent all workloads.

The Andrew benchmark [17], Compilebench [27] and the Git-Benchmark [11, 12] are application benchmarks that implicitly involve some aging. These tools emulate user behavior by performing typical activities like extracting archives, reading files, compiling code, making directories, cloning repositories, etc. Compilebench performs these tasks on Linux kernel sources, while the Git-Benchmark can be run using any git repository. Tools in this category only exercise one workload pattern.

Geriatrix belongs to the category of synthetic workload generators, which also comprises of Smith and Seltzer's aging tool [44] and Impressions [2]. Smith's tool ages by recreating each file in a given reference snapshot and then performing creates and deletes according to the deltas observed in successive reference snapshots. It was one of the first tools to point out the degradation of FS performance with age. Impressions on the other hand is a realistic FS image creator that focuses on several FS characteristics including file size and directory depth distributions along with file attributes and contents. These tools take reference from already old FSs in order to perform aging.



(a) Btrfs HDD Varmail

(b) Btrfs HDD Webserver

(c) Btrfs SSD Fileserver

Figure 2: All three graphs reproduce experiments from the Btrfs ACM TOS publication [39] on aged FS instances. The *Paper* bars are normalized to the paper's Ext4 FS measurements, while the experiments we recreated are normalized to the unaged Ext4 performance on our hardware. Figures 2a and 2b show aging experiments performed on a HDD using the varmail and webserver profiles respectively. 2a shows modest slowdown (30% in Btrfs, 13% in Ext4 and 9% in Xfs), but preserves the rank ordering published in the paper. 2b disrupts published rank ordering and displays slowdowns of 17% in Btrfs and Ext4 and 12% in Xfs. Figure 2c shows effects of aging on SSD for the fileserver profile. Here too the published rank ordering is not preserved, but we observe massive slowdowns of 65% in Btrfs and 72% in Ext4, Xfs.

Table 1: A subset of major FS publications and whether their paper reports aging experiments. The *Needed Aging?* column is our understanding of whether aging could have affected published results, i.e. was aging (or commentary about it) necessary as a part of benchmarking. The *Performed Aging?* column refers to whether any aging-like experiment was performed. Our analysis reveals two FSs - yFS [55], TFS [9] performed long-running aging experiments; Data Domain FS [56] and Panasas FS [51] had production data (and therefore had seen aging in the field), SFS [34] ran a workload twice the size of the disk and CFFS [54] ran a large trace for aging. BetrFS [11] aged using the Git-benchmark (see § 3), which highlighted file fragmentation caused by age, but induced limited free space fragmentation. The remaining 13 papers do not discuss aging or its effects on their FSs.

3 Why do we need another aging tool?

Aging any software artifact implies understanding how it will stand the test of time. Aging is used for several reasons, such as uncovering performance deterioration with use, stressing the robustness of the software, and identifying fault tolerance and scalability issues. This section discusses four aspects of aging that current approaches insufficiently satisfy.

Free space fragmentation. State-of-the-art FS aging tools either replay a trace of FS commands or run scripts of important applications. Smith's aging tool [44] and Impressions [2] come close to what we expect from an aging tool. But, Smith's tool is a twenty year old artifact with dependencies on the Fast FS (FFS) [31]. Impressions matches an impressive number of aged metrics, but is focused on generating realistic FS content, not FS layout. These tools only target file fragmentation using a metric called *layout score*, that measures the disk contiguity of files after aging.

Git-benchmark [11, 12] is a recently published aging benchmark that ages the FS by cloning a git repository, repeatedly patching code files (via git pulls) and finally grepping for random strings in the patched repository. In this study as well, the authors only measure file fragmentation by extending the layout score (which they call the *dynamic layout score*) which additionally accounts for the contiguity in the FS access pattern for a file.

We ran the Git-benchmark from [12] on a 20GB Ext4 partition and observed a $> 7\times$ slowdown when grepping for the same string after 3000 git pulls versus grepping for a string after a single git pull on a fresh Ext4 partition. In order to understand the dramatic slowdowns this workload experiences, we traced the Ext4 kernel functions to find, where in the code, most of the time was spent during the arbitrary greps. Function tracing revealed that *ext4_es_lookup_extent* is the function where most of the time is spent during grep, i.e. looking up a FS data structure. Since the capacity utilization at the end of 3000 git pulls was only 4%, we measured the free space fragmentation and observed that $> 75\%$ of the free space extents were between 1-2GB. Thus, although the Git-benchmark successfully caused some file fragmentation, it caused little of the free space fragmentation prevalent in aged FSs.

To the best of our knowledge, the above mentioned tools are the only general purpose FS aging tools; and none of them produce the required free space fragmentation which is an inevitable consequence of aging. Geriatrix's fills this void by inducing adequate free space fragmentation, proof of which is shown in § 5 and whose effect in aging SSDs has been exemplified in Figure 1.

Device aging. SSDs contain a complex translation layer in the device firmware called a flash translation layer (FTL). FTLs are the reason that an SSD can act as a drop-in replacement for an HDD despite having entirely different hardware. FTLs primarily perform the tasks of address remapping, garbage collection and wear leveling. SSD device characteristics force the FTL to operate very similarly to a complex log-structured FS [41]. With time, the increased garbage collection work (interfering with the foreground work) combined with fragmented FTL mapping tables can hurt performance. Thus, in the case of an SSD, two systems are aging simultaneously, the FTL and the FS that the SSD has been formatted with. Since FTLs are proprietary, users typically have no insight into how well (or poorly) an FTL has aged.

Shingled magnetic recording (SMR) is a new hard drive architecture wherein adjacent tracks on a HDD are partially overlapped to increase the number of tracks on the disk, thus increasing the disk capacity. This technology was an answer to the traditional HDDs having surpassed the superparamagnetic effect [45], which disallows increasing sectors-per-track in order to achieve larger disk capacities. Commercially available SMR HDDs have a firmware different from, but as complicated as the FTL. Aghayev et al. [1] showed that the interference of the firmware while performing foreground tasks caused high performance fluctuations. One of the key aspects of a firmware driven SMR disk is the existence of a persistent cache at the center of the drive. Suppose we are benchmarking a fresh FS on a SMR drive, we might conceivably never hit the persistent cache limit (which is impossible as the drive actually ages), thus circumventing the large read-modify-write cycles that the firmware would have performed leading to low throughput.

The churn that the FS and the device endure while Geriatrix attempts to age according to an aging profile forces device aging as well, providing a more realistic aging effect.

Aging write-optimized FSs. Write-optimized FSs focus on expediting writes at the cost of possibly slower reads. Log-structured FSs [41] are a classic example of a write-optimized FS. Moreover, most modern storage devices operate as log-structured FSs internally, as mentioned in Section 3. In this architecture, every file rewrite causes file fragmentation because in-place updates are disallowed. Therefore, the true impact of aging a write-optimized FS is usually noticed when garbage collection starts interfering with foreground activity, a well studied problem also known as segment cleaning [41, 6, 28, 48]. These FSs are hard to age since they need to be forced into frequent garbage collection which is only possible at high space utilization and with significant free space fragmentation. Geriatrix fulfills these two requirements allowing for effective aging of write-optimized FSs.

Aging as a stress tester. An effective use of an aging exercise could be in the form of a stress tester. The high churn expected to be exercised by an aging tool can expose design flaws like overflows / underflows, data structure inefficiencies, concurrency and consistency issues among others. Geriatrix produces orders of magnitude more churn than the state of the art aging tools present today, rewriting data amounting to several times the specified FS image size. Thus, Geriatrix is as much a FS stress tester as it is an aging tool.

4 Geriatrix design and implementation

Geriatrix exercises a non-aged FS to match an *aging profile* which is provided as input, by performing a sequence of file create and delete operations. The profile contents are inspired by a combination of the usual parameters that affect a file's on-disk layout and which are easily obtainable from an aged instance of a FS using a single metadata tree walk. A Geriatrix aging profile comprises of:

- **FS fullness (bytes, %):** Partition size and fraction containing user data.
- **File size distribution (bytes, %; bytes, %; ...):** A histogram of file sizes.
- **Directory depth distribution (1, %, # subdirs; 2, % #subdirs; ...):** Path depth to individual files and percentage of files at that path depth along with the aggregate number of subdirectories at each depth.
- **Relative age distribution (n, %; m %; ...):** A histogram of relative file ages, $n < m < ...$, where younger files, in the first histogram bin make up the first % of all files in the aged FS image, and so on. More specifically, we extract create timestamps of files from an existing old FS snapshot following which we sort, enumerate and bin files into relative age buckets. These buckets approximate the age of each file relative to the other files, decoupling them from the absolute time of their creation (thus making their age unitless).

At a high level, Geriatrix aging proceeds in two distinct phases.

1. A ***rapid aging*** phase in which files are only created (one file creation per time instant or *tick*), to rapidly achieve the fullness target. Since this phase does not perform any deletions, there is no fragmentation induced in rapid aging. It merely achieves the required fullness while ensuring that the file size and directory depth distributions are met.
2. A ***stable aging*** phase in which each operation (one operation per tick) is either a file creation or a deletion based on a fair coin toss. This phase is designed to fit the relative age distribution while maintaining all other parameters. The roughly equal number of creations and deletions are necessary to maintain the fullness target, and in some sense mimic the steady-state operation of a FS operated at a certain fullness.

We now discuss how we ensure that the distributions of the file system being aged match the target distributions at the end of a Geriatrix run. We assume that all input distributions are mutually independent. Thus, we can easily achieve the size and directory depth distributions by drawing a size and directory depth value from their respective distributions and creating or deleting a file corresponding to those values. Note that rapid and stable aging phases continuously strive to maintain both, size and directory depth distributions.

However, achieving the target age distribution is harder. Note that the relative age of a file at the end of a Geriatrix run is the ratio of the number of ticks (or operations) that have passed since the file was created to the total number of ticks (say T) in that run. Thus, without knowing T, it is impossible to determine the final relative age bucket of any file. However, to direct the algorithm towards the target age distribution, it is necessary to know the final relative age bucket and thus, T. We overcome this by theoretically estimating a sufficiently large T within which it is possible to perform create / delete operations that achieve the target age distribution. Then, during the run, we use our estimate of T to compute the index of the final relative age bucket of any file; based on this, we perform clever deletions to ensure that the target age distribution is achieved. Appendix A provides this estimate of T and shows that when we stop the algorithm at T, it has indeed converged to the target age distribution.

Geriatrix has a repository of eight built-in file system aging profiles, most of which are from long-running file system and metadata publications [3, 13, 49, 33] to assist practitioners in conducting file system aging experiments. Table 3 provides a description of all the profiles along with the age of oldest file in every profile. We also indicate the wall-clock time it took to age these profiles in a ramdisk along with the total workload size generated during aging. Finally, we also show the empirical proof of our relative age convergence theorem via the perfect convergence (a root mean-squared error of $<$0.01%) achieved on the relative age distribution graphs for each aging profile (complete overlap in the graphs in Table 3).

The aging tool is a C++ program (built using the Boost library) designed to run on UNIX platforms. It has the ability to age both POSIX and non-POSIX FSs.

- **Reducing setup complexity:** Geriatrix is profile driven with eight built-in aging profiles. We also provide a repository of popular Linux FSs aged using the built-in profiles for standardized comparison.
- **Parallel aging:** Geriatrix has a configurable thread pool that exploits multi-threading in file systems to expedite aging substantially.
- **Reproducibility:** A user-defined seed governs all the randomness in Geriatrix, thus allowing every single-threaded Geriatrix execution to be exactly reproducible. For multi-threaded executions, the operating system scheduler may interleave threads differently resulting in different execution patterns across runs.
- **Rollback utility:** Aging experiments can take a prohibitively long time. Once a FS image has been aged, taking a snapshot of the image to be able to restore the same image for multiple tests is usually faster than re-aging. This requires a whole disk overwrite, which on today's multi-TB disks can take several hours, so we have developed a rollback utility to undo the effects of a short benchmark run on an aged image without having to replay the entire aged image again. Using the *blktrace* utility [7], we monitor the blocks that were modified during benchmark execution and effectively "undo" the perturbation caused by benchmarking by overwriting the dirtied blocks from the static snapshot of the aged image. *blktrace* adds overhead when running a benchmark, but is often negligible and can be mitigated further by writing the *blktrace* output to an in-memory FS or sending it across the network.
- **Multiple stopping conditions:** For many users, waiting for $< 0.01\%$ root mean square convergence of a Geriatrix run might be overkill. Thus, we have introduced multiple stopping conditions:
  1. the amount of time the ager is allowed to run
  2. the confidence [1] of the age distribution fit
  3. the max number of disk overwrites for aging

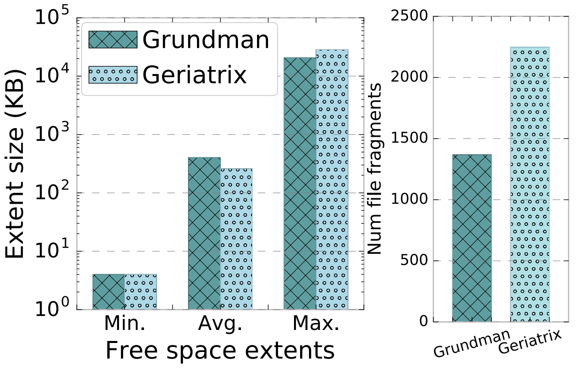
  Once any stopping condition is met, Geriatrix stops and displays the values of all three stopping conditions. The user can choose to accept the aging performed, or revise the condition(s) and resume aging.

5 Evaluation of Geriatrix as an aging tool

We evaluate the fidelity of Geriatrix's aging by comparing the file and free space fragmentation it induces on a fresh Ext4 partition to that of the source file system for the selected built-in profile. We do this comparison for two Geriatrix profiles: Grundman (extracted from a nine year old 90GB FS with approximately 90% fullness) and Dabre (extracted from a one year old 20GB FS with approximately 80% fullness). Despite being designed to only match externally visible measures of a FS, Geriatrix induces appropriate free space and file fragmentation by exercising the FS extensively.

We measure the distribution of free space extents using the *e2freefrag* utility. Figure 3 shows results for five file systems: the original Grundman FS image (aged naturally over 9 years), a fresh FS with no aging, a fresh FS aged by Geriatrix using the Grundman profile, a fresh FS

[1] Confidence of the convergence of distributions is calculated using the chi-squared goodness-of-fit statistic.



(a) Extents

(b) File Fragmentation

Figure 4: 4a compares the the minimum, average and maximum size of free space extents for a naturally aged Ext4 image and an Ext4 image aged using Geriatrix for the Grundman aging profile. 4b shows the number of fragments allocated as a result of a 2GB file being copied to both FS images.

aged by Impressions using the same file size distribution, and a fresh FS with the Grundman image files copied to it.

The primary takeaway is that the Geriatrix-aged FS matches the original Grundman FS closely, which can be seen by comparing the colorful bars, while the other three (gray bars) do not. As expected, the freshly formatted Ext4 has very large free space extents, mostly between 1-2GB. Grundman and the Geriatrix-aged FS have much smaller extents and more spread out free space extent distributions ranging from 4KB to 32MB. The "Copied" and Impressions-aged FSs are similar to the freshly-formatted file system, with low free space fragmentation. The comparison using the Dabre profile (graph omitted due to space constraints) shows very similar results.

Figure 4a compares the minimum, average and maximum free space extent sizes for Grundman and the Geriatrix-aged FSs. Both have the same smallest free space extent of 4KB. The average free space extent size of naturally-aged Grundman is only 144KB larger than its Geriatrix counterpart, while the largest free space extent is only 7.2MB smaller. These numbers are very close considering the total partition size of 90GB.

Figure 4b measures the fragmentation of a new 3GB file copied to each of the naturally-aged Grundman image and the Geriatrix-aged FS, using the *filefrag* utility. The image aged by Geriatrix splits the file into 2250 fragments while the naturally-aged FS only splits it into 1368 fragments. Despite Geriatrix over-splitting the file, its aging is two orders of magnitude higher than the number of fragments created writing 3GB to a freshly formatted Ext4.

Since Geriatrix refrains from taking shortcuts, and performs millions of operations before declaring a FS *aged*, it closely approximates the FS state caused by natural aging. The Geriatrix aging experiment reported in Figures 3 and 4 took approximately 420 minutes. Recreating the fragmentation naturally occurring in nine years with only 420 minutes of aging is an acceleration of >11000×.

6 How Geriatrix changes conclusions

To highlight the impact of aging, we recreated experiments from Btrfs [39], F2fs [24] and NOVA [52] publications on unaged and aged FS instances. We also produced aged instances of Ext4 (used for comparison across all three papers) and Xfs (used for comparison in the Btrfs and NOVA papers).

Experimental setup. We performed all our experiments on an Emulab PRObE cluster [15]. The hardware used and the setups for experiments is described in Table 2. For fairer comparison, we matched the memory and the number of cores in our benchmark when recreating expts. from the Btrfs [39] and F2fs [24] publications.

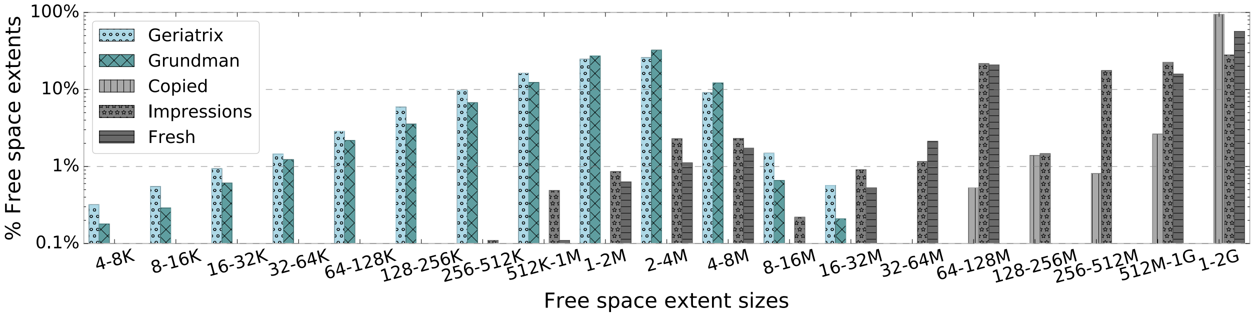


Figure 3: Free space fragmentation comparison of an actual old Ext4 FS image (Grundman) with Geriatrix driven by the Grundman profile, Impressions driven by the Grundman profile's file size distribution, a partition with the contents of the original Grundman image copied over and a freshly formatted Ext4 partition. Other than the freshly formatted image, all other FS images are approximately 90% full. Geriatrix induces free space fragmentation very similar to the naturally aged Grundman image with no large free space extents, hence causing appropriate free space fragmentation.

Paper	Disk	RAM	CPU (cores)	Linux (Kernel Version)
Btrfs [39]	500GB HDD (WDC WD5000YS-01MPB0)	2GB	Intel Xeon E7 (8)	Ubuntu 14.04 LTS (3.13.0-33)
	64GB SSD (Crucial M4-CT064M4SSD2)	2GB	AMD Opteron (8)	Ubuntu 14.04 LTS (3.13.0-33, 4.4.0-31)
F2fs [24]	64GB SSD (Crucial M4-CT064M4SSD2)	4GB	Intel Core i7 (4)	Ubuntu 14.04 LTS (4.4.0-31)
	120GB SSD (ADATA SSD S510)	4GB	Intel Core i7 (4)	Ubuntu 14.04 LTS (4.4.0-31)
NOVA [52]	64GB NVM (Emulated in DRAM)	8GB	AMD Opteron (8)	Ubuntu 14.04 LTS (4.13)

Table 2: Experimental Configuration.

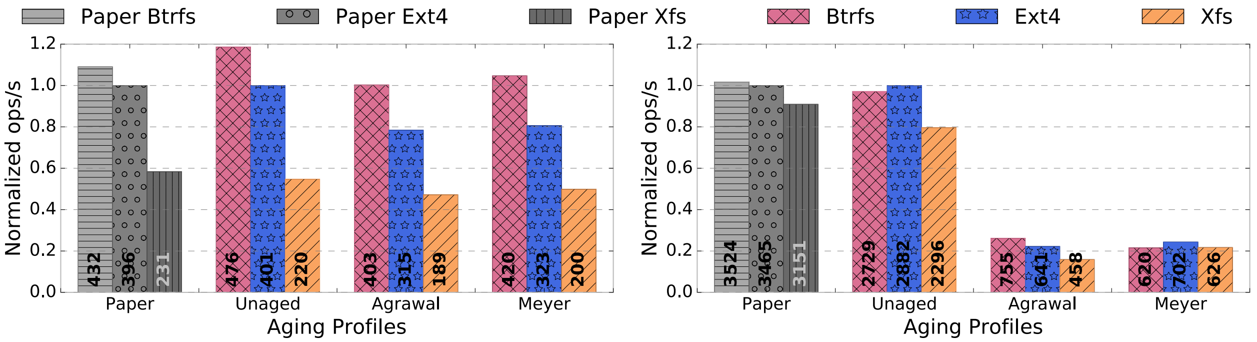
We used four of Geriatrix's built-in profiles in our experiments: Agrawal [3], Meyer [33], Dabre and Pramod. We performed aging in memory and captured the resulting aged images. We consciously decided to not age the FSs on the device as we wanted to prevent device aging from affecting the FS aging. Prior to each benchmark run we copied the corresponding aged image onto a disk (using *dd* to the raw device) and mounted the FS on the aged image. All FSs were mounted using default mount options.

The Filebench benchmark [30] was used for all performance measurements with different profiles according to the appropriate reference publication. The primary performance metric reported is *overall operations per second* as reported by Filebench. Each benchmark run lasted about 10 minutes and we performed three runs of each benchmark to capture variance. We report only the mean, since the maximum standard deviation observed was below 2. Since our hardware is not identical to what was used in the papers and since we are testing with code potentially newer than the one used for publication, exact reproduction of paper results even for unaged instances of FSs is unlikely. With SSDs, the performance variability across devices is especially high. For ease of comparison, we include raw data on the bar graphs, but normalize bar heights. The published results (leftmost gray bars) are normalized to the published Ext4 results, and the aged FS performance numbers are normalized to unaged Ext4 performance on the same hardware. We chose Ext4 because it is the default FS rolled out with most Linux distributions today. All HDD experiments were conducted using 100GB aged images with a 80% capacity utilization target being replayed on a 100GB partition of a 500GB HDD.

HDD experiments. Figure 2a in Section 1 compares the performance of Btrfs, Ext4 and Xfs on an HDD for the Filebench varmail workload, representing a mail server workload of tiny (≈16KB) file operations. After aging using the Meyer profile, we see 9-30% slowdowns, with Btrfs being most affected by aging, followed by Ext4 and then Xfs.

Figure 2b compares the same FSs using the webserver workload. The webserver workload is highly multi-threaded and again, operates on tiny files, although it avoids issuing expensive fsync operations and mimics webservers that have to perform more whole-file reads and log appends. Since FSs are usually more sensitive to small file operations, it is perhaps understandably harder to reproduce published results; indeed, unaged Btrfs performs 22% faster on our hardware than reported in the paper, while unaged Xfs also performs 10% faster than the paper. We also see a minor inversion of ranking, with unaged Btrfs outperforming unaged Xfs. The performance penalties after aging are between 12-17%. We show only the Meyer aging profile in webserver and varmail because Btrfs could not sustain aging for the Pramod profile, and although Btrfs successfully completed aging for Dabre and Agrawal profiles, it did not complete execution of the benchmark despite having the required space to do so. This exemplifies the role of Geriatrix as a stress testing tool.

Figure 5a compares the FSs on the fileserver workload,



(a) Btrfs HDD Fileserver

(b) Btrfs SSD Fileserver

Figure 5: Both graphs reproduce Filebench fileserver experiments from the Btrfs ACM TOS publication [39] on aged FS instances on a HDD (Figure 5a) and a SSD (Figure 5b). Aged Btrfs and Ext4 performed at most 22% slower on the HDD but supported the prior paper's published rank ordering whereas aged Btrfs and Ext4 on a SSD degraded benchmark performance by as much as 80%, and changed the rank ordering of compared FSs. SSD experiments in 5b were performed using the Linux kernel version 3.13.0-33

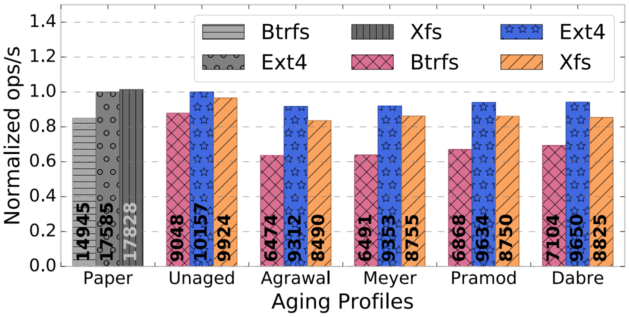


Figure 6: Filbench webserver recreations from the Btrfs paper [33] on SSD. Btrfs is most affected by aging with its performance dropping by 30%. Ext4 and Xfs performance drops by a maximum of 10% and 15% respectively.

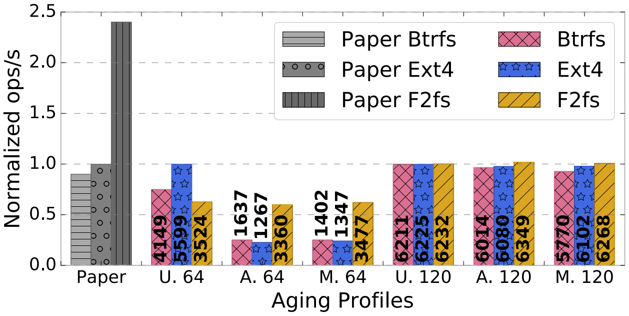

Figure 7: Recreation of the Filebench fileserver benchmark from the F2fs paper [24] on two SSDs - 64GB (labeled 64) and 120GB (labeled 120). Performance on 64 drops significantly after aging, especially for Btrfs and Ext4 resulting in a graph that looks similar to published results. Refer Section 6 for detailed explanation. 120 seems unaffected by aging, thus highlighting highly varied performance across different SSDs

which consists of relatively larger file writes and reads (≈ 128KB) compared to thousands of tiny file operations in webserver and varmail. We observe that unaged Btrfs is 10% faster in our setup, unaged Ext4 is marginally better while unaged Xfs is about 5% slower, keeping performance similar to published results with slightly increased performance gaps between the FSs. After aging using the Agrawal profile, we observe a 10-22% performance drop with Ext4 being the most affected FS.

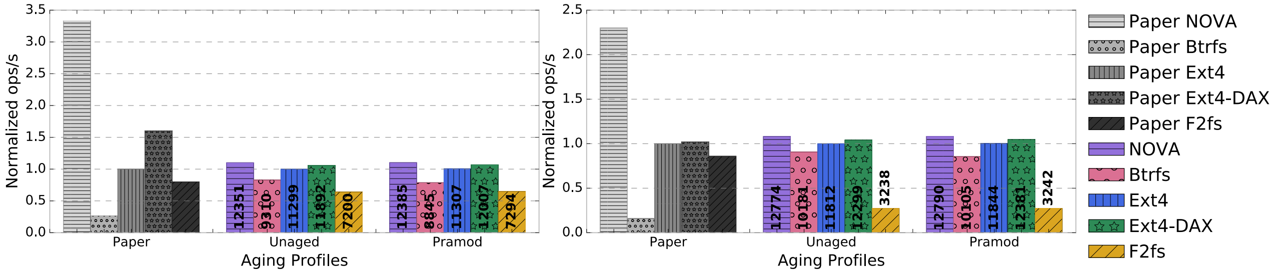
SSD experiments. The SSD experiments were conducted on a 64GB SSD with a 59GB aged FS image with a 70% fullness target. The reason for choosing 70% was to allow the benchmarking workload to fit after aging. SSDs are available in a variety of product price-point classes and have highly variable performance making reproduction of SSD results on different hardware unlikely. This is evident from figures 2c and 5b which show a completely different rank ordering of unaged Btrfs, Ext4 and Xfs compared to published results on the fileserver workload. While Btrfs had the best performance in the paper, it ranged from being the best in aged reproduction using the Dabre (Figure 2c) and Agrawal profiles to being the worst in the aged reproduction using the Meyer profile. Apart from the rank ordering, we observed massive post-aging slowdowns on SSDs from 65-80%. As explained in Sections 1 and 3, we attribute this performance drop to SSD device aging along with FS aging, with both effects being exaggerated by the free space fragmentation caused by Geriatrix.

The webserver results shown in Figure 6 also show significant slowdowns, but are not so dramatic. Btrfs appears to be the most affected by aging, showing up to a 30% performance drop, while Xfs and Ext4 degrade by ≤15% and ≤10%, respectively.

It was typical of SSDs from a few years ago to not be able to sustain more than 2 minutes of continuous writing before performing inline cleaning [37]. Our benchmarking technique involves writing an aged image on almost the entire surface of the SSD, performing a 10 minute benchmark run followed by unmounting the FS and repeating the process with 100% device utilization. An entire surface rewrite should be equivalent to a giant trim obviating the need to perform any internal garbage collection in the FTL, but this is dependent on firmware implementation which varies widely across devices.

Figure 7 is the recreation of F2fs [24] results on SSDs comparing Btrfs, Ext4 and F2fs using the Filebench fileserver profile. To capture variability of performance across devices, we chose SSDs of different makes and sizes - a 64GB Crucial SSD with 59GB aged FS images (bars labeled 64) and a 120GB ADATA SSD with 100GB aged FS images (bars labeled 120). Ext4 is the winning FS when comparing unaged FS instances on 64GB SSD, and Xfs is marginally better on the 120GB SSD, while published results report F2fs performance was 2.4× that of Ext4. Aging on 64GB SSD shows interesting behavior as the performance of all three FSs drops (61-67% for Btrfs, 76-78% for Ext4 and 2-5% for F2fs) and the outcome looks similar to results that the earlier paper reported. The authors most likely aged the SSD firmware by performing repeated benchmark runs resulting in behavior similar to what is seen when FSs are aged. In contrast, the 100GB FSs on the 120GB SSD age much more gracefully with only Btrfs showing as much as 7% performance penalty after aging. This again suggests that SSDs themselves age in different (and non-trivial) ways along with the FSs running on them.

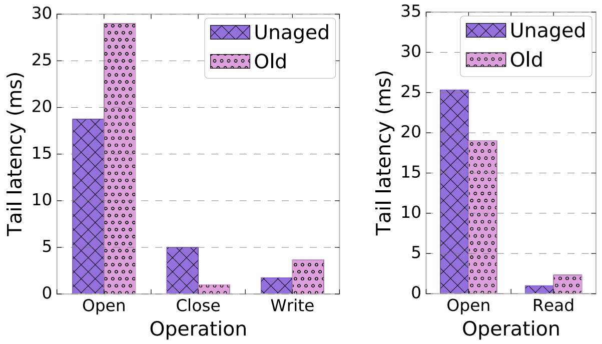
Emulated NVM experiments. We also perform aging experiments on NOVA [52] – a log-structured FS intended for non-volatile memory (NVM). We used a modified Linux kernel version 4.13 to age NOVA since it required special kernel libraries for enabling persistent memory emulation. A 64GB partition similar to the SSD experiments was aged with 70% utilization. The NOVA paper performed experiments with 64GB persis-



(a) NOVA Fileserver

(b) NOVA Varmail

Figure 8: Both graphs reproduce experiments from the NOVA FAST 2016 publication [52] on aged FS instances using emulated non-volatile memory. All FSs age gracefully with Btrfs seeing the largest performance hit of 5% on the fileserver workload (Figure 8a) and 6% on the varmail workload (Figure 8b). Graphs from the paper are for reference and in this case cannot be compared to our reproductions because of different hardware and configuration.



(a) NOVA Fileserver Latency

(b) NOVA Varmail Latency

Figure 9: 9a shows the latency of the slowest operations for the fileserver workload. Aged NOVA slows down by upto 60% on file opens and upto 2× on file writes. In 9b we see slowdowns of upto 2.3× on reads of the slowest file in the varmail workload. The aged opens are contrastingly faster for the varmail workload compared to the fileserver workload. Slowest file open during the varmail workload run is 25% faster after aging.

tent memory devoted to NOVA and 32GB DRAM for the rest of the system. The experiment dataset size was made slightly larger than DRAM (more than 32GB) forcing NVM device interaction during an experiment run. However, that meant that the authors used more than half the 64GB NVM device for their benchmark run. Generally, a <50% utilized FS would be considered too underutilized for running a realistic post-aging benchmark. Hence, we kept utilization at 70%, reduced the DRAM size to 8GB and exercised a workload of more than 8GB to still ensure that the benchmarking workload was larger than the system memory. Furthermore, the authors performed their experiments on special Intel NVM hardware. Thus, we discourage the direct comparison of performance in Figures 8a and 8b with the NOVA paper results.

Figure 8a compares NOVA's performance on the fileserver workload before and after aging with Btrfs, Ext4, Ext4-DAX and F2fs. Ext4-DAX is Ext4 mounted with the *-o dax* option to enable direct-access to the emulated NVM device bypassing the buffer cache, thus avoiding duplicate caching of data. With the largest difference of 5% observed in Btrfs, we see virtually no difference in all FSs before and after aging. The same is true in the case of the varmail workload shown in Figure 8b where Btrfs is the most affected FS with a slowdown of approximately 6%.

Although aging does not affect throughput, its effect is seen in the tail latencies. Figure 9a shows the highest latency encountered by Filebench categorized by operation. The slowest file open in the fileserver workload was 60% slower after aging. Writing the slowest file also took twice as long compared to a freshly formatted NOVA image. Surprisingly, closing the slowest file was 5× faster after aging. In the varmail workload, the slowest aged read was 2.3× slower than the slowest unaged read. In contrast, the opening of the slowest aged file was approximately 25% faster. Both these observations can be attributed to the log-structured design of NOVA, as log-structured FSs are not read-optimized. We speculate that reorganization of files after cleaning might have led to the open call being executed faster.

As expected, with no mechanical parts and DRAM-like latency, NVM or in-memory FSs do not show significant reduction in throughput after aging. An aging exercise for these FSs is mainly about exposing inefficiencies in FS implementations that usually get hidden behind massive device latencies.

7 Conclusion

The Geriatrix aging tool creates representative fragmentation of both files and free space. Unlike with HDDs, file system performance on SSDs is greatly impacted by free space fragmentation that has been largely absent from prior aging approaches. Being released as open-source, Geriatrix will enable file system benchmarking to include aging relevant to modern storage.

A Proof of convergence of the age distr.

Assume we need to age a FS that has K files at the end of the rapid aging phase, and continues to have approximately K files throughout aging (i.e. one Geriatrix run). Let T be the total number of operations (each corresponding to a tick) performed in one Geriatrix run. Let the target relative age distribution be specified by binning the T ticks into B buckets, with the oldest bucket indexed as $b = B$ and the youngest bucket as $b = 1$ (i.e., the files created at the end of the run will fall in $b = 1$). Let s_b be the relative size of the age bucket b, i.e., files created in the first Ts_B operations will fall in relative age bucket B, and those in the next Ts_{B-1} operations in bucket $B-1$ and so on). Let g_b be the relative number of files in bucket b according to the target distribution i.e., there must be approximately Kg_b files in bucket b at the end of a run. Then we can predict the number of operations required to achieve convergence as follows:

Theorem A.1. *After*

$$T = max \begin{cases} \frac{2Kg_b}{s_b}, \forall b < B \\ \\ \frac{K}{s_B} \end{cases} .$$

the Geriatrix run would have converged to the target age distribution i.e., the number of files in age bucket b would equal Kg_b (approximately).

Proof. First, let us examine how the rapid aging phase, which consists of the first K file creations, affects the age distribution of the system. Since the oldest bucket corresponds to the first Ts_B operations, and $Ts_B \geq K$, all the files created in the rapid aging phase end up falling in bucket B.

Next, we will examine how the stable aging phase can achieve the target age distribution. Let O_b be the total number of stable aging operations that correspond to the ticks corresponding to bucket b. For the oldest bucket, $O_B = Ts_B - K$ and in the other buckets $O_b = Ts_b$. Further, let C_b and D_b respectively be the number of stable aging creation and deletion operations performed corresponding to bucket b. Assume that $C_b \approx \frac{O_b}{2}$ and $D_b \approx \frac{O_b}{2}$ since we perform creations and deletions in the stable aging phase using a fair coin toss.

Now note that the C_b creations corresponding to bucket b will create files which will all fall in bucket b. On the other hand, the D_b deletions corresponding to bucket b may be performed either on files in bucket b or on any pre-existing file in an older bucket b' such that $b' > b$. We will show that we can distribute these deletions in such a manner that the target age distribution of Kg_b files in bucket b can be achieved for every b.

First, observe that in the youngest bucket $b = 1$ we create exactly $C_1 = Ts_1/2$ files. Now, since $T \geq 2Kg_1/s_1$, $C_1 \geq Kg_1$. Thus, there would be an excess of $C_1 - Kg_1 = Ts_1/2 - Kg_1$ file creations in this bucket which need to be deleted. Since we have $D_1 = Ts_1/2$ deletion operations available for this bucket, we can use $Ts_1/2 - Kg_1$ of them to remove these excess files and achieve the target for this bucket, and use the excess Kg_1 delete operations for the older buckets.

We will now use induction to show that we can similarly achieve the target number of files for the older buckets (except the oldest which we will handle separately). Specifically, assume that for operating on the files in bucket b where $b \neq B$, we have $K\sum_{b'=1}^{b-1} g_{b'}$ excess delete operations available from the operations corresponding to the younger buckets (this is equal to zero for $b = 1$). Next, recall that have $C_b = Ts_b/2$ file creations in this bucket. But since $T \geq 2Kg_b/s_b$, $C_b \geq Kg_b$. Thus, there would be an excess of $Ts_b/2 - Kg_b$ files in this bucket that need to be deleted. However, we have $Ts_b/2$ deletion operations available from the ticks corresponding to this bucket and a further $K\sum_{b'=1}^{b-1} g_{b'}$ excess deletion operations available from younger buckets. Hence, we can delete these excess $Ts_b/2 - Kg_b$ files to achieve the target of Kg_b files in this bucket. Then, we will have the remaining $Kg_b + K\sum_{b'=1}^{b-1} g_{b'} = K\sum_{b'=1}^{b} g_{b'}$ deletion operations as excess which can be used for the older buckets, thus satisfying the induction hypothesis.

Now, for the oldest bucket we will have $K\sum_{b'=1}^{B-1} g_{b'} = K(1-g_B)$ excess deletion operations available (since $\sum_{b'=1}^{B} g'_b = 1$) from the younger buckets, besides $Ts_B/2$ deletions corresponding to this bucket. At the same time, we have created K files in this bucket in the rapid aging phase and $Ts_B/2$ files in the stable aging face i.e., $K + Ts_B/2$ files in total. Hence, we will have an excess of $K + Ts_B/2 - Kg_B = K(1-g_B) + Ts_B/2$ files, which happens to be equal to the total number of deletions available. Hence, we can achieve the target file number in this bucket *while using up all the available operations*. Thus, we use exactly T operations to achieve the target age distribution.

Abstract

Deduplication systems for traditional backups have optimized for large sequential writes and reads. Over time, new applications have resulted in nonsequential accesses, patterns reminiscent of primary storage systems. The Data Domain File System (DDFS) needs to evolve to support these modern workloads by providing high performance for nonsequential accesses without degrading performance for traditional backup workloads.

Based on our experience with thousands of deployed systems, we have updated our storage software to distinguish user workloads and apply optimizations including leveraging solid-state disk (SSD) caches. Since SSDs are still significantly more expensive than magnetic disks, we make our system cost-effective by caching metadata and file data rather than moving everything to SSD. We dynamically detect access patterns to decide when to cache, prefetch, and perform numerous other optimizations. We find that on a workload with nonsequential accesses, with SSDs for caching metadata alone, we measured a 5.7× improvement on input/output operations per second (IOPS) when compared to a baseline without SSDs. Combining metadata and data caching in SSDs, we measured a further 1.7× IOPS increase. Adding software optimizations throughout our system added an additional 2.7× IOPS improvement for nonsequential workloads. Overall, we find that both hardware and software changes are necessary to support the new mix of sequential and nonsequential workloads at acceptable cost. Our updated system is sold to customers worldwide.

1 Introduction

With traditional backups, an application periodically copies the entire contents of a file system into the backup environment, with changes since the last copy added at shorter intervals. These are called *full* and *incremental* backups, respectively [8]. Deduplicating file systems leverage the redundancy across full backups by storing a single copy of data, with the granularity of duplicate detection varying from whole files [2] to individual file blocks [31] or variable-sized "chunks" that are determined on the fly via content characteristics [28, 36]. Leveraging a log-structured file system [32] to store nonduplicate data results in append-only write operations. Nonsequential reads are needed for index lookups and when deduplication results in the physical fragmentation of unique data [20]. However, index lookups can be limited to trade deduplication efficiency to improve performance both for writes and reads by writing some duplicates to improve data locality [13].

There have been recent reports about the impact of evolving workloads on system performance. An article [3] provided an overview of the impact of increasing numbers of small files and higher deduplication ratios (and other changing properties) on the Data Domain File System (DDFS) as a whole, but with relatively few details or quantitative analysis. As an example, garbage collection (GC) was slowed by these changing workloads and a new algorithm was needed [11].

Indeed, GC is not the only aspect of the system that must be rethought to handle modern workloads. While Data Domain was one of the original "purpose-built backup appliances," modern data protection workloads impose very different requirements. These workloads include frequent updates to arbitrary locations in backup files, direct access to individual files rather than the aggregates created by traditional backup applications, and direct read/write access to files in the appliance by applications on other hosts. This last class of usage is particularly demanding, as it generally involves large amounts of **nonsequential I/O (NSIO)**.

Thus, we are at an inflection point where we need to rethink and redesign backup systems to enable *optimized*

[*] Current affiliation: Perspecta Labs

performance for non-traditional data protection workloads with nonsequential accesses for our customers. This goes beyond previous work on improving deduplicating storage by reducing fragmentation of sequentially read data [20], as it strives to provide improved NSIO performance without degrading the performance of traditional, sequential, workloads. These two types of application must coexist regardless of the distribution of workloads between the two categories.

In this paper, we describe the evolution of DDFS to support both traditional and nontraditional workloads based on our experience with deployed systems. Traditional workloads mostly have large sequential writes and reads with low metadata operations. Nontraditional workloads have many small files, more metadata operations, and frequent nonsequential accesses. Our new DDFS design supports higher IOPS for both metadata operations and nonsequential reads and writes and is already used by our customers[1]

We expanded our storage system, which had used only hard disk drives (HDDs), to also use solid-state disks (SSDs). These cache index data, directory structures, deduplicating file recipes, and ultimately file data. Because the capacity of the SSDs is a small fraction of the overall system (e.g., 1%), we must make a number of tradeoffs. For instance, while the index that maps fingerprints to disk location stores information in the SSDs for all chunks, we use a shorter form of the fingerprint that can have occasional hash collisions. We rely on metadata accessed when reading a chunk to provide the full fingerprint for confirmation, and when a mismatch is detected, the full on-disk index is consulted.

In addition, we have made several changes to our software stack. These include dynamic assessment of prefetching and caching behavior based on access patterns; data alignment, using application-specific chunk size; scheduler changes for quality of service; increasing the parallelism of I/O requests to a single file; minimizing writes by queuing metadata updates in memory; and support for smaller access sizes.

Through lab experiments, we demonstrate the impact of these changes on the performance of certain applications. With a NSIO workload, with SSDs for caching metadata, we measured a 5.7× IOPS improvement relative to a system without SSDs. Adding data caching in SSDs, we measured a further 1.7× IOPS increase. Combining SSD caching with software optimizations throughout our system added an additional 2.7× IOPS increase for NSIO workloads. We measured similar factors of reductions in terms of average latency of accesses for both reads and writes. Importantly, performance for traditional workloads running concurrently remained high and even increased (when run separately) due to software improvements. We provide detailed experimental results in §6.

In summary, the main contributions of this paper are:

1. We extend support to modern backup applications, with NSIO access patterns. We ensure our new design for the DDFS software stack benefits both traditional and nontraditional backup and restore tasks.

2. We optimize the file system to better utilize the benefits of flash in our software stack, while minimizing the cost of adding flash by selectively storing metadata on SSDs.

3. Experimental results using our techniques show orders of magnitude improvement in IOPS and reduced latencies in nonsequential workloads. Even traditional backup workloads show 25%-30% improvement in restore throughput because the SSD cache reduces disk accesses. In experiments where both traditional and NSIO workloads execute concurrently, our system maintains high performance for both workloads.

The rest of the paper is organized as follows. §2 provides a brief overview of deduplication in file systems and recent changes in backup applications that motivated us to re-architect our file system design. §3 describes our high-level architecture and design and §4 presents the detailed file system modifications in the DDFS stack. §5 states our experimental platform and workloads used in our study. Detailed experimental results are provided in §6. We discuss related work in §7. §8 concludes our study and discusses future extensions.

2 Background and Motivation

Here we provide an overview of our protection storage and a more detailed discussion of the changes that motivated our architecture modifications.

2.1 Deduplicating Protection Storage

Deduplication is common in commercial products and has been widely discussed including survey articles [30, 35]. Here we provide a brief overview of the specifics of our system; see Zhu, et al. [36] for additional details.

Each file is represented by a Merkle tree [26], which is a hierarchical set of hashes. The lowest level of the tree is file data, and hashes to many chunks[2] are aggregated into a new chunk one level higher in the tree. The fingerprint of that chunk is stored a level higher, and so on. The root of the Merkle tree represents a recipe for a single

[1] The data cache is not yet commercially available.

[2] In the interest of brevity, we shall refer to the unit of deduplication as a chunk even if the system uses fixed-sized blocks.

file, and the filename-to-recipe mapping is managed by a *directory manager*. Chunks are aggregated into write units, called *containers*, which are megabytes in size, and may be compressed in smaller units of tens of chunks.

Thus if a file is read sequentially, the system uses the directory manager to find the root of the Merkle tree, makes its way to the lowest level of metadata, and identifies the fingerprints of potentially thousands of data chunks to access. The chunks themselves may be scattered throughout the system, though there are techniques to alleviate read fragmentation [13,20]. There is an index that maps each fingerprint to a container, and the container has metadata identifying chunk offsets.

The storage system is log-structured [32], so whenever new data or metadata chunks get written, they are added to new containers. Garbage collection is necessary to reclaim free space, which can arise from deleted files removing the last reference to a chunk, as well as extra duplicates that are written due to imperfect deduplication [11].

2.2 Changing Environments

The improvements to our deduplicating storage system were motivated by changes in hardware and in applications [3]. Dramatic increases in the capacity of individual disks meant that a purely disk-based system would not have sufficient input/output operations per second (IOPS) to perform the necessary index lookups to deduplicate effectively. Moving the index to SSDs was a necessary step to improving performance, but it was not sufficient to handle the other changes.

The most extreme requirements on performance derive from two changes in workload. Initially, our systems had to deal with the change from periodic full backups to generating full backups by transferring changes since the last backup with *virtual synthetic* full backups [3,12] and change-block tracking [33] backups. With virtual synthetic and change-block tracking, changes to a backup would be written into protection storage, then a new "full backup" would be created by making a copy of the file metadata with the changes included. This would often be done at intervals of hours, rather than the weekly periodic backups from traditional workloads; thus the amount of metadata in the file system would grow by orders of magnitude, could not be cached in DRAM, and was slow to access on disk. The access patterns also changed from fully sequential writes (full backups, which would write a backup from start to finish on a regular basis) to "incremental" writes that would have monotonically increasing offsets but might skip large regions of a file.

Even greater stress to system performance arose with scenarios where data in protection storage are accessed *in place* after a failure. As an example, a virtual machine (VM) backed by a `vmdk` file might be booted and run from protection storage even while its `vmdk` image is migrated to a primary storage server. Accesses to any data not yet received by primary storage would be served through explicit I/Os from protection storage. It is characterized by nonsequential accesses, with additional sequential accesses introduced by storage migration in the background. Read operations during this period often include access of backup data for browsing and recovery of small files from large backups. Read-write operations from a running VM further stress deduplicating storage due to nonsequential reads and overwrites. This is somewhat analogous to storage vMotion [24], when a virtual disk can be accessed while it migrates. This workload in turn has implications on data formats, deduplication units, and physical devices.

Data formats A number of data protection applications perform transformations on data during the backup process. For example, some legacy backup applications have been described as creating a *tar*-like file concatenating data and metadata from many individual files in primary storage, to create a single backup file in protection storage [22]. It is not feasible to restore an individual file from this large aggregate, so there has been a shift towards backing up individual files in their "native" format. This in turn can lead to millions or billions of individual files, making the performance of namespace operations very important.

Unit of deduplication While content-defined chunking is a well studied topic, there is usually an assumption of little knowledge about the data type. As an example, without application-specific knowledge, variable-sized chunks are generally able to localize the impact of small edits when forming chunks. When application knowledge is available, it can increase efficiency such as deduplicating virtual machine disk images [14] in fixed-size units corresponding to disk blocks. (That is, updates to one part of the file do not shift content in other parts of the file.) More generally, application-specific deduplication must align the unit of deduplication appropriately, whether it is a database record or a block storage system directly performing backups.

Devices In addition to using SSDs to store metadata such as the deduplication index, we need to cache file metadata (the recipes that uniquely identify the individual chunks within a file) and file data blocks themselves. SSD caching, including the implications of retrofitting this to an existing disk-based data protection system, is a focus of this paper.

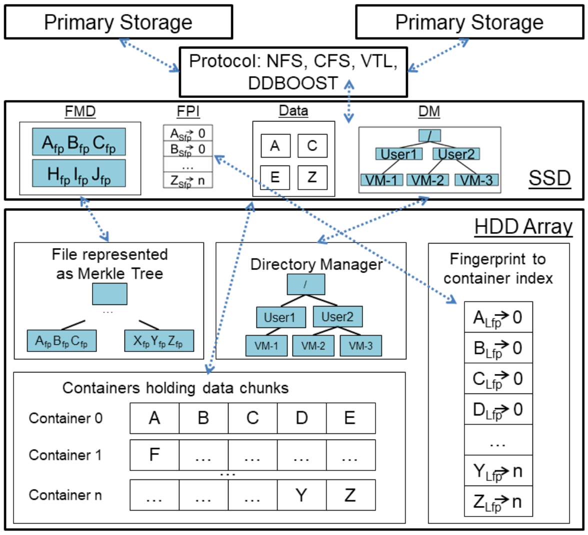

Figure 1: SSD caches: file metadata (FMD), fingerprint index (FPI), data, and directory manager (DM)

Mixed workloads While DDFS was originally designed to support large sequential access patterns, the shift to new workloads does not mean systems no longer have sequential accesses. Instead, there can be mixes of both across and within files. As an example, a system may restore a VM image by sequentially accessing it to create a copy on another system, but during the restore operation the VM image is accessed with reads and writes at more arbitrary locations. There may also be accesses related to ongoing backups relative to this file. DDFS needs to treat the types of accesses differently (*e.g.*, prefetching file data and metadata for the sequential restore) and provide different qualities of service based on resource requirements.

3 Modernizing Protection Storage

To motivate our caching decisions, consider the steps necessary to access data within a file at an arbitrary offset. Figure 1 shows four caches: file metadata (FMD), fingerprint to container index (FPI), data, and directory manager (DM). They are shown as SSD caches, though initially they existed only in DRAM. First, we find the entries in the file's Merkle tree corresponding to the desired data offset (FMD cache). Traversing the tree itself involves a level of indirection as every chunk within the tree is referenced by hash which is translated to a container using a fingerprint index (FPI cache). We then read in the portion of the file tree, which leads us back through the fingerprint index to access data chunks (data cache) that are returned to the client. Please note that the fingerprint index is shown in a simplified form relative to updates discussed in §4.7. Finding the file's top-level information involves a directory structure (DM cache) that is also used for namespace changes.

For largely sequential accesses, the overhead of retrieving various types of metadata will be amortized across many data accesses. For instance, if an application reads 1 MB of fixed-sized 4 KB chunks (256 in total), and the fingerprints of those chunks are all contained in a single chunk in the Merkle tree, then the cost of the directory lookup and the first few levels of the Merkle tree are amortized across 256 chunk reads. If the locality of those chunks is high, the first lookup in the FPI will lead to a container that populates the DRAM FPI for the rest of the 1-MB read.

For random accesses, especially to individual files, each read can result in a DM lookup, on-disk Merkle tree traversals, on-disk FPI lookups, and finally a data access. While caching will not significantly help completely random accesses, any amount of locality can result in substantial improvement.

We therefore use SSD to cache several metadata structures as well as file data. We controlled the costs of our design by using low-cost SSD that totaled 1% of the total hard drive capacity. Our selected SSDs only support three full erasures per day, so our design attempts to minimize writes. At the time of writing this article, SSD costs approximately 8× more per GB than HDD, so adding a 1% SSD cache increases the hardware capacity costs by 8% [1]. While some backup customers appreciate all-flash options, many remain sensitive to costs.

3.1 Caching the File Metadata

While our system attempts to group metadata chunks together, locality can become fragmented for multiple reasons, such as GC repositioning chunks and related files sharing previously written chunks. To decrease the latency for accessing file metadata (FMD) (i.e. the Merkle trees), we cache FMD in flash. Also for NSIO, accessing each data chunk requires accessing a metadata chunk that is unlikely to be reaccessed in the near future. This doubles the number of I/Os needed to serve a client request, so prefetching metadata chunks and caching in flash will decrease overall latency. There are multiple challenges we considered while designing the FMD cache.

We noted that metadata chunks can be of variable size, and not align with a flash erasure unit. We therefore packed metadata chunks into a multi-MB cache blocks and created a caching policy similar to Nitro [18]. Briefly, we maintain a single time stamp per cache block and perform LRU eviction using that time stamp to evict an entire cache block at a time. While LRU is a simple policy, and more advanced techniques [19] could be used, we have found that chunks within cache blocks tend to age at similar rates. We track the amount of data written to the FMD and will throttle new insertions to maintain our long term average of three writes per day times the capacity of the cache.

Importantly, we must determine which metadata chunks to add to the cache, as our capacity is insufficient to cache metadata chunks for all files in the system. 10% of the SSD cache is allocated to the FMD. Rather than simply inserting all FMD, we use admission control to determine what is appropriate to cache (§4).

3.2 Caching the Fingerprint Index

For any given chunk, on the read path the system must map from its unique fingerprint to its location in storage. The fingerprint to container index (FPI) performs that function. Historically, in DDFS the index would be on disk, with a small subset cached in DRAM. Our index design actually requires two I/Os for each access because there are typically two layers to the index. On a read operation, where the FPI mapping was not in the cache, there would be I/O to disk. However, the container that would then be loaded would include metadata for other chunks in the container, and their fingerprints would be cached. Since reads were typically large restore operations, accesses would be sequential and many other fingerprints would be found in the cache. As lower cost, denser hard drives have become available, they have been added to our systems. Unfortunately, IOPS per capacity have decreased for denser drives, and this further motivates the need to use SSD to accelerate NSIO such as fingerprint index accesses.

To support NSIO, the system keeps the entire FPI in SSD, but because space is limited, DDFS makes a concession. Each record stores a short version of each fingerprint in SSD along with the corresponding container and other information. Rather than storing all 20 bytes of a fingerprint, it stores four bytes. In the case of duplicate short fingerprints, only one copy is recorded in the FPI. More details are in §4. Figure 1 labels the full fingerprints as Lfp on disk and the short fingerprints as Sfp in SSD. It is possible the FPI will incorrectly match a query fingerprint based on the first bytes of a short fingerprint in the cache, but this false positive case will be detected. If the needed chunk is not found in the container referenced by the short fingerprint, then the full on-disk index is consulted. Latency is higher in this case, but as it is infrequent, overall performance improves dramatically while controlling SSD costs. FPI occupies 50% of the SSD cache.

For the data locality of traditional backups, for every 1MB external read, we issue an average of eight I/Os to disk where two are for the FPI. When the FPI is moved to SSD, we should see a benefit of at least 25% on disk bound systems. For data with bad locality, we will issue multiple FPI lookups per client read, so FPI in SSD would offer even more benefit. In Figure 2, we compare overall throughput of our system when the FPI is in SSD versus only on HDD. We show that having a fingerprint cache in SSD improves restore performance at higher stream counts, when disk is a bottleneck, by up to 32%. More experimental details are provided in §6.

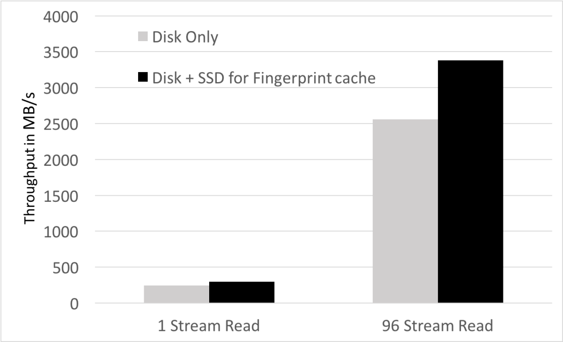

Figure 2: Performance evaluation of a NSIO workload with and without the fingerprint index cache in SSD.

3.3 Caching the Chunks

Once the system knows where to find a chunk, it loads the storage container holding it. With traditional workloads and significant spatial locality, two properties hold that are not true for NSIO workloads:

1. Once accessed, a particular chunk is unlikely to be accessed again unless the same content appears multiple times in the restore stream.

2. Other chunks in the same storage container are reasonably likely to be accessed as well, so the system benefits from caching that container's data and metadata. The container metadata can be used to avoid FPI lookups when locality is high [36].

For NSIO, in contrast, the locality of access within a container may be highly variable, and the reuse of specific data may be more commonplace. For instance, a data chunk might be written and then read, with a gap between the accesses that would be too large for the data to reside in a client or server DRAM cache. The SSD data cache is intended to provide a large caching level to optimize those access patterns, but it needs to dynamically identify what patterns it encounters.

On a data miss for sequential reads, we load the desired chunk as well as the following chunks that may be accessed. This helps to warm our cache and improves access times. We avoid loading chunks during writes except when read-modify-write operations are necessary. Techniques to identify such cases and modifications to DDFS are described in §4. 35% of the SSD cache is reserved for data chunks.

3.4 Caching Directories

The directory manager (DM) manages the mapping from file paths to Merkle trees. Thus, the first time a file is opened, the system must access this mapping to find the root of the tree. For large files such as VM images that are opened once and then accessed over time, the cost of the DM lookup is insignificant (once for a large file), but if there are numerous files to open (such as the result of backing up a file system as individual files); this cost can be a significant performance penalty.

In DDFS, data for DM resides on HDD, but a full copy is now cached in SSD for performance. Since such a cache is straightforward, our experiments focus on applications that are not namespace-intensive, so we do not consider the DM cache further. DM is allocated 5% of the SSD cache.

4 File System Modifications to Support Nonsequential Workloads

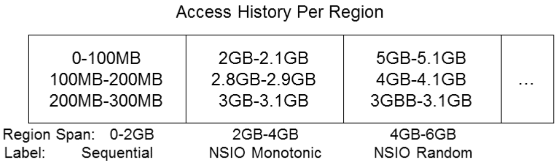
Our goal is to enable faster accesses for new workloads while continuing to support traditional sequential backup/restore workloads without performance degradation. Besides the flash caches described previously, numerous changes were needed in the file system to support NSIO. We begin by presenting our technique for identifying the type of client access, which determines if optimizations are applied. We then describe the most important file system changes.

4.1 Detecting Workload Types

To decide whether NSIO processing is needed, the incoming I/O requests must be analyzed to determine the type of access. Defining “sequential” is itself a challenge, as access patterns may not be strictly *sequential* even if they are *predictable* [17].

The access pattern detection algorithm partitions large files into regions and keeps a history of recent I/Os (specifically, 16 I/Os) per region as shown in Figure 3. There are two kinds of detection to check for data sequentiality and access patterns.

By default, all incoming I/Os are assumed to be sequential until there is enough history of previous I/Os to check for other types. Once the history buffer is full, if a new I/O is not within a threshold distance of one of the previous 16 I/Os, it is considered nonsequential.



Access History Per Region

	0-100MB 100MB-200MB 200MB-300MB	2GB-2.1GB 2.8GB-2.9GB 3GB-3.1GB	5GB-5.1GB 4GB-4.1GB 3GBB-3.1GB	...
Region Span:	0-2GB	2GB-4GB	4GB-6GB	
Label:	Sequential	NSIO Monotonic	NSIO Random	

Figure 3: Access history for three regions of a file, labeled sequential, NSIO monotonic, and NSIO random.

The reason for comparing with several past accesses is to avoid detecting re-ordered asynchronous I/O operations from a client as NSIO. By keeping multiple regions of access patterns within a file, we allow combinations of sequential and NSIO accesses to the same file to coexist without NSIO patterns hiding the existence of simultaneous sequential access. One example of this is NSIO from accessing a live VM image while simultaneously performing vMotion; another is the result of reordering of asynchronous I/O operations on a client. Our region size is a minimum of 2GB and grows to maintain at most 16 regions per file. The memory required for tracking a file is ≤3KB.

Referring to Figure 3, besides sequential I/O, we also label two variants of NSIO: NSIO monotonic and NSIO random. Monotonic refers to accesses that are to the same or non-consecutive increasing offsets. Random refers to accesses that do not have a discernible pattern. The monotonic pattern is particularly common when a backup client generates a synthetic full backup by first copying the previous full backup (an efficient metadata operation in deduplicated storage) and then overwrites regions at increasing offsets in the file. Distinguishing NSIO monotonic from random patterns allows us to implement different caching and eviction methodologies.

4.2 Prefetching Content

One of the uses of identifying accesses based on history per region is to prefetch and cache content. Importantly, we also avoid caching content that will not be reused. Our options are to load data into DRAM for immediate use or load into SSD if reuse is expected.

Specifically, when access patterns are labeled as sequential or NSIO monotonic, we can prefetch and load into DRAM, because we know the data or metadata will be used soon and SSD caching is unlikely to provide further benefit. For NSIO random I/O, we prefetch into SSD because we need to cache most of the active data set, which is larger than DRAM, to get the benefit of caching. In order to warm-up the cache sooner for every file with NSIO random I/O, we first load 128KB around the current I/O (e.g. 8KB) for caching in SSD since it may be reused, and there is little additional latency for

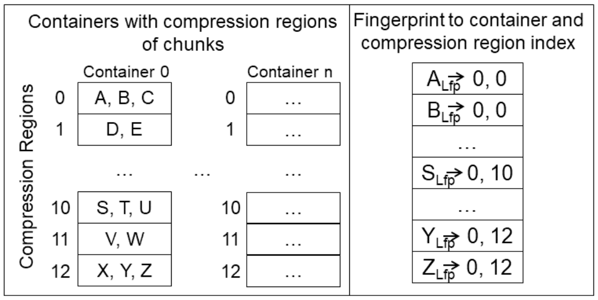


Figure 4: The fingerprint index is updated to map from fingerprint to container and compression region. The structured is presented in a simplified form.

loads of that size in our system.

4.3 Direct Read of Compression Regions

As described in §3, accessing a region of a file involves identifying the fingerprint representing that chunk from the file recipe, checking the fingerprint index for the corresponding location on disk, and then reading the chunk. For sequential accesses, we implemented an optimization in the early versions of the file system. The fingerprint index maps to container, so we read in the container's metadata region into RAM, which consists of a list of fingerprints for chunks within each compression region. We then determine which compression region to read and decompress to find the needed chunk. For sequential (or nearly sequential) accesses, we typically find most needed fingerprints in the RAM cache without the need to query the fingerprint index [36].

While this previous optimization dramatically reduces fingerprint index accesses for sequential I/O, it is inefficient for NSIO. A client's nonsequential read requires a fingerprint index read, container metadata read, and compression region read, *i.e.* three reads in total. Because future accesses are unlikely to remain within the same container, there is no amortization of reading a container's metadata. To remove the container metadata read for NSIO cases, we adjusted our fingerprint index to map from fingerprint to a compression region offset and size *within* a container (Figure 4). This allows us to perform direct compression region reads without first reading in container metadata, reducing the number of accesses from three to two. We dynamically decide based on access patterns whether to read compression region metadata or not.

To reduce SSD space for the FPI entries, we limit the entry size to twelve bytes. Four bytes come from the shortened fingerprint. Four bytes are used for the container ID, which is sufficient since it is relative to the lowest container ID within the system. The remaining four bytes are used to describe the compression region within the container with bits allocated to the compression region offset and size within the container as well as internal uses. To reduce the number of bits required, compression regions are written at sector boundaries. When indexing a fingerprint, we use a hash of the first eight bytes to select a FPI bucket. In combination with the four bytes short fingerprint, the collision rate is below 0.01%.

4.4 Higher Concurrency with Queue Changes

Applications directly accessing files from backup storage have high performance requirements, and latency is an important aspect, so I/Os must be processed as soon as they enter the file system. Unlike traditional workloads that tend to be highly sequential, with one client I/O effectively dependent on earlier I/Os to complete, NSIO has a greater need and opportunity for parallelism. For NSIO, FMD required to process the I/O may not be in memory and will require disk I/Os. Requests that are dependent on the same FMD will be processed serially in the order received; however, requests that do not require the same FMD are processed in any order and in parallel. Once the required FMD is loaded for any I/O, that request is given priority for further processing to avoid starvation. Apart from issuing parallel I/Os for FMD on disk, fingerprint lookups for multiple reads within the same file take place in parallel for NSIO.

4.5 Adjusting the Chunk Size to Improve Nonsequential Writes

For traditional large backup files, variable chunking achieves better deduplication than fixed-size chunks because it better identifies consistent chunks in the presence of insertions and deletions [34, 36], which we refer to as *shifts*. For new use cases that have block-aligned writes, such as change block tracking for VMs, shifts do not occur, and fixed-sized deduplication is effective [14]. Although variable-sized chunking has better deduplication, the performance gains achieved with fixed-size chunks outweighs the deduplication loss [27].

Based on customer configuration or backup software integration, we label workloads that will benefit from fixed-sized chunks. This simplifies the write path, as we do not need to find chunk boundaries or perform a read-modify-write for a partial overwrite of a chunk. For certain applications, such as VMs and databases, the block size is predetermined, and we set our chunk size accordingly for further efficiency.

4.6 Delayed Metadata Update

Switching to fixed-sized chunks has the added benefit that it allows for more efficient updates of file recipes during nonsequential writes. Traditionally, we would need to read in portions of the file recipe to provide fingerprints for chunks that must be read before being modified. With fixed-size chunks, we never need to modify existing chunks as they are simply replaced. We do need to update the file recipe to reference new chunks, but this can be delayed until sufficient updates have been accumulated. Since our chunk references are 28 bytes, 1MB of non-volatile memory can buffer references for nearly 300MB worth of logical writes.

4.7 Selective Fingerprint Index Queries

While our file system is designed to perform deduplication by identifying redundant chunks, we may choose to skip redundancy checks to improve performance [3]. We have found that nonsequential writes tend to consist of unique content. So to avoid fingerprint index queries that are unlikely to find a match, we disable querying the fingerprint index for small nonsequential writes (<128KB). Any duplicate chunks written to storage will be removed during periodic garbage collection [11].

4.8 Quality of Service and Throttling

DDFS has a quality of service (QoS) mechanism that assigns shares for external and internal workloads such as backup, restore, replication and garbage collection. These shares are used in the CPU and disk scheduler to provide QoS for the workloads. NSIO can happen as part of backup or restore, so we made changes to further split the backup and restore workload shares into sequential and nonsequential shares. The number of shares assigned to these workloads is tunable based on a customer's desired system behavior. By default, the shares for NSIO workloads are kept at 20% so as to not impact other critical workloads, but as reads and writes on backups during a restore becomes commonplace, shares may need to be increased for NSIO.

On non-uniform memory access architectures, jobs pertaining to a task are assigned a particular CPU for cache locality. Our earlier implementation used round robin assignment of jobs to CPUs. However, the resource requirements between NSIO workloads vary greatly and hence a simple round robin is insufficient. In the latest version of DDFS we have changed this assignment to least-loaded CPU instead. NSIO performance greatly depends on read performance, so we have modified our I/O scheduler to avoid read starvation and provide higher priority for read requests.

With all of the changes to increase NSIO performance, accepting more I/Os in parallel at the protocol layer usually improves overall performance. However, beyond a limit, further client requests will cause RPC timeouts, and hence I/O throttling per workload type becomes important. Based on the type of workload and the average latency, we have implemented an edge throttling mechanism where the protocol layer can query the subsystem health and insert queue delays to dynamically change the number of client accesses supported.

5 Experimental Methodology

This section describes our experimental methodology and the test environment including the system configuration and workloads used. All our results are measured on a Data Domain DD9800 [10] configured with maximum capacity. It has 60 Intel(R) Xeon(R) CPU E7-4880 v2 processors @2.50GHz, with 775GB DRAM, 8 10Gb network ports, 10.9TB SSD, and 1008 TB disk storage across 6 shelves with 4TB HDDs. Each shelf has between 1 and 4 packs, with 15 HDDs per pack. There are 20 spare HDDs. We produce accesses to the DD9800 using up to 8 clients running Linux version 2.6.32 with Intel(R) Xeon(R) CPU E5-2620 with 2.00GHz cores, 64 GB of memory, and a 10Gb Ethernet card.

We primarily use traditional and NSIO workloads for our measurements. Performance numbers for traditional backup and restore are reported using an in-house synthetic generator that randomly creates first generation backups for each stream and then modifies following generations with deletions (1%), shuffles (1%), and additions (1%) [7]. Across clients, the total size of first generation backups is 3TB, and metadata is approximately 1% of the data size. We wrote every 5th generation, though we allowed changes to accumulate in memory even for unwritten generations. This workload has 100% sequential read/write accesses to data for all generations. However, metadata accesses are NSIO. We report throughput numbers as the average of generations 41 and 42.

For a NSIO workload, we use the industry standard FIO benchmark [6] to simulate large sequential and NSIO reads as well as small NSIO reads and writes. We also present results when accessing 32 100GB VM images with mixtures of sequential I/O and NSIO, as described in each experiment. While customer VMs often share content, in order to reduce factors affecting our experiments, we have confirmed that there was no potential deduplication within or across the images. Here we report performance numbers in terms of IOPS and average latency. Unless otherwise noted, experiments were performed on an isolated system configured with fixed-sized chunks and without other read/write operations or background tasks such as garbage collection or replication.

All metadata fit within SSD without the need for admission control.

We show the benefits of our hardware and software optimizations in the following experiments. Each data point in our experiments with traditional backup workload was collected in runs that lasted multiple days and on data sets that were aged up to 42 generations of backups. Multiple clients were used to generate the backup workload, and results are averaged across clients. Each data point in our experiments with NSIO workload was collected by measuring the average performance (IOPS and latency) with at least three runs, and the standard deviation of results is <1.5% in all cases.

6 Evaluation

We begin by exploring the impact of caching metadata and data as well as software optimizations within DDFS for NSIO workloads. Then we investigate the impact on traditional, sequential workloads using different protocols. Finally, we study the sensitivity to different read/write ratios in NSIO workloads and the impact when storage vMotion occurs in parallel.

6.1 Caching and Software Optimizations

We investigate the impact of progressively adding metadata and data to a SSD cache as well the value of software optimizations in terms of average IOPS (Figure 5(a)) and latency (Figure 5(b)). Metadata include the FPI, FMD, and DM caches, though our tests do not perform directory operations. To avoid direct comparisons, the experiments with optimizations disabled are separated by a dashed line in each set of bars

We vary the number of VM images accessed from 1 to 32 and plot the average IOPS and latency for a NSIO workload. In these experiments, we study a read-only workload, and each VM is issued a maximum of 8 concurrent I/Os. When the flash cache is disabled, each external I/O will translate to six internal I/Os to disk. This includes two I/Os for FPI lookup to then perform one I/O for file metadata. From the file metadata, we have the chunk fingerprint and then perform two I/Os for FPI lookup and one I/O to load the data. The total number of HDD IOPS available on the test system is 24K. So, the theoretical achievable client IOPS when the cache is not available would be 4,000. Software optimizations are enabled except in one set of runs.

We see in the experiment with 32 VMs and the cache disabled, we achieve 3,200 IOPS with a latency of 35ms. When we enable the caching of metadata, every external NSIO will result in one I/O to HDD for data. We show that we can achieve 28K IOPS in a 32 VM experiment, with an average latency of 10ms. When both data and metadata are in the flash cache, IOPS are only limited by the data set size we can cache. On the test system, we can cache 100% of the data for up to 24 VMs and 75% of the data with 32 VMs. We achieve peak performance of 57K IOPS for 24 VMs with a cache hit ratio of 95%. The overall latency stays under 5ms even at peak IOPS.

We next consider the benefit of software optimizations (§4) to improve NSIO performance. Results show that using a SSD cache for NSIO without software changes would limit us to a peak NSIO performance of 20K IOPS, compared to 56K IOPS when software enhancements are enabled. Similarly, even when data and metadata are cached, latency decreases from 13ms to 5ms with the addition of software optimizations.

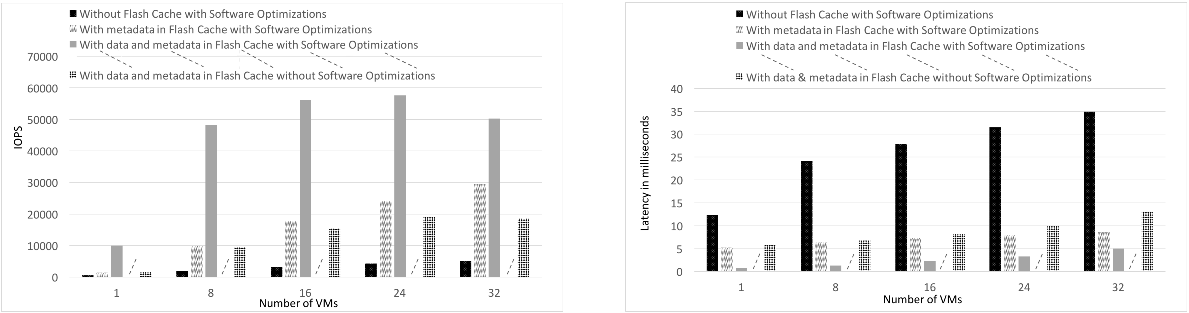
With a small cache and high churn in application workload, some portion of the I/Os will be serviced from disk. Our software optimizations remove unnecessary I/Os to disk (§4.2, §4.3, and §4.5), increase parallelism (§4.3), and improve the I/O scheduler (§4.8). With these changes, we are able to to achieve high NSIO IOPS and maintain a low latency with a SSD cache sized at 1% of the total system capacity.

6.2 Traditional and NSIO Workloads

In this experiment, we evaluate both traditional and NSIO workloads running concurrently to measure the impact on traditional workloads. We run both workloads through NFS and DDBOOST protocols. DDBOOST is our proprietary protocol where segmenting and fingerprinting of data is offloaded to backup clients and only changed data is sent across the network [12]. DDBOOST performance is typically higher than NFS because deduplication reduces the amount of data transferred, and the backup server has fewer computational demands.

In this experiment, we throttle NSIO workloads on 32 VMs to a total of 10K IOPS. 2.4TB of the 3.2TB data set fit in the data cache. In Figure 6, we measure the performance of 96 streams of backup and restore workloads while varying the protocol and the fraction of reads versus writes of the NSIO workload. A 100% read NSIO workload is possible when the client writes are redirected to primary storage during a recovery operation. 70% reads are common in other recovery use cases where both writes and reads are directed to backup storage. Read/write numbers represent restore and backup performance for high-generation backups with an equal split of 48 backups and 48 restores.

Considering the difference between NFS and DDBOOST, we find the expected result that DDBOOST has higher overall throughput because of offloading tasks to clients. Across protocols, backup and restore performance is not degraded more than than 10% when NSIO runs in parallel, though there is greater impact



(a) IOPS

(b) Latency

Figure 5: Average IOPS and latency as caching and software optimizations are varied. Up to 24 VMs, 100% of the data can be cached. Caching decreases to 75% for 32 VMs. Experiments without software optimizations are separated from the rest by a dashed line.

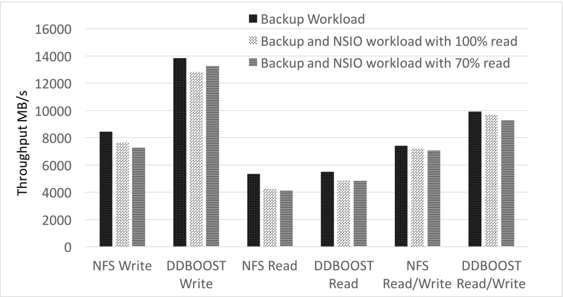


Figure 6: Traditional backup workloads have a 10% degradation when NSIO workloads are added with the DDBOOST protocol outperforming NFS.

when NSIO includes writes.

When more NSIO performance is required than the sustained IOPS specified for the product, a system level QoS parameter (§4.8) allows users to choose the amount of impact on traditional workloads they find acceptable to further increase NSIO performance. Though not shown due to space limitations, we experimented with varying the QoS share allotted to NSIO versus sequential workloads. As the share for NSIO increased from 25% to 50%, IOPS increased by 32%. Increasing the share from 50% to 75% increased IOPS 18% more. When NSIO was allocated 100% of the resources, IOPS increased an additional 125% due to the complete removal of sequential I/O interference.

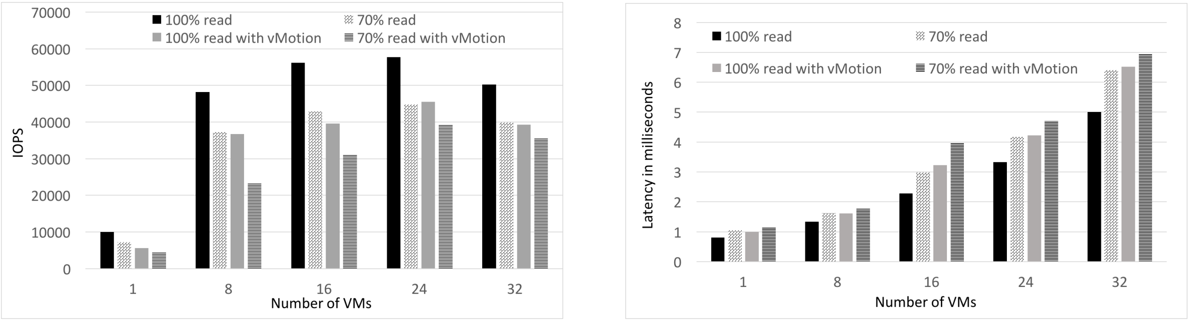
6.3 Performance during Restores

Some backup applications provide a Instant Access/Instant Restore feature where an application may be able to perform read/writes from the backup copy while a restore takes place. This feature may expose a read-only copy of a backup image for the applications to access while redirecting any writes to a write log typically located on primary storage. We simulate this workload using 100% NSIO reads. Other backup applications expose a read/write copy and send both reads and writes from the application to the exposed copy. This is simulated using a 70/30% reads/write NSIO workload. While a VM image is being accessed, backup applications also offer an option to perform storage vMotion of the VM back to primary storage. This workload is simulated by issuing sequential reads on the same VM image on which NSIO is taking place.

Figures 7(a) and 7(b) show an experiment where NSIO activity takes place with either 100% reads or 70/30% read/writes. With 24 VMs we see a peak of 56K IOPS and under 4 ms of latency with 100% reads. For the 70/30% read/write mix, we see a peak of 44k IOPS at 24 VMs where the cache gets nearly 95% hits. We also show that when vMotion on the same VM takes place, IOPS for NSIO drop by at most 20% and achieves a peak of 45K IOPs for 100% reads. At 70/30% read/write with vMotion, we achieve 40K IOPS. The overall result is acceptably high performance NSIO performance while vMotion takes place.

6.4 Fingerprint Cache Impact on Backup and Restore Workloads

For traditional backup workloads, even with software optimizations, disk I/O becomes a bottleneck. We previously presented experimental results for placing a FPI cache in SSD in Figure 2. For this test, we limited the total IOPS available on the test system to 4,200 by using only four disk groups, the smallest configuration possible. Other metadata and data accesses may still go to HDD, so the overall throughput improvement has many components besides fingerprint access speed. With a high stream count of 96, overall throughput increases with the SSD cache by up to 32%, which corresponds to the fraction of I/O that can be satisfied by the FPI cache in SSD.



(a) IOPS

(b) Latency

Figure 7: Average IOPS and latency for NSIO read/write access to VMs, with and without vMotion in parallel.

7 Related Work

A recent article [3] described the changes to data protection workloads and some of the changes DDFS made to address them. However, the changes were described very generally, focusing on qualitative issues but not quantitative ones. As an example, the article mentioned the addition of SSDs, short fingerprints in SSD, and selectively writing duplicates, but there were few implementation details and no experiments. While we have focused on improvements to backup storage for NSIO, backup software drives most of the client-initiated workloads [4, 8]. The work on improving garbage collection enumeration performance [11] to handle high deduplication rates and numerous individual files provided detailed performance measurements, but that effort is largely orthogonal to the improvements for NSIO described here.

SSD-assisted deduplication has taken many forms. DedupeV1 [25] and ChunkStash [9] were two early systems that moved the fingerprint index into SSD to improve performance. ChunkStash used Cuckoo Hashing [29] to reduce the impact of hash collisions, something we have not found to be a significant performance issue. PLC-cache [23] categorized deduplicated chunks by popularity to determine what to cache. Nitro [18] presented a technique for caching and evicting data chunks in large units to SSD to improve performance while reducing SSD writes, which influenced our metadata and data cache design. Kim et al. [16] modeled deduplication overheads and benefits within SSD and then accelerated performance with selective deduplication against recently written fingerprints. We view the contribution of our work as lessons learned from a deployed storage system pertaining to caching, prefetching, and scheduling, and not simply the addition of SSDs.

While there have been multiple papers regarding sequential write and read performance for deployed deduplicated storage products [5, 15, 20, 21], there has been little discussion of nonsequential workloads. Discussing the architectural changes needed to support both sequential and NSIO workloads in deduplicated storage will hopefully drive further research.

8 Conclusion and Future Work

New workloads for backup appliances and denser HDDs have placed demands on backup storage systems. DDFS has had to evolve to support not only traditional workloads (full and incremental backups with occasional restores) but also newer nonsequential workloads for thousands of customer deployments. Such workloads include direct access for reads and writes in place, as well as other workload changes such as storing individual files and eschewing periodic full backups. Additionally, traditional and newer workloads must *peacefully coexist* within the same product.

Because of the cost difference between SSDs and disk, we have chosen to cache a limited amount of metadata and file data in SSD rather than moving the entire system to SSD. We demonstrate that these caches not only improve NSIO by up to two orders of magnitude, but our system can also simultaneously support traditional workloads with consistent performance. In summary, improvements to our software and the addition of SSD caches allow DDFS to support both new and traditional workloads.

In the future, we expect NSIO workloads to become more common as customers increase the frequency of backups. In combination with decreasing SSD prices (though likely still more expensive than HDD), it may become worthwhile to increase our SSD cache to include most metadata and a larger fraction of active data. We will need to revisit our software design as bottlenecks shift between I/O and CPU.

Acknowledgments

We would like to acknowledge the contributions of the DDFS team including: Uday Kiran Jonnala, Sirisha Kaipa, Vrushali Kulkarni, Shuang Liang, Valiveti Narasimha, Shantanu Patwardhan, Balaji Subramanian, Pradeep Thomas, Satish Vishwanathan, Grant Wallace, Sailu Yallapragada, and Sean Ye. Abstract

Using multiple interfaces on mobile devices to get high throughput is promising to improve the user experience. However, Multipath TCP (MPTCP), the de-facto standardized solution, suffers when different paths have heterogeneous quality. This problem is especially severe when the difference is the path latency. Our experimental results show that it causes the burst sending of packets from the fast path, which requires the in-network buffer to be big to achieve the full benefit of the bandwidth aggregation. In addition, it also requires bigger host buffer to fully utilize the fast path. To solve these problems, we propose and implement a new scheduler, which pre-allocates packets to send over the fast path for in-order arrival. Instead of relying on the estimation of network path condition, our scheduler dynamically adapts the MPTCP-level send window based on the packets acknowledged. Our evaluation shows that our scheduler can improve the throughput by 30% when the in-network buffer is limited, 15% when the host buffer is limited.

1 Introduction

There is a huge demand on network bandwidth with the rapid growth of network users and applications, as well as the emergence of bandwidth hungry applications such as multimedia streaming, cloud computing and virtual reality. To obtain high network throughput, a lot of recent interests have been drawn to exploit multi-path transmissions and aggregate the bandwidth through Multi-path TCP (MPTCP) [12]. As an example application, many wireless devices have two network interfaces, one to the local-area WiFi network and another to the wide-area cellular network. As wireless bandwidth is limited, a data stream can go through both networks to increase the transmission rate.

MPTCP is expected to be backward-compatible with conventional TCP and work with existing network components such as middle-boxes [26]. For the practical deployment of MPTCP, it is designed to be transparent to both applications and middle-boxes. From the perspective of applications, a single standard TCP is seen, whereas lower in the stack, MPTCP splits the data over multiple sub-flows. From the perspective of middle-boxes, each sub-flow is a normal TCP connection. MPTCP has already been implemented in Linux kernel [7] and used in iOS [4] and Giga Path in Korean Telecom [27]. Agache *et al.* [2] deploy MPTCP in the datacenter network to obtain better network utilization. Han *et al.* [15] apply MPTCP to improve the user experience on video streaming.

The core element of MPTCP design is the scheduler [28], which determines when and how to distribute packets to each sub-flow. MPTCP's default scheduler (minRTT) [26] sends packets through the available path with the smallest estimated Round-Trip Time (RTT). However, this scheduler does not take into account the path heterogeneity while there often exist different types and quality of paths in practical use and this is especially the case for wireless applications [17, 29]. The measurement of Alexa top-500 U.S. websites from Nikravesh *et al.* [24] shows that the difference in RTT between WiFi and Cellular paths is common and big. When RTTs in separate paths differ, the default scheduler will cause an out-of-order arrival of packets at the receiver side. Thus the memory requirements of MPTCP are much higher than those of conventional TCP. To alleviate this problem, opportunistic retransmission and penalization mechanism is proposed [26] and improved [25] along with the progress of the default scheduler.

Despite these efforts, we find that the complete gain from bandwidth aggregation of MPTCP is still far from being achieved. In our experiments conducted in the controlled lab environment (§ 2), we observe that when the host buffer is limited, the aggregation throughput is far smaller than two single-path TCP combined under

[*] Corresponding author

the same network and buffer settings. Sometimes it can only reach 40% the throughput of two single-path TCP together, which is even worse than a single-path TCP running over the best network interface.

Apart from the host buffer problem, we find that it also requires a big in-network buffer on the fast path to reach the full-bandwidth allowed by multiple paths. The in-network buffer requirement for the fast path is increased by 4X when using both paths compared with those for single-path TCP. Examining the problem carefully, we find that the default scheduler breaks down the ACK clocking [19] on the fast path, which gives rise to the burst sending of packets during fast sub-flow's transmission. Thus more in-network buffers are necessitated to hold the burst packets, otherwise the packets that cannot be stored have to be dropped, resulting in the throughput degradation on the fast path. This problem is more serious in the wireless networks where WiFi path is usually the fast one and has less buffer than that of the Cellular path [20]. Therefore when competing with single-path TCP, MPTCP is more likely to experience loss and the throughput will suffer. To the best of our knowledge, we are the first to identify the burst transmission pattern on the fast-path of MPTCP.

In this work, we propose a new scheduler to reduce both host buffer and in-network buffer requirements in MPTCP, called STMS (**S**lide **T**ogether **M**ultipath **S**cheduler). To solve the above two problems fundamentally, we need to reduce the out-of-order arrival. Our scheduler preallocates packets for the fast path and sends packets with larger sequence number through slow path so that packets can arrive at the receiver in order. This task appears to be straightforward, but it faces several challenges. As a matter of fact, there exists a ”visibility gap” between the sender and the receiver. Therefore, it is hard for the scheduler that runs at the sender to ensure that packets arrive in order at the receiver. A sender can choose to utilize the measurement of path condition to schedule the packets, but the network condition is fluctuated in nature. Consequently, it is hard to measure the delay and bandwidth accurately especially in wireless networks. Even under stable network conditions, we can only obtain RTT but not one-way delay (OWD) in a practical distributed network. To address these challenges, we design an adaptation scheme that exploits the intelligent transmission of feedback signal *Data ACK* existing in MPTCP to dynamically schedule packet transmissions.

We implemented STMS as a Linux kernel module (§ 4) and evaluated it extensively in both emulated and real Cellular/WiFi networks. The results show that, compared with state-of-the-art schedulers [23, 25], STMS achieves significantly higher performance under a wide range of buffer/network conditions. We highlight some of results as follows:

- Under stable network conditions, STMS can achieve higher throughput under any buffer conditions. When the host buffer is extremely limited, STMS can fall back to using the single-path TCP, while the default scheduler still uses slow path of MPTCP and its fast path suffers from significant throughput degradation. In this case, our scheduler can improve the throughput as much as 400%. When the host buffer is small, STMS can bring 15% improvement over the default scheduler. When in-network buffer is limited, STMS improves the throughput as much as 30% due to the reduction of the burst.

- Under varying network conditions, STMS also performs well, and brings 8% to 40% throughput improvement. Our adaptive scheduling scheme is reactive to network condition changes.

- In real world test, STMS can reduce the file downloading time by 20% even when the host buffer is big enough, proving that the limited in-network buffer does exist in real network and our scheme effectively alleviates the problem.

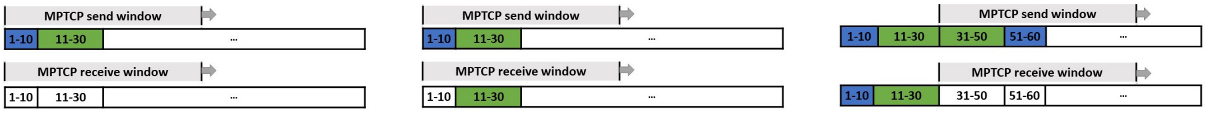
Overall, our results show that by strategically scheduling packet transmissions to reduce the out-of-order arrival, STMS can significantly improve the throughput of MPTCP under heterogeneous networks. The rest of the paper is organized as follows. Firstly, we analyze the reason that lead to the throughput degradation when using the default scheduler in § 2. Then in § 3, we present the design and analysis of STMS. Next we introduce our implementation of STMS in § 4. We further present our performance evaluations in a controlled-lab environment in § 5, and the results from the real-world test in § 6. Finally, related work is discussed in § 7 and we conclude the paper in § 8.

2 Background and Motivation

In this section, we first identify and analyze the problem associated with the in-network buffer. Then we demonstrate that host buffer problem still remains unsolved and discuss why the existing solution is still inadequate. We support our analyses with experiments conducted in the controlled lab environment.

2.1 Controlled experiment setup

In our experiment setup in fig. 2, we use two PCs running the version 0.92 kernel of MPTCP [7] as the client and server respectively. The client has two interfaces, and the server has one interface. Under this topology, MPTCP will establish two sub-flows. We use the decoupled TCP



(a) t = δ

(b) t = RTT_f

(c) t = RTT_s

Figure 1: Out-of-order arrival and burst transmissions on the fast path due to the use of default scheduler. Green (lighter) packets are sent/received through the fast path, while blue (darker) ones are sent/received through the slow path.

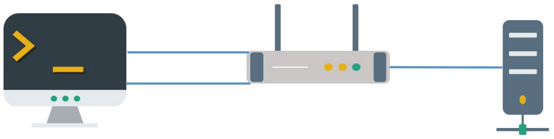


Figure 2: Topology setup

congestion control to obtain the best bandwidth aggregation effect [9]. Ethernet is used to simulate WiFi and LTE to avoid the interference of the wireless network. Client and server are connected through a router running OpenWrt. We use tc [30] in OpenWrt to regulate the bandwidth and latency of the two paths. The bandwidths of both paths are set to 30 Mbits and the loss rate is set to 0.01%. The in-network buffer is set to 50ms for Wifi path unless specified otherwise and 500ms for LTE path based on [20]. Both receiving and sending buffers are set to the Linux default size (6MB) unless specified otherwise. Only the RTT of slow path varies. In each network setup, we run iPerf 3 [18] 90s five times to measure the throughput.

2.2 Big in-network buffer requirement

Guido *et al.* [3] points out that it becomes more and more difficult to design the router with the buffer size equal to the bandwidth-delay product as the link speed increases. The router buffer is limited especially in the bottleneck of path. However, we find that the aggregated throughput is subject to the in-network buffer on the fast path as shown in fig. 3. For conventional TCP, 8ms network buffer (30KB) is enough to reach the full bandwidth. However, for MPTCP under different RTT paths, the in-network buffer requirement increases as much as 4X to fully unleash the power of the bandwidth aggregation. The bigger the difference of RTT between two paths, the bigger the in-network buffer of the fast path is needed.

When there is a space in the congestion window, the default MPTCP scheduler sends a set of packets with the smallest sequence numbers on the path with the smallest estimated RTT. This approach will produce the out-of-order arrivals at the receiver, as is elaborated in the following example (fig. 1). At the time $t = 0$, we assume the fast path is unavailable while the slow path has space,

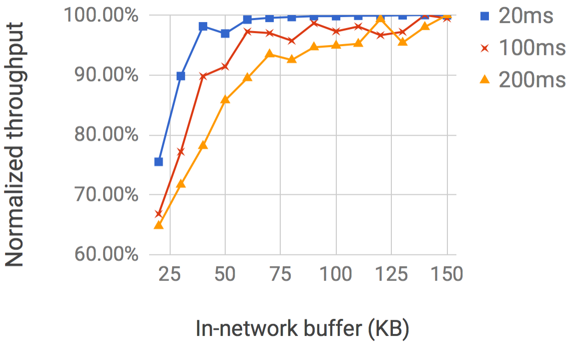

Figure 3: MPTCP throughput degradation when in-network buffer is limited

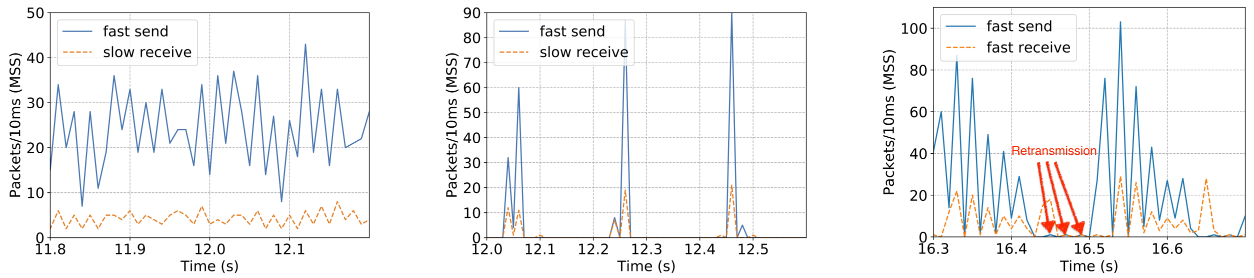
then packets 1-10 will be sent on the slow path. Later on at $t = \delta$, the fast path becomes available, packets 11-30 will be sent on the fast path. After the round-trip time of the fast path RTT_f, packets 11-30 arrive at the receiver but packets 1-10 do not, and the send/receive window is blocked as shown in fig. 1b.

TCP has the delayed ACK mechanism [6] to avoid the overhead of sending ACK packets. It works as follows. Upon receiving a data packet, if it is in order, *i.e.,* the right edge of the receiving window advances, the receiver can choose to delay the sending of ACK hoping to piggy-back the ACK with other packets to send in the reverse direction. Nevertheless, RFC 1122 [6] suggests that each ACK acknowledge at most two packets regardless of whether the delayed ACK mechanism is used, *i.e.,* upon receiving two successive packets, an ACK must be sent. Thus, during the congestion avoidance phase, upon receiving one ACK, the sender's send window can have the space for at most two packets so that it can send at most two packets at a time. This is also known as ACK clocking.

In MPTCP, the semantics of the TCP send window is generalized. Instead of maintaining a separate window for each sub-flow, a single buffer pool is shared by all sub-flows at the MPTCP-level to avoid deadlock [26]. To remain compatible with TCP, MPTCP needs a separate ACK for MPTCP-level send window, called Data ACK. The delayed ACK mechanism of conventional TCP is adapted to Data ACK. When receiving data packets in-order on the MPTCP-level, Data ACK will still be



(a) $RTT_f = 20ms, RTT_f = 20ms$ w/o PR (b) $RTT_f = 20ms, RTT_s = 200ms$ w/o PR (c) $RTT_f = 20ms, RTT_s = 200ms$ w/ PR

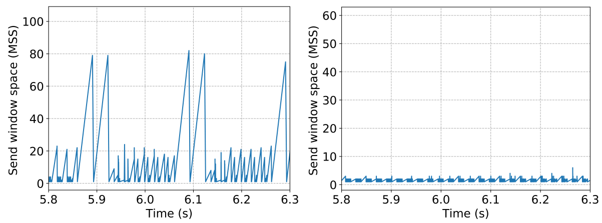
Figure 5: The Data ACK of fast path.



(a) $RTT_f = 20ms, RTT_s = 200ms$ (b) $RTT_f = 20ms, RTT_s = 20ms$

Figure 6: Send window free space jitter when RTT differs

generated every other packet. However, when receiving out-of-order packets on the MPTCP-level, it will not send a duplicate Data ACK immediately since out-of-order packets on the MPTCP-level is a normal behavior especially when paths are heterogeneous. The Data ACK won't be sent until the packets from the slow path reach the receiver, *i.e.,* the hole is filled. This Data ACK will acknowledge many packets sent from the fast path at the same time, thus fast path can send many packets at once, leading to the burst sending. In a nutshell, the out-of-order arrival of packets breaks down the ACK clocking effect of fast sub-flow, causing the burst sending behavior. This is shown in fig. 1c. At t = RTT_s, packets 1-10 arrive at the receiver and packets 1-30 are acknowledged to the sender. So both the send and receive window will progress with a large step, and packets 31-50 are sent from the fast path in a burst. Simply removing the delayed ACK mechanism can not solve the problem, since the MPTCP-level send window progress is still blocked by the late arriving packets from the slow path.

We conduct a simple experiment to demonstrate the burst transmission pattern of the fast sub-flow.

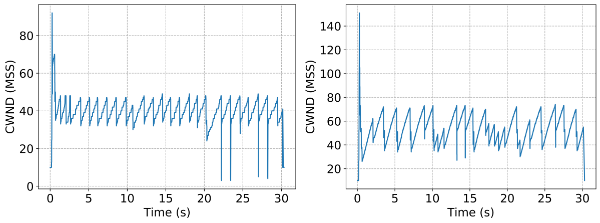
First we analyze the progress of Data ACK of the fast path from the trace file. The result is shown in fig. 5. Only when packets from the slow path arrive, the Data ACK can make a progress with a large step (fig. 5a). When RTT is the same, no sudden Data ACK progress happens. Then we check the free space in the send window of the fast path. We record the free space of send window when the sub-flow receive ACK (fig. 6). When RTT is the same, the ACK clocking is maintained like the conventional TCP (fig. 6b). However, when RTT over two paths significantly differs, the ACK clocking of the fast path is broken down. Consequently, MPTCP-level send window is stalled until the packets from the slow path arrive. As a result, the free space of the send window of the fast sub-flow will accumulate as we see in fig. 6a.

The sudden progress of MPTCP-level window and the big send window space of fast path will lead to the burst packet transmissions on the fast path as we see in fig. 4b. Compared to the sending behavior of the fast path when RTT is similar (fig. 4a), the fast sub-flow clearly demonstrates an on-off transmission pattern that leads to the burst of the fast sub-flow. When the network buffer is not big enough, the loss will happen and the Congestion window (CWND) is capped to a small value as we see in fig. 7a. When there is a difference between RTT on the two paths, the CWND of the fast path is capped around 40, compared to 60 when RTT values of two paths are the same. Note that there is usually a large space in fast path's CWND when RTT is different, so the area below the CWND line is actually bigger than the total throughput.

We also verify the loss rate under different in-network

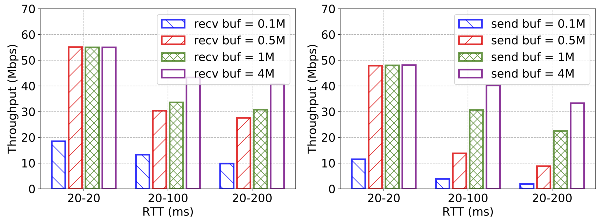
Table 1: Loss rate of fast path under different in-network buffer setting

in-network buffer/KB	observed loss rate	Fast path in MPTCP/Mbps	Single TCP/Mbps	Utilization
30	0.05%	12.1	28.4	42.76%
60	0.02%	20.8	28.4	73.50%
90	0.02%	25	28.4	88.34%
150	0.01%	26.5	28.4	93.64%



(a) $RTT_f = 20ms, RTT_s = 200ms$ (b) $RTT_f = 20ms, RTT_s = 20ms$

Figure 7: CWND of fast sub-flow is capped when in-network buffer is limited and RTTs are different.



(a) Receive buffer (b) Send buffer

Figure 8: MPTCP throughput degradation when host buffer is limited

buffer configurations (table 1). Note that this loss is more detrimental to the throughput than the random packet loss since each time CWND grows to certain value, the packet burst will exceed the in-network buffer size and the loss will happen. As a result, the throughput of the fast path is significantly limited. As shown in table 1, to reach the same throughput as that of single-path TCP, the buffer for two-path MPTCP has to be increased by 4X from 30KB to 150KB.

2.3 Big host buffer requirement

Another problem of MPTCP when RTTs are different is the big host buffer requirement. Let us denote the bandwidth of fast and slow sub-flow as B_f and B_s respectively. The one-way delay (OWD) values of both paths are denoted as OWD_f and OWD_s respectively. The RTTs of both paths are denoted as RTT_s and RTT_f. Raciu *et al.* [26] derives that the default scheduler buffer requirement is:

$$Buf(default) = (B_f + B_s) \times RTT_s \tag{1}$$

From eq. (1) we can see that the key to reducing the buffer requirement is to reduce the effective RTT of the connection *i.e.,* to acknowledge packet as soon as possible so that the buffer can get freed.

Raiciu *et al.* [26] proposed the penalize and opportunistic retransmission mechanism (PR) to deal with the host buffer problem. When it detects the left edge of the send window blocks the sending of packets, it will retransmit the packet from the fast path. To avoid constant retransmissions, it will penalize the slow sub-flow by halving the CWND of slow sub-flow. This approach does improve the throughput when the receiving buffer is limited because the blocked packets will get retransmitted and acknowledged through the fast path. Thus the effective RTT of MPTCP connection can be reduced to $OWD_s + OWD_f$ ideally. As shown in fig. 4c, the packets marked get retransmitted and the new Data ACK goes back through the fast path so many packets can be sent. Due to its opportunistic nature, the PR scheme can not always reduce the RTT to the optimal value. Moreover, the retransmission wastes the bandwidth. fig. 4c also shows that the retransmission does not change the fast path's burst transmission pattern, as the Data ACK coming back through the fast path will still acknowledge many packets. Hence the in-network buffer requirement issue remains unsolved which is also shown in the in-network buffer requirement measurement. Enabling retransmission doesn't improve the throughput at all.

Despite the PR approach, the throughput of MPTCP is still unsatisfactory as shown in fig. 8. When evaluating the receiving buffer, the sending buffer size is set to the default value of Linux which is 6 MB (Big enough under our network setting). As we can see in fig. 8a: the bigger the RTT difference of two paths, the more receiving buffer is needed to get full bandwidth aggregation effect of MPTCP. The same conclusion goes to the sending buffer as is shown in fig. 8b.

Actually, the burst sending pattern can be fixed by adding traditional pacing to the fast path. Linux has supported pacing in tc qdisc fq [13] since the version 2.4. However the pacing rate argument needs to be manually tuned according to the bandwidth of the network path. New congestion control algorithm Bottleneck Bandwidth and Round-trip propagation time (BBR) [8] incorporates the pacing and can set the pacing rate equal to the measured bottleneck bandwidth automatically. However the congestion control of MPTCP needs to be fair with the conventional TCP. Many active research efforts [5, 21, 31] have been put into developing the coupled congestion control algorithms of MPTCP, but there is no coupled BBR congestion control for MPTCP yet. To put it another way, this approach is not congestion control agnostic. Besides, the pacing can not solve the big host buffer requirement issue. Pacing works only on sub-RTT level and thus the packet sent from the slow path will still arrive later than packets sent from the fast path. We verify that by adding pacing manually and it turns out that the throughput is not improved at all.

3 Design

The root cause of the throughput degradation is the stall and sudden progress of MPTCP-level send window. To solve both host buffer and in-network buffer problems, we need to restore the ACK clocking for MPTCP. To achieve this, packets need to arrive in order at the receiver.

In this section, we first present our algorithm design, then derive the size required from the host-buffer for no-blocked transmissions, and finally compare the transmission latency of different schemes.

3.1 STMS algorithm

We propose STMS to schedule the packets strategically so that they arrive in order. This solution is congestion control agnostic which allows for separate evolving of congestion control algorithm and scheduler algorithm.

Scheduler algorithm The core idea of our scheduler is to buffer packets for the fast sub-flow and assign packets with larger sequence numbers to the slow sub-flow so that they arrive in order. The running process of our algorithm is shown on fig. 9 and algorithm 1. The scheduler runs when at least one of paths is available to send packets. The fast sub-flow always sends the packets with the smallest set of sequence numbers in the buffer. As illustrated in fig. 9a, the slow sub-flow sends packets with bigger sequence numbers. Rather than taking packets whose numbers are right after those transmitted on the fast path, it leaves a sequence gap for the fast path to send the corresponding packets in the future. By the time the packets from the slow path arrive, all packets from the fast path which have smaller sequence numbers should have already arrived (fig. 9b). Since packets arrive in order, the normal ACK clocking is ensured, so there are no burst transmissions on the fast path and the send/receive window will not be blocked.

Algorithm 1 Slide Together Scheduler

```
procedure ST_SCHEDULE($unsentPackets$)    ▷ Scheduler runs when one of sub-flow is available
    if Fast sub-flow has space in send window then
        $Fast\ sub-flow \leftarrow$ unsentPackets[0]
    elseSlow sub-flow has space in send window
        $Slow\ sub-flow \leftarrow$ unsentPackets[$Gap$]
    end if
end procedure
```

The key parameter of the scheduler algorithm is *Gap*, which is the number of packets pre-allocated for fast path to send. The efficiency of the scheduler algorithm depends on the accuracy of the gap value. Any deviation from the true value will cause out-of-order arrival of packets.

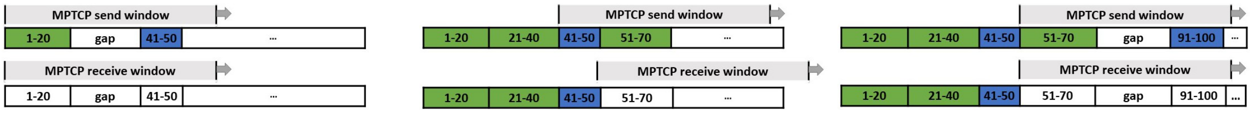
The naive way to get the gap value is to utilize the measurement of path conditions. If we can measure network conditions accurately, then we can derive the true gap value in the following way. It takes $OWD_f + \frac{Gap}{B_f}$ for all packets in the gap to arrive at the receiver through the fast path, where B_f is the bandwidth of the fast path. This should be equal to OWD_s so that the first packet from the slow path arrives at the same time as packets from the fast path. Then we have the true Gap value:

$$True\_Gap = B_f \times (OWD_s - OWD_f) \qquad (2)$$

However, the naive solution has two fundamental flaws. One is that the one-way delay of path can not be measured accurately. We can not assume the uplink delay and the downlink delay are the same on both paths. If we modify the protocol to carry the one-way delay information, it may cause other compatibility problem with middleboxes [16]. The other one is that the bandwidth of the path can not be measured accurately, especially when the in-network buffer is limited. Because of the burst sending pattern of fast sub-flow, it can never reach the actual available bandwidth. So we design the feedback-based gap adjustment scheme to adjust the value of gap more accurately and quickly.

Key insight: Every out-of-order packet in the receiver will generate duplicate Data ACK or burst Data ACK.

What STMS actually does is moving stalled packets from the receiver to the sender (*i.e.,* the packets inside gap). The out-of-order packets will be acknowledged at one time when packets from the slow path arrive to fill in the hole. The number of packets acknowledged by Data ACK reflects the degree of out-of-order arrival of packets. Accordingly we can use this as the feedback signal to adjust the gap value. Since Data ACK is presented in MPTCP, our scheme remains compatible with current MPTCP. In addition, this scheme does not require



(a) t = 0

(b) t = $2RTT_f$

(c) t = RTT_s

Figure 9: Demonstration of STMS, with green and blue for packets over fast and slow paths respectively. Let $RTT_s = 3RTT_f$ and assume the uplink delay and downlink delay are symmetric, then we have $gap = CWND_f$ according to eq. (2). Note that slow path always send packets with sequence numbers bigger than those of the fast path.

any modification at the receiver, which further eases the deployment process.

How to adjust The gap adjustment algorithm is shown in algorithm 2. Let $delta\_gap$ and $adjust\_interval$ be the gap adjustment step and interval. When the gap is smaller than the true gap value, the packets from the slow path arrive late and the send window of MPTCP-level will be stalled by packets sent from the slow path. Therefore the left edge of the send window is determined by unacknowledged packets from the slow path. Symmetrically, when the gap is bigger than the true gap value, the left edge of the send window will be determined by the packets sent from the fast path. Each time we receive a Data ACK, we first calculate how many packets this Data ACK acknowledges ($data\_acked$). If the $data\_acked$ is bigger than 2, we will adapt the gap value. We check the packet of the left edge of the send window. If the packet is the first one sent from the slow path, $delta\_gap = data\_acked$; otherwise, $delta\_gap = -data\_acked$. We use the Exponentially Weighted Moving Average (EWMA) of $delta\_gap$ over $adjust\_interval$ to adjust the gap value. The $adjust\_interval$ is a tunable parameter, which determines how fast the gap adjustment can react to the network change. Setting it too small will cause the gap overshoot and oscillation since the previous gap adjustment has not taken into effect yet. However, setting it too big leads to the slow convergence time.

Algorithm 2 Gap Adjustment Algorithm

```
procedure GAP_ADJUST($data\_acked$)    ▷ This function gets called when receiving Data ACK
    if $data\_acked > 2$ then
        $send\_una \leftarrow$ left edge of MPTCP-level send window
        if $send\_una$ was sent from slow path then
            $delta\_gap = data\_acked$
        else$send\_una$ was sent from fast path
            $delta\_gap = -data\_acked$
        end if
    end if
    $gap+ = EWMA(delta\_gap, adjust\_interval)$
end procedure
```

3.2 Analysis of host buffer size requirement

At a first glance, buffering packets for the fast path may require a big buffer on the sender side. However, we can prove that when both paths are fully utilized, the send buffer requirement is actually less than that of the default scheduler without PR (eq. (1)).

When using STMS the send buffer consists of three parts:

1. sent but unacknowledged packets from the fast path: $B_f \times RTT_f$
2. sent but unacknowledged packets from the slow path: $B_s \times (OWD_s + OWD_f)$ (Data packet is sent through the slow path, but ACK returns from the fast path).
3. buffered packets for the fast path *i.e.,* $True\_Gap$ (eq. (2))

By adding these three parts together, we get the buffer requirement of STMS:

$$Buf(STMS) = (B_f + B_s) \times (OWD_S + OWD_f) \qquad (3)$$

This is smaller than $Buf(default)$ (eq. (1)). It also reveals that STMS reduces the effective RTT of the MPTCP connection to $OWD_s + OWD_f$, which is the smallest RTT when both paths are utilized. Thus our STMS can reduce the send buffer requirement.

If we take into consideration the opportunistic retransmission, then in the ideal case, upon receiving the late arrival packet from the slow path, the Data ACK of the retransmitted packet will go back through the fast path. Therefore the effective RTT of the MP connection is reduced to $OWD_s + OWD_f$, which is the same as STMS and the buffer requirement is also the same.

When the host buffer is between [$Buf(STMS)$, $Buf(default)$], both retransmission and STMS can improve the throughput. But STMS can always achieve the optimal throughput by ensuring RTT of MP connection to be the minimum.

If the host buffer is smaller than $Buf(STMS)$, neither STMS nor default scheduler can get the full bandwidth aggregation. In this case, STMS will prefer to use the fast path. The slow path will be used only if it will not cause the blocking. The buffer requirement to take advantage of the use of the slow path is:

$$\begin{aligned} Buf(fallback) &= RTT_f \times B_f + Gap \\ &= B_f \times (OWD_s + OWD_f) \end{aligned} \tag{4}$$

When the host buffer is between [$Buf(fallback)$, $Buf(STMS)$], STMS will use the fast path first, as the slow path will not block the fast path. However, for the default scheduler, the slow path will get the frequent use, which would trigger the retransmission of packets. This will further lead to the goodput degradation and the big end-to-end latency.

What if the host buffer is even smaller than $Buf(fallback)$? Then STMS will fall back to the single TCP over the fast path. But the default scheduler will still send some packets from the slow path, which pushes the effective RTT of MPTCP connection to at least $OWD_s + OWD_f$. Thus the throughput will be even worse than the bandwidth B_f allowed by the fast path alone. Actually, in this case, falling back to the single-path TCP is the optimal choice.

So our scheduler can get the optimal throughput across all range of host buffer sizes.

3.3 Analysis of latency

It seems that STMS will cause the inflation of transmission latency because it holds packets in the gap longer than the default scheduler. However, it also reduces the time duration for the packets to be stalled in the receiver. Using both types of scheduler, the end-to-end latency of packets sent from the slow path is OWD_s. The latency of the fast path is $OWD_f + Delay(Stalled)$. For each packet sent from the fast path, it is either stalled at the receiver buffer or held at the send buffer. $Delay(Stalled)$ remains the same. Therefore STMS does not increase the average end-to-end latency of packets.

4 Implementation

We implement STMS in the Linux kernel based on MPTCP version 0.92 from [7]. The algorithm 1 is implemented as a scheduler module.

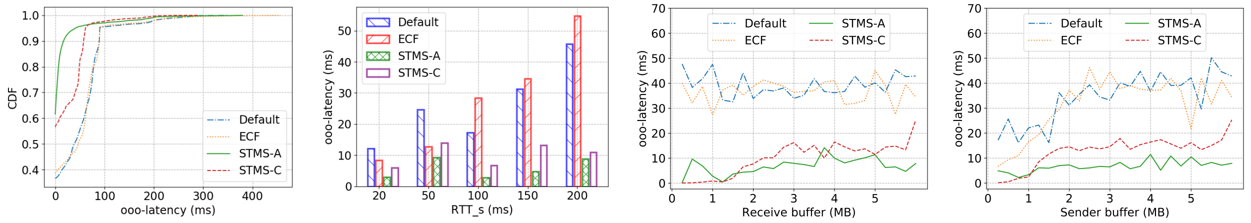
The MPTCP scheduler will run when two types of event happen. The first type of event happens when ACK returns from one of the sub-flows, which means there will be space in the sub-flow send window. The second type of event happens when application sends more data. The scheduler makes the decision every data segment. For each segment pushed in by the application, the scheduler will determine which sub-flow to send the packet. This framework of scheduler limits how we can implement our scheduler, since we can not access an arbitrary segment inside the send buffer. To remain compatible with this framework. We implement our scheduler as follows.

When the scheduler picks the next segment to send, we first check if the fast path is available, *i.e.,* there is space in the send window. If the space is available, then send the packet over the fast path; otherwise, we check if the slow path is available. If it is available, we find the packet according to the gap value, *i.e.,* jump across the gap packets to find the packets to send over the slow path. If the packet does not exist, that means either the packet is out of the right boundary of the send window or the application has not pushed enough data yet, in either of which case we skip this round of scheduling. Note that we need to mark the packets sent from the slow path so that we can skip the out-of-order packets when finding the next packet to send from the slow path. To avoid traversing the send buffer from the beginning each time, we save the pointer of the last send packet of the slow path as the beginning point for the next search.

We implement two variants of STMS: STMS-C ("Calculation") and STMS-A ("Adjustment"). They both preallocate packets for the fast sub-flow so that packets can arrive in-order at the receiver side (§ 3.1). They differ in how they obtain the gap value. Each time a packet is sent from the slow path, STMS-C extracts the bandwidth estimation of smoothed RTT from subflow TCP's algorithm and calculates the gap value (assume the uplink and downlink delay are symmetric). For STMS-A the Data ACK process function is modified to calculate $delta\_gap$ according to algorithm 2.

5 Evaluation in a controlled lab environment

In this section, we test both STMS-C and STMS-A in a controlled lab setting, which allows us to evaluate the performance across a wide variety of network conditions. We compare our scheduler with the default scheduler with PR (denoted as Default thereafter) and ECF [23]. ECF uses the send buffer length to estimate the flow complete time(FCT) of using each path. If using slow path will cause inflation of FCT, it will wait for fast sub-flow. However, for elephant flow, the send buffer is full for most of the time. Only when flow is about to finish, the send buffer length can be small enough to wait for fast sub-flow. Besides, when calculating the FCT, ECF does not take into account the one way delay thus it is not able to achieve accurate in-order arrival. STMS schedules the packets out-of-orderly to achieve the in-order arrival regardless of the send buffer status so STMS can outperform ECF. For apples-to-apples comparison, we port the ECF



(a) OOO delay distribution

(b) Varying slow path latency

(c) Varying receive buffer

(d) Varying send buffer

Figure 10: Out-of-order latency of different schedulers

code [10] to the same MPTCP version as our scheduler. The experiment setup is the same as § 2.1. We tune the $adjust\_interval$ of STMS-A to $\frac{RTT_s+RTT_f}{2}$ according to the analysis in § 3.1. The parameter of ECF is chosen as the same as [23].

5.1 Microbenchmarks

We first focus on some micro-benchmarks to see whether our scheduler can accomplish the design goal.

5.1.1 Reducing the out-of-order arrival at the receiver side

We first investigate whether our scheduler can achieve the in-order arrival at the receiver side. We use the out-of-order (OOO) delay as the metric. The OOO delay of a packet is defined as the time difference between when a packet arrives at the receiver to when the packet can be submitted to the application (*i.e.,* all packets with the smaller data sequence numbers have already arrived).

fig. 10a shows the CDF of the OOO delay of each packet with different schedulers. STMS-C and STMS-A can both achieve smaller OOO delay than Default and ECF. The largest OOO delay is around 300ms. Default effectively pushes the OOO delay of most packets sent from fast path to OWD_s. ECF sends tail packets out-of-orderly so it can reduce OOO delay for those tail packets. However since we transmit many packets for a test, this delay reduction is negligible. STMS-A can effectively push the OOO delay close to zero.

We vary the latency of slow path and calculate average of OOO latency. The result of one experiment is shown in fig. 10b. When paths become more heterogeneous, both Default and ECF have larger OOO delay. However STMS-A can keep its average OOO delay at a very small value. When RTT of two paths are similar(20ms and 50ms), ECF, STMS-C and STMS-A get close performance.

We also test the OOO delay under different host buffer sizes. The result is shown in fig. 10. It demonstrates that both STMS-A and STMS-C can effectively reduce the OOO delay regardless of the host buffer size, and the gain is larger when the host buffer sizes are larger with more packets stalled at the receiver. For ECF, only when the send buffer is very small, it wait for fast sub-flow to reduce the OOO delay.

5.1.2 Reducing the burst on the fast path

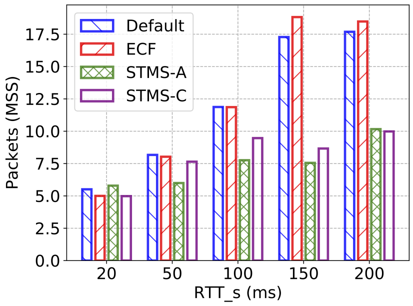


Figure 11: Burstness of all four schedulers under different path latencies

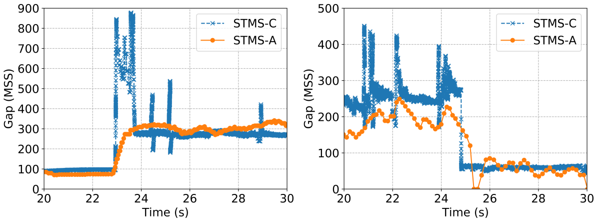
We now study whether our scheduler can reduce the burst of the fast path thus the in-network buffer requirement accordingly. We print the CWND free space of the fast sub-flow when it receives ACK. Since all schedulers try to fill this free space, the peak value of CWND free space reflects the burst of fast path. The average CWND free space throughout the running time is used as a metric of burstness of fast subfow. The result is shown in fig. 11. The trend is the same as fig. 10b. Our scheduler can reduce the burstness of the fast path and makes it close to that of the single-path TCP.

5.1.3 Gap adjustment is reactive to network change

To understand how STMS-A handles dynamic network conditions, we change the network conditions in the middle of MPTCP flow and record the gap value changes around the condition changing point. Recall that the true gap value is calculated using eq. (2). It is affected by the accuracy of the measurement of the fast path bandwidth and the one-way delay of both fast path and slow path. We choose to change the latency of the fast path and slow path to demonstrate how our Gap adjustment algorithm reacts to the network change. In fig. 12a, the latency of the fast path changes from 20ms to 5ms. Therefore there will be many ACK packets and the fast path can send a lot of packets out which leads to the wrong estimation of the bandwidth. Thus, we see the peak of the gap calculated value. However, our gap adjustment algorithm can converge to the new value smoothly. In fig. 12b, the latency of the slow path changes from 200ms to 100ms. Again STMS-A converges to the new value smoothly and fast.



(a) Gap increase

(b) Gap decrease

Figure 12: Gap adjustment is reactive to network change

5.2 Macrobenchmark: improving aggregated throughput

We then investigate how our scheduler improves the aggregated throughput under different buffer sizes setting.

Stable network condition We begin by investigating whether our scheduler improves the throughput when the network condition is stable. fig. 13 shows the result. When the in-network buffer is limited, our scheduler can improve the throughput by about 30% compared to Default and ECF. When the host buffer is extremely limited, our scheduler falls back to single path TCP and outperforms Default as analyzed in § 3.2. When the host buffer is big enough(>4MB), there is no blocking, so all four schedulers can get the full bandwidth aggregation effect. The STMS-C and STMS-A produce analogous results under the same buffer settings, which indicates the gap adjustment algorithm can track the true gap value precisely.

We then vary the latency of slow path. Both STMS-C and STMS-A improve the aggregation throughput over Default and ECF. We pick the improvement of STMS-A over Default as an example. fig. 14 shows the throughput of STMS-A normalized relative to that of Default. The improvement become more prominent as the paths become more heterogeneous and the buffer gets smaller.

Varying bandwidth Then we investigate the performance of our scheduler under network fluctuations. Here we change the bandwidth of both path randomly every 10 seconds. The bandwidth value is chosen from set {5, 10, 20, 30} Mbps. We generate 5 network configurations using different random seeds and run test five times for each network configurations.

fig. 15a shows the average throughput of four schedulers for each configuration. Note the error bar indicates the variability of the same configuration. Our scheduler outperforms other schedulers in every configuration. STMS-A performs even better than the STMS-C. This indicates that STMS-A is more adaptive to network fluctuations than the STMS-C.

Varying latency We simulate the varying latency condition using tc netem module. Both paths' latency is changed every 10 seconds, and the stddev of latency is set to 40% of the mean latency. We generate five latency configurations and run the test five times (fig. 15b). Similar to the bandwidth change scenario, STMS-A always performs best.

6 Evaluation in the wild

We next evaluate our scheduler in more realistic environments. The server is deployed in Aliyun [1] and has only one interface. The client is located inside our campus and connects to the server through WiFi and LTE. The China Telecom LTE cellular network incurs higher delay than the WiFi network. The average bandwidth and latency characteristic of each path are shown in table 2. We use tc to add extra latency on LTE path.

Table 2: Path characteristics

	Bandwidth(Mbps)	Latency(ms)
WiFi	40	50
LTE	30	70

We compare our scheduler against Default and ECF. We measure the download time of 200MB file of different schedulers. For each latency setting, we run the test five times. The result is shown in fig. 16. Both STMS-C and STMS-A outperform Default and ECF. The STMS-A can get the best performance, reducing the file download time by as much as 20% over Default.

7 Related work

There are many studies on the improvement of MPTCP scheduler. To solve the host buffer problem, Raiciu *et al.* [26] propose the PR mechanism. Ferlin *et al.* [11] propose the Blocking Estimation-based Scheduler (BLEST) which aims to prevent the blocking by reducing the usage of slow path even if it has available CWND space. Both schedulers try to restrict the use of the slow path to alleviate the need of big host buffer resulting in the under-utilization of slow path.

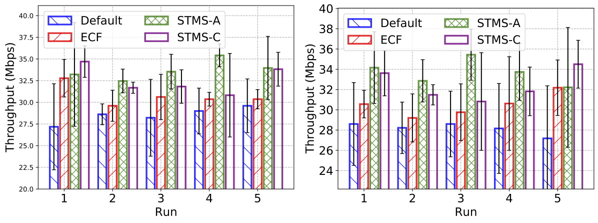
Figure 14: STMS-A throughput normalized by Default



(a) Bandwidth change

(b) Latency change

Figure 15: Throughput under dynamic network conditions

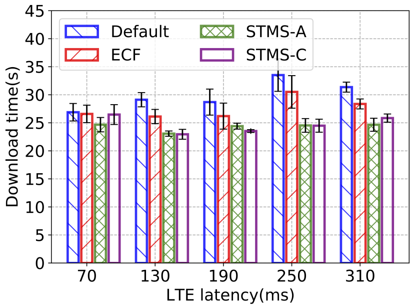


Figure 16: Average file download time in the wild (lower is better)

Kuhn *et al.* [22] propose DAPS to address the RTT difference of two paths. But it only considers the stable CWND and the scheduler running interval is very big thus can not react to the dynamic network changes.

Lim *et al.* [23] propose ECF which outperforms both DAPS and BLEST. But it only considers the tail packets.

Guo *et al.* [14] propose a new scheduler to balance two sub-flow completion time by sending packets inside a ”chunk” in the opposite direction. Nonetheless, this approach will require a huge host buffer to store the whole chunk.

8 Conclusion

In this work, we identify a new root cause of MPTCP throughput degradation under heterogeneous path conditions. We propose STMS to effectively alleviate the problems due to the limitation in the host buffer size and in-network buffer size. Our experimental results show that STMS outperforms state-of-the-art schedulers in diverse network and buffer settings, especially when the path heterogeneity is large.

Abstract

Internet transport algorithms are foundational to the performance of network applications. But a number of practical challenges make it difficult to evaluate new ideas and algorithms in a reproducible manner. We present the Pantheon, a system that addresses this by serving as a community "training ground" for research on Internet transport protocols and congestion control (https://pantheon.stanford.edu). It allows network researchers to benefit from and contribute to a common set of benchmark algorithms, a shared evaluation platform, and a public archive of results.

We present three results showing the Pantheon's value as a research tool. First, we describe a measurement study from more than a year of data, indicating that congestion-control schemes vary dramatically in their relative performance as a function of path dynamics. Second, the Pantheon generates calibrated network emulators that capture the diverse performance of real Internet paths. These enable reproducible and rapid experiments that closely approximate real-world results. Finally, we describe the Pantheon's contribution to developing new congestion-control schemes, two of which were published at USENIX NSDI 2018, as well as data-driven neural-network-based congestion-control schemes that can be trained to achieve good performance over the real Internet.

1 Introduction

Despite thirty years of research, Internet congestion control and the development of transport-layer protocols remain cornerstone problems in computer networking. Congestion control was originally motivated by the desire to avoid catastrophic network collapses [22], but today it is responsible for much more: allocating capacity among contending applications, minimizing delay and variability, and optimizing high-level metrics such as video rebuffering, Web page load time, the completion of batch jobs in a datacenter, or users' decisions to engage with a website.

In the past, the prevailing transport protocols and congestion-control schemes were developed by researchers [18, 22] and tested in academic networks or other small testbeds before broader deployment across the Internet. Today, however, the Internet is more diverse, and studies on academic networks are less likely to generalize to, e.g., CDN nodes streaming video at 80 Gbps [26], smartphones on overloaded mobile networks [8], or security cameras connected to home Wi-Fi networks.

As a result, operators of large-scale systems have begun to develop new transport algorithms in-house. Operators can deploy experimental algorithms on a small subset of their live traffic (still serving millions of users), incrementally improving performance and broadening deployment as it surpasses existing protocols on their live traffic [1, 7, 24]. These results, however, are rarely reproducible outside the operators of large services.

Outside of such operators, research is usually conducted on a much smaller scale, still may not be reproducible, and faces its own challenges. Researchers often create a new testbed each time—interesting or representative network paths to be experimented over—and must fight "bit rot" to acquire, compile, and execute prior algorithms in the literature so they can be fairly compared against. Even so, results may not generalize to the wider Internet. Examples of this pattern in the academic literature include Sprout [42], Verus [43], and PCC [12].

This paper describes the **Pantheon**: a distributed, collaborative system for researching and evaluating end-to-end networked systems, especially congestion-control schemes, transport protocols, and network emulators. The Pantheon has four parts:

1. a software library containing a growing collection of transport protocols and congestion-control algorithms, each verified to compile and run by a continuous-integration system, and each exposing the same interface to start or stop a full-throttle flow,

2. a diverse testbed of network nodes on wireless and wired networks around the world, including cellular networks in Stanford (U.S.), Guadalajara (Mexico), São Paulo (Brazil), Bogotá (Colombia), New Delhi (India), and Beijing (China), and wired networks in all of the above locations as well as London (U.K.), Iowa (U.S.), Tokyo (Japan), and Sydney (Australia),
3. a collection of network emulators, each calibrated to match the performance of a real network path between two nodes, or to capture some form of pathological network behavior, and
4. a continuous-testing system that regularly evaluates the Pantheon protocols over the real Internet between pairs of testbed nodes, across partly-wireless and all-wired network paths, and over each of the network emulators, in single- and multi-flow scenarios, and publicly archives the resulting packet traces and analyses at https://pantheon.stanford.edu.

The Pantheon's calibrated network emulators address a tension that protocol designers face between experimental realism and reproducibility. Simulators and emulators are reproducible and allow rapid experimentation, but may fail to capture important dynamics of real networks [15, 16, 31]. To resolve this tension, the Pantheon generates network emulators calibrated to match real Internet paths, graded by a novel figure of merit: their accuracy in matching the performance of a set of transport algorithms. Rather than focus on the presence or absence of modeled phenomena (jitter, packet loss, reordering), this metric describes how well the end-to-end performance (e.g., throughput, delay, and loss rate) of a set of algorithms, run over the emulated network, matches the corresponding performance statistics of the same algorithms run over a real network path.

Motivated by the success of ImageNet [11, 17] in the computer-vision community, we believe a common reference set of runnable benchmarks, continuous experimentation and improvement, and a public archive of results will enable faster innovation and more effective, reproducible research. Early adoption by independent research groups provides encouraging evidence that this is succeeding.

Summary of results:

- Examining more than a year of measurements from the Pantheon, we find that transport performance is highly variable across the type of network path, bottleneck network, and time. There is no single existing protocol that performs well in all settings. Furthermore, many protocols perform differently from how their creators intended and documented (§4).
- We find that a small number of network-emulator parameters (bottleneck link rate, isochronous or memoryless packet inter-arrival timing, bottleneck buffer size, stochastic per-packet loss rate, and propagation delay) is sufficient to replicate the performance of a diverse library of transport protocols (with each protocol matching its real-world throughput and delay to within 17% on average), in the presence of both natural and synthetic cross traffic. These results go against some strains of thought in computer networking, which have focused on building detailed network emulators (with mechanisms to model jitter, reordering, the arrival and departure of cross traffic, MAC dynamics, etc.), while leaving the questions open of how to configure an emulator to accurately model real networks and how to quantify the emulator's overall fidelity to a target (§5).
- We discuss three new approaches to congestion control that are using the Pantheon as a shared evaluation testbed, giving us encouragement that it will prove useful as a community resource. Two are from research groups distinct from the present authors, and were published at USENIX NSDI 2018: Copa [2] and Vivace [13]. We also describe our own data-driven designs for congestion control, based on neural networks that can be trained on a collection of the Pantheon's emulators and in turn achieve good performance over real Internet paths (§6).

2 Related work

Pantheon benefits from a decades-long body of related work in Internet measurement, network emulation, transport protocols, and congestion-control schemes.

Tools for Internet measurement. Systems like PlanetLab [10], Emulab [40], and ORBIT [30] provide measurement nodes for researchers to test transport protocols and other end-to-end applications. PlanetLab, which was in wide use from 2004–2012, at its peak included hundreds of nodes, largely on well-provisioned (wired) academic networks around the world. Emulab allows researchers to run experiments over configurable network emulators and on Wi-Fi links within an office building.

While these systems are focused on allowing researchers to borrow nodes and run their own tests, the Pantheon operates at a higher level of abstraction. Pantheon includes a *single* community software package that researchers can contribute algorithms to. Anybody can run any of the algorithms in this package, including over Emulab or any network path, but Pantheon also hosts a common repository of test results (including raw packet traces) of scripted comparative tests.

Network emulation. Congestion-control research has long used network simulators, e.g., ns-2 [28], as well as real-time emulators such as Dummynet [6, 33], NetEm [20], Mininet [19], and Mahimahi [27].

These emulators provide increasing numbers of parameters and mechanisms to recreate different network behaviors, such as traffic shapers, policers, queue disciplines, stochastic i.i.d. or autocorrelated loss, reordering, bit errors, and MAC dynamics. However, properly setting these parameters to emulate a particular target network remains an open problem.

One line of work has focused on improving emulator precision in terms of the level of detail and fidelity at modeling small-scale effects (e.g., "Two aspects influence the accuracy of an emulator: how detailed is the model of the system, and how closely the hardware and software can reproduce the timing computed by the model" [6]). Pantheon takes a different approach, instead focusing on accuracy in terms of how well an emulator recreates the performance of a set of transport algorithms.

Congestion control. Internet congestion control has a deep literature. The original DECBit [32] and Tahoe [22] algorithms responded to one-bit feedback from the network, increasing and decreasing a congestion window in response to acknowledgments and losses. More recently, researchers have tried to formalize the protocol-design process by generating a congestion-control scheme as a function of an objective function and prior beliefs about the network and workload. Remy [37, 41] and PCC [12] are different kinds of "learned" schemes [35]. Remy uses an offline optimizer that generates a decision tree to optimize a global utility score based on network simulations. PCC uses an online optimizer that adapts its sending rate to maximize a local utility score in response to packet losses and RTT samples. In our current work (§ 6), we ask whether it is possible to quickly train an algorithm from first principles to produce good *global* performance on real Internet paths.

3 Design and implementation

This section describes the design and implementation of the Pantheon, a system that automatically measures the performance of many transport protocols and congestion-control schemes across a diverse set of network paths. By allowing the community to repeatably evaluate transport algorithms in scripted comparative tests across real-world network paths, posted to a public archive of results, the Pantheon aims to help researchers develop and test algorithms more rapidly and reproducibly.

Below, we demonstrate several uses for Pantheon: comparing existing congestion-control schemes on real-world networks (§4); calibrating network emulators that accurately reproduce real-world performance (§5); and designing and testing new congestion-control schemes (§6).

Figure 1: The Pantheon's transport schemes (§3.1.1) and the labels used for them in figures in this paper. Shown are the number of lines of Python, C++, or Javascript code in each wrapper that implements the common abstraction. Schemes marked † are modified to reduce MTU.

3.1 Design overview

Pantheon has three components: (1) a software repository containing pointers to transport-protocol implementations, each wrapped to expose a common testing interface based on the abstraction of a full-throttle flow; (2) testing infrastructure that runs transport protocols in scripted scenarios, instruments the network to log when each packet was sent and received, and allows flows to be initiated by nodes behind a network address translator (NAT); and (3) a global observatory of network nodes, enabling measurements across a wide variety of paths. We describe each in turn.

3.1.1 A collection of transport algorithms, each exposing the same interface

To test each transport protocol or congestion-control scheme on equal footing, Pantheon requires it to expose a common abstraction for testing: a full-throttle flow that runs until a sender process is killed. The simplicity of this interface has allowed us (and a few external contributors so far) to write simple wrappers for a variety of schemes and contribute them to the Pantheon, but limits the kinds of evaluations the system can do.[1]

Figure 1 lists the currently supported schemes, plus the size (in lines of code) of a wrapper script to expose the required abstraction. For all but three schemes, no modification was required to the existing implementation. The remaining three had a hard-coded MTU size and

[1] For example, the interface allows measurements of combinations of long-running flows (with timed events to start and stop a flow), but does not allow the caller to run a scheme until it has transferred exactly *x* bytes. This means that the Pantheon cannot reliably measure the flow-completion time of a mix of small file transfers.

required a small patch to adjust it for compatibility with our network instrumentation; please see §3.1.2 below.

As an example, we describe the Pantheon's wrapper to make WebRTC expose the interface of a full-throttle flow. The Pantheon tests the Chromium implementation of WebRTC media transfer [4] to retrieve and play a video file. The wrapper starts a Chromium process for the sender and receiver, inside a virtual X frame buffer, and provides a signaling server to mediate the initial connection. This comprises about 200 lines of JavaScript.

Pantheon is designed to be easily extended; researchers can add a new scheme by submitting a pull request that adds a submodule reference to their implementation and the necessary wrapper script. Pantheon uses a continuous-integration system to verify that each proposed scheme builds and runs in emulation.

3.1.2 Instrumenting network paths

For each IP datagram sent by the scheme, Pantheon's instrumentation tracks the size, time sent, and (if applicable) time received. Pantheon allows either side (sender or receiver) to initiate the connection, even if one of them is behind a NAT, and prevents schemes from communicating with nodes other than the sender and receiver. To achieve this, Pantheon creates a virtual private network (VPN) between the endpoints, called a *Pantheon-tunnel*, and runs all traffic over this VPN.

Pantheon-tunnel comprises software controlling a virtual network device (TUN) [39] at each endpoint. The software captures all IP datagrams sent to the local TUN, assigns each a unique identifier (UID), and logs the UID and a timestamp. It then encapsulates the packet and its UID in a UDP datagram, which it transmits to the other endpoint via the path under test. The receiving endpoint decapsulates, records the UID and arrival time, and delivers the packet to its own Pantheon-tunnel TUN device.

This arrangement has two main advantages. First, UIDs make it possible to unambiguously log information about every packet (e.g., even if packets are retransmitted or contain identical payloads). Second, either network endpoint can be the sender or receiver of an instrumented network flow over an established Pantheon-tunnel, even if it is behind a NAT (as long as one endpoint has a routable IP address to establish the tunnel).

Pantheon-tunnel also has disadvantages. First, encapsulation costs 36 bytes (for the UID and headers), reducing the MTU of the virtual interface compared to the path under test; for schemes that assume a fixed MTU, Pantheon patches the scheme accordingly. Second, because each endpoint records a timestamp to measure the send and receive time of each datagram, accurate timing requires the endpoints' clocks to be synchronized; endpoints use NTP [29] for this purpose. Finally, Pantheon-tunnel makes all traffic appear to the network as UDP, meaning it cannot measure the effect of a network's discrimination based on the IP protocol type.[2]

Evaluation of Pantheon-tunnel. To verify that Pantheon-tunnel does not substantially alter the performance of transport protocols, we ran a calibration experiment to measure the tunnel's effect on the performance of three TCP schemes (Cubic, Vegas, and BBR). We ran each scheme 50 times inside and outside the tunnel for 30 seconds each time, between a colocation facility in India and the EC2 India datacenter, measuring the mean throughput and 95th-percentile per-packet one-way delay of each run.[3] We ran a two-sample Kolmogorov-Smirnov test for each pair of statistics (the 50 runs inside vs. outside the tunnel for each scheme's throughput and delay). No test found a statistically significant difference below $p < 0.2$.

3.1.3 A testbed of nodes on interesting networks

We deployed observation nodes in countries around the world, including cellular (LTE/UMTS) networks in Stanford (USA), Guadalajara (Mexico), São Paulo (Brazil), Bogotá (Colombia), New Delhi (India), and Beijing (China), wired networks in all of the above locations as well as London (U.K.), Iowa (U.S.), Tokyo (Japan), and Sydney (Australia), and a Wi-Fi mesh network in Nepal. These nodes were provided by a commercial colocation facility (Mexico, Brazil, Colombia, India), by volunteers (China and Nepal), or by Google Compute Engine (U.K., U.S., Tokyo, Sydney).

We found that hiring a commercial colocation operator to maintain LTE service in far-flung locations has been an economical and practical approach; the company maintains, debugs, and "tops up" local cellular service in each location in a way that would otherwise be impractical for a university research group. However, this approach limits us to available colocation sites and ones where we receive volunteered nodes. We are currently bringing up a volunteered node with cellular connectivity in Saudi Arabia and welcome further contributions.

3.2 Operation and testing methods

The Pantheon frequently benchmarks its stable of congestion-control schemes over each path to create an archive of real-world network observations. On each path, Pantheon runs multiple benchmarks per week. Each benchmark follows a software-defined scripted workload (e.g., a single flow for 30 seconds; or multiple flows of

[2] Large-scale measurements by Google [24] have found such discrimination, after deployment of the QUIC UDP protocol, to be rare.

[3] For BBR running outside the tunnel, we were only able to measure the average throughput (not delay). Run natively, BBR's performance relies on TCP segmentation offloading [9], which prevents a precise measurement of per-packet delay without the tunnel's encapsulation.

cross traffic, arriving and departing at staggered times), and for each benchmark, Pantheon chooses a random ordering of congestion-control schemes, then tests each scheme in round-robin fashion, repeating until every scheme has been tested 10 times (or 3 for partly-cellular paths). This approach mirrors the evaluation methods of prior academic work ([12, 42, 43]).

During an experiment, both sides of a path repeatedly measure their clock offset to a common NTP server and use these to calculate a corrected one-way delay of each packet. After running an experiment, a node calculates summary statistics (e.g., mean throughput, loss rate, and 95th-percentile one-way delay for each scheme) and uploads its logs (packet traces, analyses, and plots) to AWS S3 and the Pantheon website (https://pantheon.stanford.edu).

4 Findings

The Pantheon has collected and published measurements of a dozen protocols taken over the course of more than a year. In this section, we give a high-level overview of some key findings in this data, focusing on the implications for research and experimental methodology. We examine comparative performance between protocols rather than the detailed behavior of particular protocols, because comparative analyses provide insight into which protocol end hosts should run in a particular setting.

To ground our findings in examples from concrete data, we select one particular path: AWS Brazil to Colombia. This path represents the performance a device in Colombia would see downloading data from properly geo-replicated applications running in AWS (Brazil is the closest site).

Finding 1: Which protocol performs best varies by path. Figure 2a shows the throughput and delay of 12 transport protocols from AWS Brazil to a server in Colombia, with an LTE modem from a local carrier (Claro).[4] Figure 2b shows the throughput and delay for the same protocols from a node at Stanford University with a T-Mobile LTE modem, to a node in AWS California. The observed performance varies significantly. In Brazil-Colombia, PCC is within 80% of the best observed throughput (QUIC) but with delay 20 times higher than the lowest (SCReAM). In contrast, for Stanford-California, PCC has only 52% of the best observed throughput (Cubic) and the lowest delay. The Sprout scheme, developed by one of the present authors, was designed for cellular networks in the U.S. and performs well in that setting (Figure 2b), but poorly on other paths.

These differences are not only due to long haul paths or geographic distance. Figure 2c shows the performance of the transport protocols from AWS Brazil to a wired device in Colombia. Performance is completely different. Delays, rather than varying by orders of magnitude, differ by at most 32%. At the same time, some protocols are strictly better: QUIC (Cubic) and (TCP) Cubic have both higher throughput and lower delay than BBR and Verus.

Differences are not limited to paths with cellular links. Figure 2e shows performance between Stanford and AWS California using high-bandwidth wired links and Figure 2f shows performance between the Google Tokyo and Sydney datacenters. While in both cases PCC shows high throughput and delay, in the AWS case BBR is better in throughput while between Google data centers it provides 34% less throughput. Furthermore, LEDBAT performs reasonably well on AWS, but has extremely low throughput between Google datacenters.

This suggests that evaluating performance on a small selection (or, in the worst case, just one) of paths can lead to misleadingly positive results, because they are not generalizable to a wide range of paths.

Finding 2: Which protocol performs best varies by path direction. Figure 2d shows the performance of the opposite direction of the path, from the same device with cellular connection in Colombia to AWS Brazil. This configuration captures the observed performance of uploading a photo or streaming video through a relay.

In the Brazil to Colombia direction, QUIC strictly dominates Vegas, providing both higher throughput and lower delay. In the opposite direction, however, the tradeoff is less clear: Vegas provides slightly lower throughput with a significant (factor of 9) decrease in delay. Similarly, in the Brazil to Colombia direction, WebRTC provides about half the throughput of LEDBAT while also halving delay; in the Colombia to Brazil direction, WebRTC is strictly worse, providing one third the throughput while quadrupling delay.

This indicates that evaluations of network transport protocols need to explicitly measure both directions of a path. On the plus side, a single path can provide two different sets of conditions when considering whether results generalize.

Finding 3: Protocol performance varies in time and only slightly based on competing flows. Figure 2g shows the Brazil-Colombia path measured twice, separated by two days (the first measurement shown in open dots is the same as in Figure 2a). Most protocols see a strict degradation of performance in the second measurement, exhibiting lower throughput and higher delay. Cubic and PCC, once clearly distinguishable, merge to have equivalent performance. More interestingly, the performance of Vegas has 23% lower throughput, but cuts delay by more than a factor of 2.

[4] All results in this paper and supporting raw data can be found in the Pantheon archive; e.g. the experiment indicated as P123 can be found at https://pantheon.stanford.edu/result/123/.

(f) GCE Tokyo to GCE Sydney (wired), 3 flows, 10 trials. P1442.

(g) AWS Brazil to Colombia (cellular), 1 flow, 3 trials. 2 days after Figure 2a (shown in open dots). P1473.

(h) AWS Brazil to Colombia (cellular), 3 flows, 3 trials. P1405.

Figure 2: Compared with Figure 2a, scheme performance varies across the type of network path (Figure 2c), number of flows (Figure 2h), time (Figure 2g), data flow direction (Figure 2d), and location (Figure 2b). Figure 2e and 2f show that the variation is not limited to just cellular paths. The shaded ellipse around a scheme's dot represents the 1-σ variation across runs. Given a measurement ID, e.g. P123, the full result can be found at https://pantheon.stanford.edu/result/123/.

Finally, Figure 2h shows performance on the Brazil-Colombia path when 3 flows compete. Unlike in Figure 2a, PCC and Cubic dominate Vegas, and many protocols see similar throughput but at greatly increased latency (perhaps due to larger queue occupancy along the path).

This indicates that evaluations of network transport protocols need to not only measure a variety of paths, but also spread those measurements out in time. Furthermore, if one protocol is measured again, all of them need to be measured again for a fair comparison, as conditions may have changed. Cross traffic (competing flows) is an important consideration, but empirically has only a modest effect on relative performance. We do find that schemes that diverge significantly from traditional congestion control (e.g., PCC) exhibit poor fairness in some settings; in a set of experiments between Tokyo and Sydney (P1442), we observed the throughput ratios of three PCC flows to be 32:4:1. This seems to contradict fairness findings in the PCC paper and emphasizes the need for a shared evaluation platform across diverse paths.

5 Calibrated emulators

The results in Section 4 show that transport performance varies significantly over many characteristics, including time. This produces a challenge for protocol development and the ability of researchers to reproduce each others' results. One time-honored way to achieve controlled, reproducible results, at the cost of some realism, is to measure protocols in simulation or emulation [14] instead of the wild Internet, using tools like Dummynet [6, 33], NetEm [20], Mininet [19], or Mahimahi [27].

These tools each provide a number of parameters and mechanisms to recreate different network behaviors, and there is a traditional view in computer networking that the more fine-grained and detailed an emulator, the better. The choice of parameter values to faithfully emulate a particular target network remains an open problem.

In this paper, we propose a new figure of merit for network emulators: the degree to which an emulator can be substituted for the real network path in a full system, including the endpoint algorithm, without altering the system's overall performance. In particular, we define the emulator's accuracy as the average difference of the throughput and of the delay of a set of transport algorithms run over the emulator, compared with the same statistics from the real network path that is the emulator's target. The broader and more diverse the set of transport algorithms, the better characterized the emulator's accuracy will be: each new algorithm serves as a novel probe that could put the network into an edge case or unusual state that exercises the emulator and finds a mismatch.

In contrast to some conventional wisdom, we do not think that more-detailed network models are necessarily preferable. Our view is that this is an empirical question, and that more highly-parameterized network models create a risk of overfitting—but may be justified if lower-parameter models cannot achieve sufficient accuracy.

5.1 Emulator characteristics

We found that a five-parameter network model is sufficient to produce emulators that approximate a diverse variety of real paths, matching the throughput and delay of a range of algorithms to within 17% on average. The resulting calibrated emulators allow researchers to test experimental new schemes—thousands of parallel variants if necessary—in emulated environments that stand a good chance of predicting future real-world behavior.[5]

The five parameters are:

1. a bottleneck link rate,
2. a constant propagation delay,
3. a DropTail threshold for the sender's queue,
4. a stochastic loss rate (per-packet, i.i.d.), and
5. a bit that selects whether the link runs isochronously (all interarrival times equal), or with packet deliveries governed by a memoryless Poisson point process, characteristic of the observed behavior of some LTE networks [42].

To build emulators using these parameters, the Pantheon uses Mahimahi container-based network emulators [27]. In brief: Mahimahi gives the sender and receiver each its own isolated Linux network namespace, or container, on one host. An emulator is defined by a chain of nested elements, each one modeling a specific network effect: e.g., an `mm-loss` container randomly drops packets in the outgoing or incoming direction at a specified rate.

5.2 Automatically calibrating emulators to match a network path

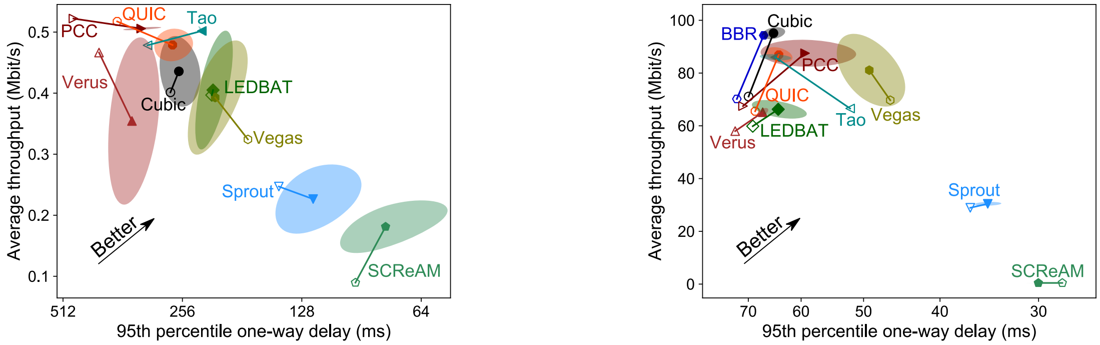
Given a set of results over a particular network path, Pantheon can generate an emulator that replicates the same results in about two hours, using an automated parameter-search process that we now describe.

To find an appropriate combination of emulator parameters, Pantheon searches the space using a non-linear optimization process that aims to find the optimal value for a vector x, which represents the <*rate*, *propagation delay*, *queue size*, *loss rate*> for the emulator.[6]

The optimization derives a replication error for each set of emulator parameters, $f(x)$, which is defined as the

[5] In a leave-one-out cross-validation experiment, we confirmed that emulators trained to match the performance of $n-1$ transport algorithms accurately predicted the unseen scheme's performance within about 20% (results not shown).

[6] The optimization is run twice, to choose between a constant rate or a Poisson delivery process.



(a) Nepal to AWS India (wireless), 1 flow, 10 trials. Mean replication error: 19.1%. P188.

(b) AWS California to Mexico (wired), 3 flows, 10 trials. Mean replication error: 14.4%. P1237.

Figure 3: Examples of per-scheme calibrated emulator errors. The filled dots represent real results over each network path; the open dots represent the corresponding result over the emulator that best replicates all of the results. Emulators for all-wired paths give better fidelity than emulators for partly-wireless paths (§5.3).

Path	Error (%)
Nepal to AWS India (Wi-Fi, 1 flow, P188)	19.1
AWS Brazil to Colombia (cellular, 1 flow, P339)	13.0
Mexico to AWS California (cellular, 1 flow, P196)	25.1
AWS Korea to China (wired, 1 flow, P361)	17.7
India to AWS India (wired, 1 flow, P251)	15.6
AWS California to Mexico (wired, 1 flow, P353)	12.7
AWS California to Mexico (wired, 3 flows, P1237)	14.4

Figure 4: Replication error of calibrated emulators on six paths with a single flow, and one path with three flows of staggered cross traffic.

Path	Feature change	Error (%)
China wired	link rate only	211.8
	add delay	211.8 → 189.7
	add buffer size	189.7 → 32.3
	add stochastic loss	32.3 → 17.7
Colombia cellular	constant → Poisson	23.7 → 13.0

Figure 5: Each of the emulator's five parameters is helpful in reducing replication error. For the China wired path, we started with a single parameter and added the other three features one by one, in the order of their contribution. The Colombia cellular path required jitter (Poisson deliveries) to achieve good accuracy.

average of the percentage changes between the real and emulated mean throughput, and the real and emulated mean 95th-percentile delay, across each of the set of reference transport algorithms. To minimize $f(x)$, nonlinear optimization is necessary because neither the mathematical expression nor the derivative of $f(x)$ is known. In addition, for both emulated and real world network paths, $f(x)$ is non-deterministic and noisy.

The Pantheon uses Bayesian optimization [25], a standard method designed for optimizing the output of a noisy function when observations are expensive to obtain and derivatives are not available.[7] The method starts with the assumption that the objective function, $f(x)$, is drawn from a broad prior (Gaussian is a standard choice and the one we use). Each sample (i.e., calculation of the emulator replication error for a given set of emulator parameters x) updates the posterior distribution for $f(x)$. Bayesian optimization uses an *acquisition function* to guide the algorithm's search of the input space to the next value x. We use the Spearmint [38] Bayesian-optimization toolkit, which uses "expected improvement" as its acquisition function. This function aims to maximize the expected improvement over the current best value [25].

5.3 Emulation results

We trained emulators that model six of Pantheon's paths, each for about 2 hours on 30 EC2 machines with 4 vCPUs each. Figure 3 shows per-scheme calibration results for two representative network paths, a wireless device in Nepal and a wired device in Mexico. Filled dots represent the measured *mean* performance of the scheme on the real network path, while the open dot represents the performance on the corresponding calibrated emulator. A closer dot means the emulator is better at replicating that scheme's performance.

We observe that the emulators roughly preserve the relative order of the mean performance of the schemes on each path. Figure 4 shows mean error in replicating the

[7] Each evaluation of $f(x)$ involves running all of Pantheon's congestion-control schemes in a scripted 30-second scenario, three times, across the emulated path. This is done in parallel, so each evaluation of $f(x)$ takes about 30 seconds of wall-clock time.

throughput and delay performance of all of Pantheon's congestion-control schemes by a series of emulators. To ensure each parameter is necessary, we measured the benefits of adding delay, queue size, and loss information to a base emulator that uses a constant rate, in replicating the China wired device path. For the cellular device path we measured the benefit of using a Poisson based link rate rather than a constant rate. As shown in Figure 5, each added parameter improves the emulator's fidelity.

Pantheon includes several calibrated emulators, and regularly runs the transport algorithms in single- and multi-flow scenarios over each of the emulators and publishes the results in its public archive. Researchers are also able to run the calibrated emulators locally.

In addition, Pantheon includes, and regularly evaluates schemes over, a set of "pathological" emulators suggested by colleagues at Google. These model extreme network behaviors seen in the deployment of the BBR scheme: very small buffer sizes, severe ACK aggregation, and token-bucket policers.

Overall, our intention is that Pantheon will contain a sufficient library of well-understood network emulators so that researchers can make appreciable progress evaluating schemes (perhaps thousands of variants at once) in emulation—with some hope that there will be fewer surprises when a scheme is evaluated over the real Internet.

6 Pantheon use cases

We envision Pantheon as a common evaluation platform and an aid to the development of new transport protocols and congestion-control schemes. In this section, we describe three different ways that Pantheon has been helpful. Two are based on experiences that other research groups have had using Pantheon to assist their efforts. The third is an example of a radical, data-driven congestion-control design based on neural networks learned directly from Pantheon's network emulators.

Case 1. Vivace: validating a new scheme in the real world. Dong et al. [13] describe a new congestion-control scheme called Vivace, the successor to PCC [12]. They contributed three variants of the scheme to Pantheon in order to evaluate and tune Vivace's performance, by examining Pantheon's packet traces and analyses of Vivace in comparison with other schemes across an array of real-world paths. This is consistent with Pantheon's goal of being a resource for the research community (§1).

Case 2. Copa: iterative design with measurements. Arun and Balakrishnan [2] describe another new scheme, Copa, which optimizes an objective function via congestion window and sending rate adjustments. In contrast to Vivace, which was deployed on Pantheon largely as a completed design, Copa used Pantheon as an integral part of the design process: the authors deployed a series of six prototypes, using Pantheon's measurements to inform each iteration. This demonstrates another use of Pantheon, automatically deploying and testing prototypes on the real Internet, and gathering *in vivo* performance data.

Case 3. Indigo: extracting an algorithm from data. As an extreme example of data-driven design, we present Indigo, a machine-learned congestion-control scheme whose design we extract from data gathered by Pantheon.

Using machine learning to train a congestion-control scheme for the real world is challenging. The main reason is that it is impractical to learn directly from the Internet: machine-learning algorithms often require thousands of iterations and hours to weeks of training time, meaning that paths evolve in time (§4) more quickly than the learning algorithm can converge. Pantheon's calibrated emulators (§5) provide an alternative: they are reproducible, can be instantiated many times in parallel, and are designed to replicate the behavior of congestion-control schemes. Thus, our high-level strategy is to train Indigo using emulators, then evaluate it in the real world using Pantheon.

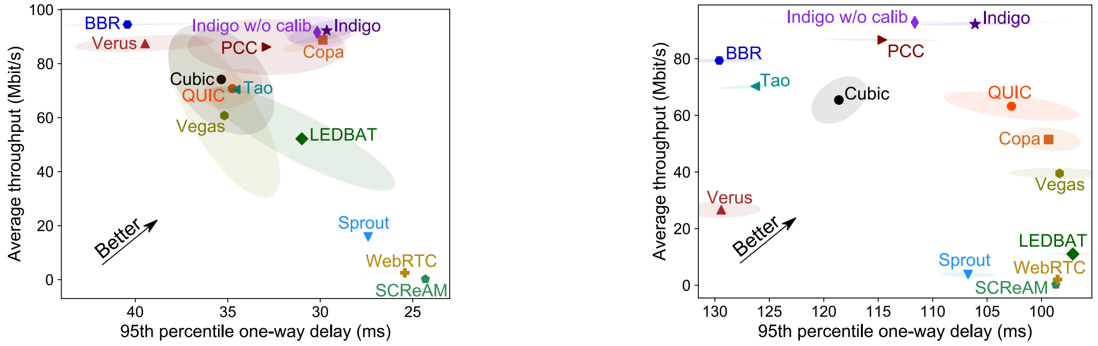
Indigo is one example of what we believe to be a novel family of data-driven algorithms enabled by Pantheon. Specifically, Pantheon facilitates realistic offline training and testing by providing a communal benchmark, evolving dataset, and calibrated emulators to allow approximately realistic offline training and testing. Below, we briefly describe Indigo's design; we leave a more detailed description to future work.

Overview of Indigo

At its core, Indigo does two things: it observes the network state, and it adjusts its *congestion window*, i.e., the allowable number of in-flight packets. Observations occur each time an ACK is received, and their effect is to update Indigo's internal *state*, defined below. Indigo adjusts its congestion window every 10 ms. The state vector is:

1. An exponentially-weighted moving average (EWMA) of the queuing delay, measured as the difference between the current RTT and the minimum RTT observed during the current connection.
2. An EWMA of the sending rate, defined as the number of bytes sent since the last ACK'ed packet was sent, divided by the RTT.
3. An EWMA of the receiving rate, defined as the number of bytes received since the ACK preceding the transmission of the most recently ACK'ed packet, divided by the corresponding duration (similar to and inspired by TCP BBR's delivery rate [7]).
4. The current congestion window size.
5. The previous action taken.

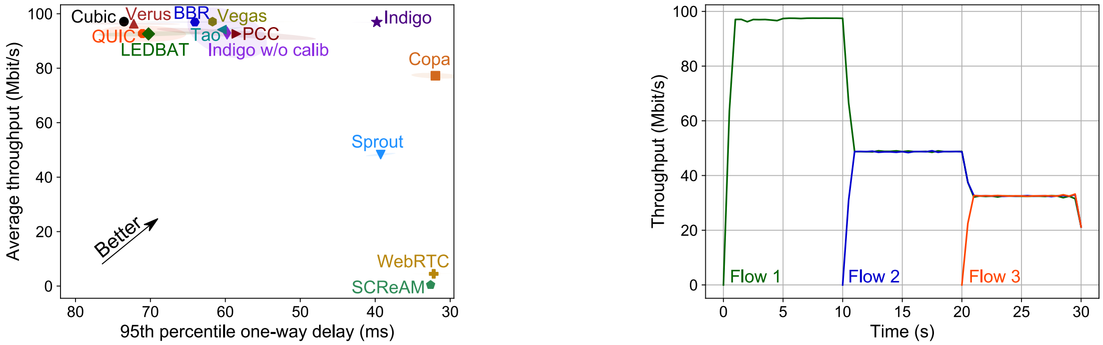
Indigo stores the mapping from states to actions in a Long Short-Term Memory (LSTM) recurrent neural



(a) Mexico to AWS California, 10 trials. P1272.

(b) AWS Brazil to Colombia, 10 trials. P1439.

Figure 6: Real wired paths, single flow. Indigo's performance is at the throughput/delay tradeoff frontier. Indigo without calibrated emulators ("Indigo w/o calib") gives worse performance.



(a) India to AWS India, 10 trials. P1476.

(b) Time-domain three-flow test. One trial in Figure 7a.

Figure 7: Real wired paths, multiple flows. Figure 7a shows the performance of all congestion-control schemes on multi-flow case. Figure 7b shows throughput vs. time for a three-flow run in Figure 7a starting 10 seconds apart. Indigo shares the bandwidth fairly.

network [21] with 1 layer of 32 hidden units (values chosen after extensive evaluation on the Pantheon). Indigo requires a *training phase* (described below) in which, roughly speaking, it learns a mapping from states to actions. Once trained and deployed, this mapping is fixed.

We note that there may be better parameter choices: number of hidden units, action space, state contents, etc. We have found that the above choices already achieve good performance; further improvements are future work. As one step toward validating our choices, we trained and tested several versions of Indigo with a range of hidden units, from 1 to 256, on an emulated network; choices between 16 and 128 yielded good performance.

Indigo's training phase. Indigo uses imitation learning [3, 34] to train its neural network. At a high level, this happens in two steps: first, we generate one or more *congestion-control oracles*, idealized algorithms that perfectly map states to correct actions, corresponding to links on which Indigo is to be trained. Then we apply a standard imitation learning algorithm that use these oracles to generate training data.

Of course, no oracle exists for real-world paths. Instead, we generate oracles corresponding to *emulated* paths; this is possible because Pantheon's emulators (§5) have few parameters. By the definition of an oracle, if we know the ideal congestion window for a given link, we have the oracle for the link: for any state, output whichever action results in a congestion window closest to the ideal value.

A key insight is that for emulated links, we can very closely approximate the ideal congestion window. For simple links with a fixed bandwidth and minimum one-way delay, the ideal window is given by the link's bandwidth-delay product (BDP) per flow. For calibrated emulators (which have DropTail queues, losses, etc.), we compute the BDP and then search near this value in emulation to find the best fixed congestion window size.

After generating congestion-control oracles corresponding to each training link, we use a state-of-the-art imitation learning algorithm called DAgger [34] to train the neural network. For each training link, DAgger trains Indigo's neural network as follows: first, it allows the neural network to make a sequence of congestion-control decisions on the training link's emulator, recording the state vector that led to each decision. Next, it uses the congestion-control oracle to label the correct action corresponding to each recorded state vector. Finally, it updates the neural network by using the resulting state-action mapping as training data. This process is repeated until further training does not change the neural network.

Indigo's performance. In this section, we compare Indigo's performance with that of other congestion-control schemes, and we evaluate the effect of Pantheon's calibrated emulators on performance, versus only training on fixed-bandwidth, fixed-delay emulators.

We trained Indigo on 24 synthetic emulators uncorrelated to Pantheon's real network paths, and on the calibrated emulators (§5). The synthetic emulators comprise all combinations of (5, 10, 20, 50, 100, and 200 Mbps) link rate and (10, 20, 40, 80 ms) minimum one-way delay, with infinite buffers and no loss.

Indigo on Pantheon. We find that Indigo consistently achieves good performance. Figure 6 compares Indigo to other schemes in single flow on two wired paths. In both cases, Indigo is at the throughput/delay tradeoff frontier.

Figure 7 shows Indigo's performance in the multi-flow case. Figure 7a shows the performance of all of Pantheon's congestion-control schemes on a wired path from India to AWS India; Indigo is once again on the throughput/delay tradeoff frontier. Figure 7b is a time-domain plot of one trial from Figure 7a, suggesting that Indigo shares fairly, at least in some cases.

Benefit of calibrated emulators. Figures 6 and 7 also depict a variant of Indigo, "Indigo w/o calib," that is only trained on the synthetic emulators, but not the calibrated emulators. The version trained on calibrated emulators is always as least as good or better.

7 Discussion, limitations, and future work

Improving Pantheon. Pantheon would be more useful if it collected more data about congestion-control schemes. For instance, Pantheon currently gathers data only from a handful of nodes—vastly smaller than the evaluations large-scale operators can perform on even a small fraction of a billion-user population.

Moreover, geographic locality does not guarantee network path similarity: two nodes in the same city can have dramatically different network connections. Pantheon also only tests congestion-control schemes at full throttle; other traffic patterns (e.g., Web-like workloads) may provide researchers with valuable information (e.g., how their scheme affects page-load times).

Finally, Pantheon currently measures the interaction between multiple flows of cross-traffic governed by the same scheme, but we are working to make it measure interactions between different schemes. These measurements will help evaluate fairness in the real world.

Improving the calibrated emulators. Our current emulators replicate throughput and delay metrics only within 17% accuracy on average. An open question is whether we can improve emulator fidelity—especially on cellular paths—without risk of overfitting. Considering metrics other than 95th-percentile delay and mean throughput may be one path forward. Adding more schemes to Pantheon could also help—or it might reveal that the current set of emulator parameters, which we have empirically determined, is insufficient for some schemes.

Indigo. We have presented a case study on Indigo, a data-driven approach to congestion-control design that crucially relies on Pantheon's family of emulators. Indigo's trained model is complex and may have unknown failure modes, but the results to date demonstrate how Pantheon can enable new approaches to protocol design.

8 Conclusion

The Pantheon is a collection of transport protocols and a distributed system of measurement points and network emulators for evaluating and developing them. By measuring many transport protocols and congestion-control algorithms across a diverse set of paths, Pantheon provides a training ground for studying and improving their performance. Furthermore, by generating calibrated emulators that match real-world paths, Pantheon enables researchers to measure protocols reproducibly and accurately.

Pantheon has assisted in the development of two recently-published congestion-control algorithms [2, 13], and has supported our own data-driven approach to protocol design. In other areas of computer science, community benchmarks and recurrent bakeoffs have fueled advances and motivated researchers to build on each others' work: ImageNet in computer vision, the TPC family and Sort Benchmarks for data processing, Kaggle competitions in machine learning, etc. We are hopeful that Pantheon will, over time, serve a similar role in computer networking.

Acknowledgments

We thank the USENIX ATC reviewers for their helpful comments and suggestions. We are grateful to Yuchung Cheng, Janardhan Iyengar, Michael Schapira, and Hari Balakrishnan for feedback throughout this project. ClickNF: a Modular Stack for Custom Network Functions

Massimo Gallo and Rafael Laufer
Nokia Bell Labs

Abstract

Network function virtualization has recently allowed specialized equipment to be replaced with equivalent software implementation. The Click router was a first step in this direction, defining a modular platform for generalized packet processing. Despite its major impact, however, Click does not provides native L4 implementation and only uses nonblocking I/O, limiting its scope to L2-L3 network functions. To overcome these limitations we introduce ClickNF, which provides modular transport and application-layer building blocks for the development of middleboxes and server-side network functions. We evaluate ClickNF to highlight its state-of-the-art performance and showcase its modularity by composing complex functions from simple elements. ClickNF is open source and publicly available.

1 Introduction

Software-defined networking had a significant impact on the packet forwarding infrastructure, providing flexibility and controllability to network and datacenter operators [37]. In a similar trend, network function virtualization (NFV) is sparking novel approaches for deploying flexible network functions [19], ranging from virtual machine orchestration [24, 36, 34] to new packet processing frameworks [8, 40]. Network functions can combine packet forwarding and simple header rewriting with awareness of stateful transport logic, and possibly execute complex application-layer operations.

A modular L2–L7 data plane would offer several advantages for the development of new network functions, such as decoupling state and packet processing, extensibility of fine-grained protocol behavior, module reuse, and a simplification of cross-layer protocol optimizations and debugging. Among existing approaches, Click [29] is arguably the best starting point for such an architecture due to its modularity and extensibility. However, several functionalities are still missing to make Click into a full-stack modular data plane for network functions. First, it lacks L4 native implementation, preventing cross-layer optimizations and stack customization. Second, it has no support for blocking I/O primitives, forcing developers to use more complex asynchronous non-blocking I/O. Third, Click applications must resort to the OS stack, which leads to severe I/O bottlenecks. Finally, despite recent improvements, Click does not support hardware offloading and efficient timer management preventing it to scale at high-speed in particular scenarios.

In this paper we introduce ClickNF, a framework that overcomes the aforementioned limitations and enables L2–L7 modular network function development in Click. Along with legacy Click elements, ClickNF enables developers to overhaul the entire network stack, if desired. First, it introduces a modular TCP implementation that supports options, congestion control, and RTT estimation. Second, it introduces blocking I/O support, providing applications with the illusion of running uninterrupted. Third, it exposes standard socket, zero-copy, and socket multiplexing APIs as well as basic application layer building blocks. Finally, to improve scalability, ClickNF integrates I/O acceleration techniques first introduced in Fastclick [9], such as Data Plane Development Kit (DPDK) [33] and batch processing with additional support for hardware acceleration, as well as an improved timer management system for Click.

ClickNF can be used to deploy a vast class of network functions. For middleboxes, TCP termination is needed for Split TCP, L7 firewalls, TLS/SSL proxies, HTTP caches, etc. At the network edge, ClickNF can be used to implement high-speed modular L7 servers using socket multiplexing primitives to handle I/O events efficiently. As proof of concept, we compose an HTTP cache server with optional SSL/TLS termination and a SOCKS4 proxy. We show that ClickNF provides equivalent performance and scalability as existing user-space stacks while enabling L2–L7 modularity.

The paper is organized as follows. Section 2 describes ClickNF design. Section 3 details our TCP implementation in Click and Section 4 presents application layer modularity. Section 5 highlights a number of original aspects about the ClickNF implementation that are evaluated in Section 6. Section 7 reviews the related work and Section 8 concludes the paper.

2 ClickNF

ClickNF leverages Click [29], a software architecture for building modular and extensible routers. Before introducing its design, we first provide an overview of Click.

2.1 Background

A router in Click is built from a set of fine-grained packet processing modules, *elements*, implementing simple functions (e.g., IP routing). A *configuration* file connects these elements together into a directed graph, whose edges specify the path that packets shall traverse. Depending on the configuration, users can implement network functions of arbitrary complexity (e.g., switch).

Each element may define any number of input and output *ports* to connect to other elements. Ports operate in either *push* or *pull* mode. On a push connection, the packet starts at the source element and moves to the destination element downstream. On a pull connection, in contrast, the destination element requests a packet from the upstream one, which returns a packet if available or a null pointer otherwise. In addition to push or pull, a port may also be *agnostic* and behave as either push or pull depending on the port it is connected to.

In its underlying implementation, Click employs a task queue and a timer priority queue. An infinite loop runs tasks in sequence and timers at expiration. Tasks are element-defined functions that require CPU scheduling, and initiate a sequence of push or pull requests. Most elements, however, do not require their own task, since their `push` and `pull` methods are called by a scheduled task. Timer callback functions are similar to tasks, except for being scheduled at a particular time.

2.2 Design

Network protocol stacks are typically implemented as monolithic packages, either in kernel or user-space. Network function developers often experience hurdles when attempting to debug and customize their software to obtain the desired effects, as the inner workings of the stacks are not exposed. Indeed, recent work [22, 17, 39, 38] advocates that legacy network stacks prevent innovation due to the lack of flexibility and propose to move some of their functionalities outside of the data path.

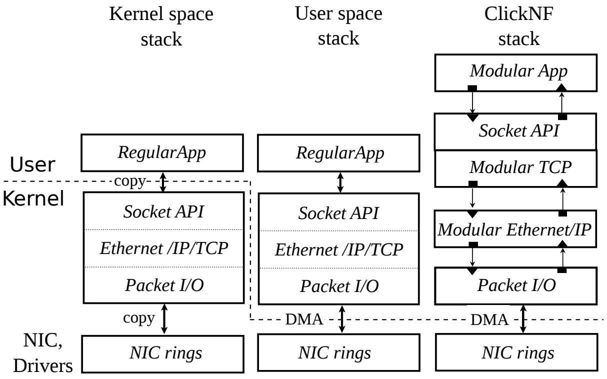

Figure 1: ClickNF design compared to alternatives.

Modular, configurable, and extensible transport protocols were proposed in the past by the research community [16, 13] and by the Linux kernel one [1] constituting a first step in the right direction. Our goal, is along the same lines but broader. ClickNF aims to give developers unfettered access to the entire stack by providing a framework for the construction of modular L2-L7 network functions without the concerns for the correctness of its behavior nor the constraints added by event-driven domain-specific APIs [26].

The design of ClickNF combines the modularity and flexibility of Click with high-speed packet I/O and ready-made protocol building blocks for transport and application-layer features. Figure 1 compares ClickNF design against legacy OSs and user space stacks. In contrast with other approaches that conceal network stack complexity into a monolithic package or does not introduce modularity at all layers, we decompose the full L2–L7 stack into several simple elements that can be individually replaced, modified or removed by rewiring the configuration file, providing a level of flexibility that is not available with alternative solutions. Additionally, elements can be aggregated into a single macro-element to hide complexity when desired. The rationale behind this fine-grained decomposition is twofold. First, simple elements allow the modification and control of each aspect and mechanism of network protocols. This enables module reuse in other contexts, such as recycling existing congestion control strategies to implement new protocols like QUIC [30], or new strategies such as BBR [14] or DCTCP [6] with little effort. Second, this approach helps decoupling protocol state management and packet processing, simplifying complicated tasks such as full state migration between servers or across heterogeneous hardware (e.g., between CPUs and smart NICs).

In the rest of the paper we focus on the description and evaluation of ClickNF transport and application layers, and on some important implementation details that allows ClickNF to sustain line-rate.

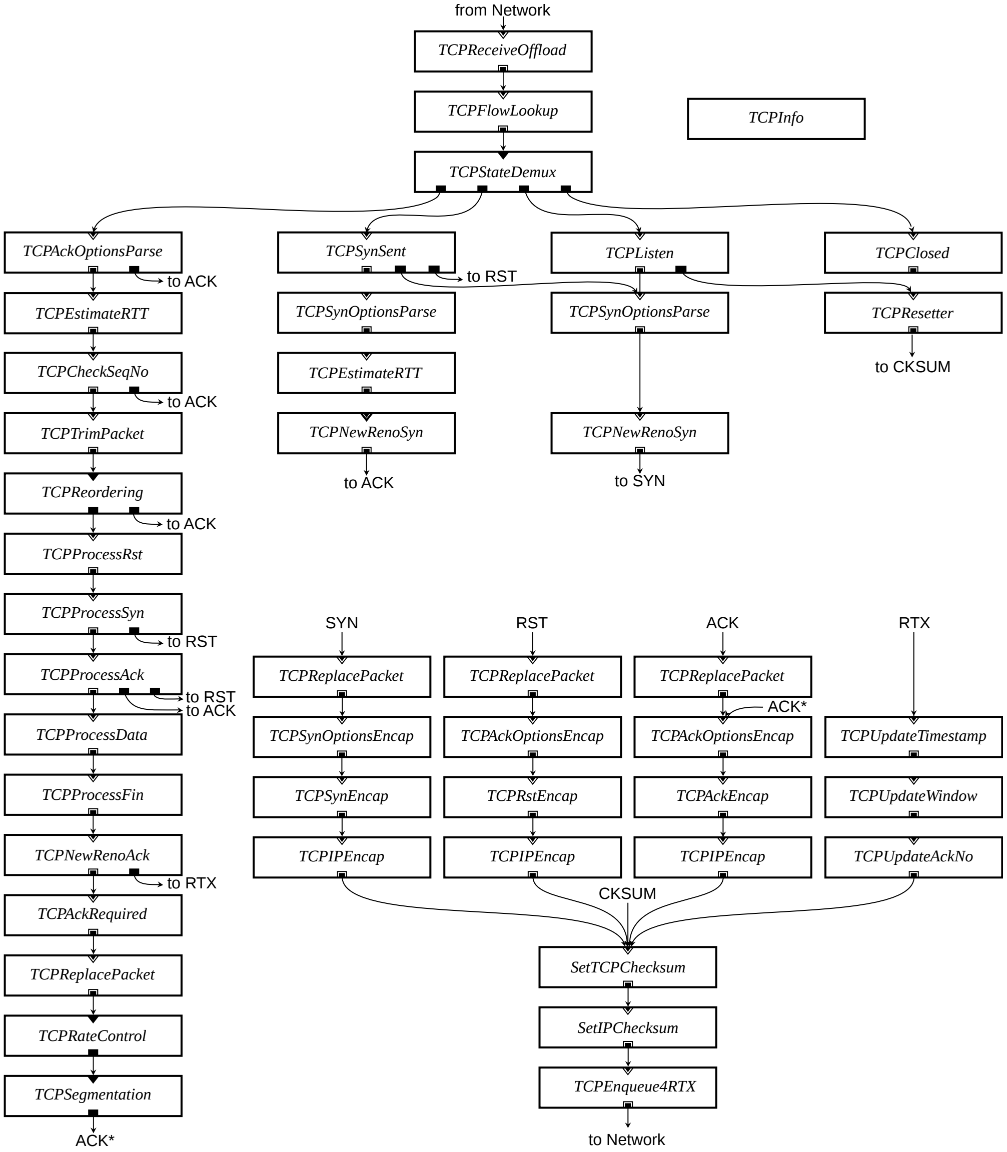

Figure 2: cTCP configuration for incoming network packets.

3 Click TCP

Our modular Click TCP (cTCP) implementation is compliant with IETF standards (RFCs 793 and 1122) and supports TCP options (RFC 7323), New Reno congestion control (RFCs 5681 and 6582), timer management, and RTT estimation (RFC 6298). In this section we describe the cTCP element graphs used to process incoming and outgoing TCP packets.

3.1 Incoming packets

The key element of cTCP is *TCPInfo*, which enables state decoupling by providing other elements with access to important data structures (*i.e.,* TCP Control Block). Figure 2 shows the cTCP element graph for processing incoming packets. In essence, elements access and/or modify the TCP control block (TCB) via the *TCPInfo*, as the packet moves along the edges of the graph. The vertical paths are the directions that most received packets take. The long element sequence on the left represents the packet processing of an established TCP connection. The three other paths to the right take care of special situations, such as connection establishment and termination. Other paths in the graph represent a disruption in the expected packet flow, e.g., *TCPCheckSeqNo* sends an ACK back if the data is outside the receive window.

Most elements in cTCP only require the TCB to process packets. For instance, *TCPTrimPacket* trims off any out-of-window data from the packet. *TCPReordering* enforces in-order delivery by buffering out-of-order packets and releasing them in sequence once the gap is filled.

Elements like *TCPProcess*{*Rst, Syn, Ack, Fin*} inspect the respective TCP flags and react accordingly. In presence of new data, *TCPProcessData* clones the packet (*i.e.,* only packet's metadata are copied) and places it on the RX queue for the application. After receiving three duplicate ACKs, *TCPNewRenoAck* retransmits the first unacknowledged packet. Related elements, such as *TCPNewRenoSyn* and *TCPNewRenoRTX*, handle initialization and retransmissions in congestion control.

In addition to the TCB, other cTCP elements require information previously computed by other elements. This is supported in Click via *packet annotations*, *i.e.,* packet metadata. cTCP packet annotations include:

TCB pointer: The TCB table is stored as a per-core hash table in *TCPInfo* and accessed by other elements using static functions. For each packet, *TCPFlowLookup* looks the TCP flow up in the table and sets the TCB annotation to allow other elements to easily access/modify the TCB avoiding multiple flow table lookups.

RTT measurement: *TCPAckOptionsParse* computes the RTT from the TCP timestamp, Karn's algorithm, and sets it as an annotation. If TCP timestamps are not provided by NICs or by packet I/O elements, *TCPEnqueue4RTX* timestamps each transmitted packet before storing it in the retransmission (RTX) queue. In both cases, *TCPEstimateRTT* uses these annotations to estimate the RTT and update the retransmission timeout.

Acknowledged bytes: *TCPProcessAck* computes the number of acknowledged bytes in each packet and sets it as an annotation. This is later read by *TCPNewRenoAck* to increase the congestion window. If this number is zero and a few other conditions hold (e.g., the receive window is unchanged), the packet is considered a duplicate ACK and may trigger a fast retransmission.

Flags: TCP flags are used to indicate certain actions to other elements. For instance, *TCPProcessData* sets a flag when the received packet has new data. *TCPAckRequired* then checks this flag and, if set, pushes the packet out to trigger an ACK transmission.

3.2 Outgoing packets

Figure 3 shows the cTCP element graph for processing outgoing packets. Applications send data using socket or zero-copy APIs (Section 3.3) that invoke static functions in *TCPSocket*. For each socket call, this element looks up the socket file descriptor in a per-core socket table in *TCPInfo*. For transmissions, *TCPNagle* first checks if the packet should be sent according to Nagle's algorithm. *TCPRateControl* then verifies whether send and congestion windows allow packet transmission. If so, *TCPSegmentation* breaks the data up into MTU-sized packets, and *TCPAckOptionEncap*, *TCPAckEncap*, and *TCPIPEncap* prepend TCP and IP header respectively. Before sending it to lower layers, *TCPEnqueue4RTX* clones the packet and saves it in the retransmission queue until acknowledged by the other end. To initiate a TCP connection, *TCPSynOptionEncap* and *TCPSynEncap* generate the TCP options and header and forward the packet downstream. Similarly, to terminate the connection, *TCPAckOptionEncap* and *TCPFinEncap* form a TCP packet with the FIN flag set.

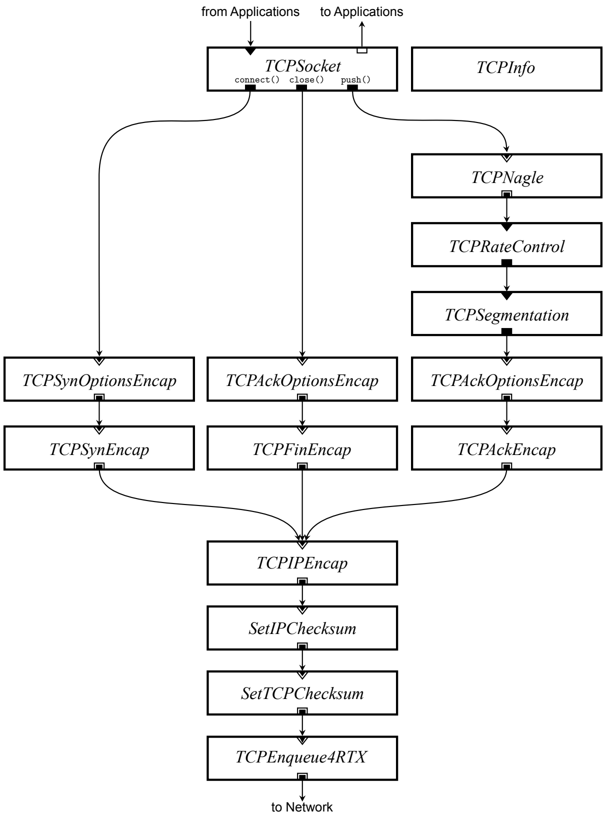

Figure 3: cTCP configuration for outgoing packets.

3.3 Transport APIs

cTCP APIs are designed with two contrasting objectives in mind: (*i*) minimize the efforts required to port application logic in ClickNF; and (*ii*) provide primitives to guarantee high performance at the cost of more complex development. We therefore provide two APIs to interact with the ClickNF transport layer, and one for socket I/O multiplexing.

Socket API: For each socket system call (e.g., `send`), cTCP provides a corresponding function (e.g., `click_send`) for both blocking or non-blocking mode. As in Linux, the operation mode is set on a per-socket basis using the `SOCK_NONBLOCK` flag. In case of blocking sockets, the application is blocked when waiting on I/O; in case of non-blocking sockets, the socket calls return immediately.

Zero-copy interface: In addition to standard Socket API, cTCP provides `click_push` and `click_pull` functions to enable zero-copy operations. For transmissions, applications first allocate a packet and write data to it before pushing it down. cTCP then adds the protocol headers and transmits the packet(s) to the NIC. For receptions, packets are accessed, processed, and placed into the RX queue of applications. To amortize per-packet overhead, both functions can also send and receive batches, and operate in either blocking or non-blocking mode.

Socket I/O multiplexing: To avoid busy-waiting on I/O, cTCP provides a `click_poll` and a `click_epoll_wait` functions to multiplex events from several socket file descriptors. As in the regular epoll API provided by Linux kernel, applications must first register the monitored socket file descriptors with `click_epoll_ctl` and then use `click_epoll_wait` to wait on I/O.

3.4 Timer Management

In Click, timers corresponds to tasks scheduled at a given time in the future. TCP timers are used for retransmissions, keepalive messages, and delayed ACKs. Their implementation in cTCP is critical for performance and scalability reasons. Figure 4 shows cTCP timers' configuration. After a retransmission timeout task is scheduled, *TCPTimer* dequeues the head-of-line packet from the RTX queue and pushes it out. *TCPUpdateTimestamp*, *TCPUpdateWindow*, and *TCPUpdateAckNo* update the respective TCP header fields. Similarly when a keepalive timeout expires, *TCPTimer* pushes an empty packet, and *TCPAckOptionsEncap*, *TCPAckEncap* generate the TCP header of a regular ACK packet. *DecTCPSeqNo* then decrements the TCP sequence number to trigger an ACK back from the other host. Finally, delayed ACKs are sent for every pair of received data packets unless a 500 ms timeout elapses. In this case, a regular ACK is sent using the modules described above.

3.5 Customization and Element Reuse

cTCP modularity enables code reuse and fine-grained customization of the network stack. For instance, TCP reliability can be disabled by simply removing *TCPEnqueue4RTX* from the configuration file. In this section, we present concrete examples to showcase the benefits of our modular TCP implementation.

Building a traffic generator that emulates several TCP flows concurrently sending at a constant rate is straightforward with ClickNF elements. The *TCPInfo* element is inserted in the configuration file and initialized with the corresponding TCBs. Data packets are generated and shaped at a constant rate by regular Click elements, *InfiniteSource* and *Shaper*, and then forwarded to a new element, *TCBSelector*, that randomly associates the packet to an existing TCB using ClickNF annotations. Afterwards, packets go through ClickNF elements such as *TCPAckEncap*, *TCPIPEncap* (plus optionally *SetTCPChecksum*, *SetIPChecksum*) to fill IP and TCP headers before being forwarded to an I/O element.

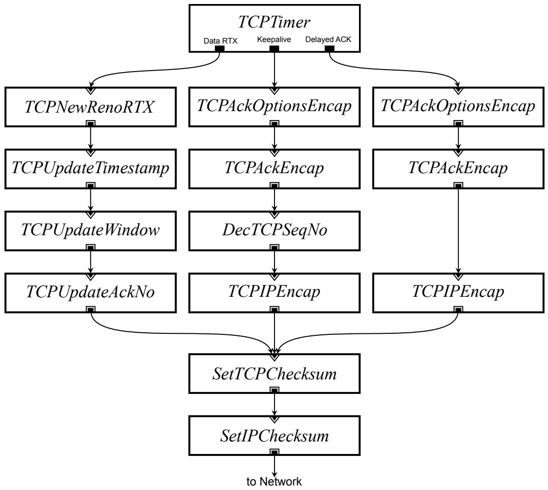

Figure 4: cTCP configuration for TCP timers.

Moreover, per-flow congestion control can be used to ensure that specific traffic classes are processed using appropriate algorithms. Implementing such a feature in a monolithic OS network stack (e.g., Linux kernel one) is, however, quite complicated. Due to its modularity, ClickNF allows the definition of per-flow congestion control by simply inserting a *Classifier* element that modifies the behavior of cTCP for specific flows.

Finally, changing TCP New Reno to match data center TCP (DCTCP) [6] is as simple as adding a new *DCTCP-ProcessECN* element right after *TCPProcessAck* (Figure 2). This element modifies the TCP window behavior in presence of explicit congestion notification. Similarly, the introduction of a new congestion control algorithm, such as BBR [14], requires the development of few additional elements of low complexity.

4 Modular application

ClickNF enables the development of modular applications on top of cTCP. L7 network functions can be implemented using several flow-oriented elements, enabling the programmer to decouple packet processing from application state management logic. To do so, ClickNF separates network and application execution contexts in order to allow applications to block their execution when waiting for I/O operations. ClickNF also provides two fundamental building blocks, *i.e.,* socket I/O multiplexing and SSL/TLS termination elements, that enable rapid composition of complex and customized L7 functions.

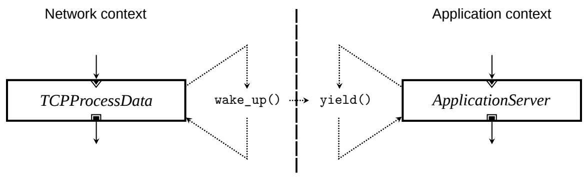

Figure 5: Context switch: *TCPProcessData* reschedules a blocked task waiting on I/O.

4.1 Blocking Tasks

ClickNF implements blocking I/O to provide developers with a broader range of I/O options. In Click, *tasks* are element-defined functions that require frequent CPU scheduling, and initiate a sequence of packet processing in the configuration graph. We introduce the concept of *blocking tasks*, which can yield the CPU if a given condition does not hold, e.g., an I/O request cannot be promptly completed. When rescheduled, the task resumes exactly where it left off, providing applications with an illusion of continuous execution. Blocking tasks are backward compatible with regular tasks, and require no modifications to the Click task scheduler.

Context switching between tasks is light-weight, saving and restoring registers required for task execution. ClickNF uses low-level functions to save and restore the tasks context, just as in POSIX threads. Differently than POSIX threads, however, ClickNF has access to the Click task scheduler and relies on cooperative, as opposed to preemptive, scheduling. ClickNF uses the Boost library to perform context switches in a handful of CPU cycles, *i.e.,* ≈20 cycles in x86_64 (few nanoseconds).

4.2 Network and Application Contexts

ClickNF uses blocking tasks to separate network and application execution contexts. The network context is active during packet reception (cf. Figure 3) and timeouts (cf. Figure 4), and runs through regular Click tasks. The application context, in contrast, is active during application processing and packet transmission (cf. Figure 2) and runs through blocking tasks.

A blocked application is scheduled when the event it is waiting on occurs, e.g., a task blocked on `accept` . Figure 5 presents an example of an application task being rescheduled by an event. In the example, *ApplicationServer* calls `epoll_wait` to monitor a group of active file descriptors. Since no one is ready to perform I/O, it calls `yield` to save the current context and unschedule the task. Later on, when a data packet is received, *TCPProcessData* checks if the application task is waiting for data packets and calls `wake_up` to reschedule it. The event is then inserted into a per-core event queue that stores the events that occurred for the sockets monitored by *ApplicationServer* (*i.e.,*different applications have separate event queues). When the application task is executed, to amortize the cost of the context switch, a batch of events is handled before the network context is re-scheduled.

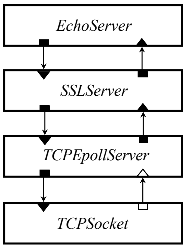

Figure 6: Configuration graph of a modular echo server in ClickNF that uses SSL/TLS encryption.

In ClickNF we specify a list of events needed to manage cTCP states and error conditions. For instance, events are generated when the accept queue becomes non-empty, or when the connection is established to wake up application tasks waiting on these conditions. Similarly, events are also generated when the TX queue becomes non-full, the RX queue becomes non-empty, and also when the RTX queue becomes empty. Other events signal that the remote peer wants to close the connection, the connection was closed, or an error occurred (e.g., a reset or timeout). Despite this fine grain event characterization, to remain compliant with the original epoll API, we map cTCP events to standard `EPOLLIN`, `EPOLLOUT`, and `EPOLLERR` events.

4.3 Application Building Blocks

To simplify application-level programming and promote code reuse, ClickNF provides four building blocks useful for practically relevant network functions. Such building blocks exchange control information with application layer elements using packet annotations. In this way, application elements are informed about the socket file descriptor to which the packets belongs and about new or closed connections. This allows them to efficiently multiplex data between different applications and multiple sockets in both directions.

The first application-layer building block, *TCPEpollServer*, implements an epoll server concealing the complexity of cTCP event handling and can be used to rapidly implement server-side network functions. Similarly, *TCPEpollClient* implements an epoll client to multiplex outgoing connections. Finally, *SSLServer* and *SSLClient* provide SSL/TLS encryption through the OpenSSL library, and may be used to implement network function that require end-to-end encryption. Application data enters in an input port of *SSLServer* as plaintext and leaves its output port as ciphertext; received packets take the reverse path to decrypt ciphertext into plaintext.

Figure 6 shows an echo server using SSL/TLS encryption as a straightforward example of a modular application assembled from ClickNF building blocks. Upon reception at *TCPEpollServer*, packets are decrypted by *SSLServer* and forwarded upstream. *EchoServer* is a stateless application that simply redirects the received data back to the client. On the way back, *SSLServer* encrypts the data and forwards it downstream to *TCPEpollServer*. This simple example shows how ClickNF enables a large number of possibilities for customizing the entire network stack of an application since any of its building blocks can be easily disabled or rewired. For instance, the echo server in Figure 6 can easily disable SSL/TLS for selected flows by introducing a classifier element into the configuration graph, without any change to the element that implements the application logic.

5 Implementation

ClickNF benefits from several improvements that the Click codebase received over time, such as fast packet I/O and multicore, besides introducing a brand new timer subsystem that copes with the scaling requirements of TCP support. This section highlights some notable technical details that characterize ClickNF implementation.

5.1 Packet I/O

Similarly to Fastclick [9], ClickNF provides fast packet I/O by using DPDK [33] to directly interface with network cards from user space. For packet reception, the DPDK element continuously poll the NIC to fetch received packet batches. In order to amortize the PCIe overhead, the DPDK element waits for a batch of 64 packets before transmitting them. To avoid head-of-line blocking and reduce latency, batches are transmitted after at most 100 μs. When needed, ClickNF performs batch processing (*i.e.,* Click elements process packet batches – implemented through packets' linked lists – instead of single packets) to optimize CPU cache performance. Also in this case, a batch is forwarded downstream after 100 μs even if it is not complete.

As in Fastclick, we modify the Click packet data structure to be a wrapper around a DPDK memory buffer (`mbuf`) to avoid additional memory allocation and copy operations. Each packet has a fixed size of 8 KB and consists of four sections, namely, the `mbuf` structure itself, packet annotations, headroom, and data. DPDK uses the `mbuf` for packet I/O whereas ClickNF uses annotations to store packet metadata (e.g., header pointers) and the headroom space to allow elements to prepend headers. Applications allocate a packet by filling only the data portion before pushing the packet down to lower layers.

Notice that, differently form Fastclick, we use a single element for both input and output operations in order to simplify the configuration. Moreover, ClickNF can also leverage common NIC features to perform flow control, TCP/IP checksum offloading, TCP segmentation (TSO), and large receive offloading (LRO) using hardware acceleration. Flow control prevents buffer overflows by slowing down transmitters when the RX buffer in the NIC becomes full. TCP/IP checksum offloading allows the NIC to compute header checksums in hardware. TSO segments a large packet into MTU-sized packets, whereas LRO aggregates multiple received packets into a large TCP segment before dispatching it to higher layers. All of these features can be toggled in ClickNF at run-time.

5.2 Multicore Scalability

Multithreading is implemented to exploit the processing power in multicore CPUs and improve scalability. We design per-core lock-free data structures aiming for high performance. Each core maintains dedicated packet pools, timers, transport, and application layer data structures. Receive Side Scaling (RSS) is used to distribute packets to different cores according to their flow identifier, *i.e.,* flow 5-tuple. Each DPDK thread is pinned to a CPU core and provided with a TX and a RX hardware queue at the NIC, preserving flow-level core affinity.

To avoid low-level CPU synchronization primitives each core maintains separate cache-aligned data structures. In case of multi-connection dependency, such as a proxy server establishing a connection on behalf of a client, the source port of the new outgoing connection is selected such that RSS maps it to the same core of the original connection, thus avoiding locks at the application level. Finally, each application-layer network function is spawned on multiple cores so that flows directed can be handled entirely on a specific core.

5.3 Timer Subsystem

Click implements its timer subsystem using a priority queue in which the root node stores the timer closer to expire. Given that TCP timers are often canceled before expiration, we implement a timing wheel scheduler for efficiency [47]. Its key advantage is that timing wheels schedule and cancel timers in $O(1)$, as opposed to $O(\log n)$ in priority queues currently used in Click.

A timing wheel is composed of n buckets, an index b, a timestamp t, and a tick granularity g (e.g., 1 ms). The timestamp t keeps the current time and the index b, points to its corresponding bucket. Each bucket contains timers expiring in the future, such that bucket b contains timers expiring within $[t, t+g)$, and so on. To schedule a timer, we must first find its corresponding bucket. For an expiration time e in the interval $t \leq e < t + ng$, its bucket index is computed as $\lfloor(e-t)/g\rfloor$. Each bucket contains a doubly linked list to store the timers expiring within the same interval. Therefore, once the index is computed, the timer is inserted at the end of the list of the bucket. To cancel a timer, the timer is just removed from the doubly linked list. Both operations are done in $O(1)$ with simple modulo operation to compute the bucket index b.

6 Evaluation

In this section, we evaluate ClickNF with three goals: (i) evaluate its performance through a series of microbenchmarks; (ii) compare it against Linux and state-of-the-art user space stacks; and (iii) showcase the usage of ClickNF and its performance when building network functions. Our evaluation setup consists of 3 machines with Intel Xeon® 40-core E5-2660 v3 2.60GHz processors, 64 GB RAM, each equipped with an Intel® 82599ES network card containing two 10 GbE interfaces. The machines run Ubuntu 16.10 (GNU/Linux 4.4.0-51-generic x86_64), Click 2.1, and DPDK 17.02.

6.1 Microbenchmarks

We start by analyzing individual aspects of our system using microbenchmarks, including packet I/O throughput, the cost of modularity, and the impact of hardware offloading. We then evaluate two applications, namely bulk transfer and echo server, to understand the system performance in common scenarios. Unless otherwise specified, the experiments presented in this section are performed on single-core ClickNF instances.

Packet I/O and the cost of modularity: To evaluate the throughput of our DPDK element, we run a set of tests with the DPDK traffic generator (DPDK-TG) [25] on one side and ClickNF on the other one. For ClickNF, we use four configurations that respectively generate and immediately discard (no I/O), receive (RX), forward (FW), and transmit (TX) 64-byte packets. Finally, we evaluate the cost of modularity by adding *PushNull* elements that receive packets on the input port and send them on the output port without doing anything else.

Figure 7 presents the average throughput for the different scenarios with a series of *PushNull* elements. Without I/O, ClickNF throughput is limited by the CPU at 43 Mpps. Increasing the number of elements increases the time spent by a packet inside the Click graph, considerably reducing the system throughput. For the RX, FW, and TX scenarios, the throughput is limited by the NIC line rate at 14.88 Mpps. ClickNF is still able to sustain the line rate with up to 15–20 *PushNull* elements. At this point, the throughput is limited by CPU and decreases further as more elements are placed in the configuration.

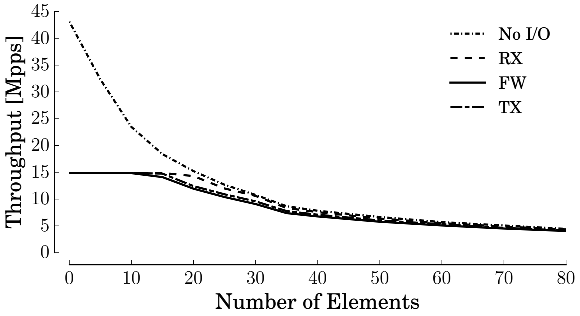

Figure 7: Throughput with 64-byte packets and increasing number of Click elements in different scenarios.

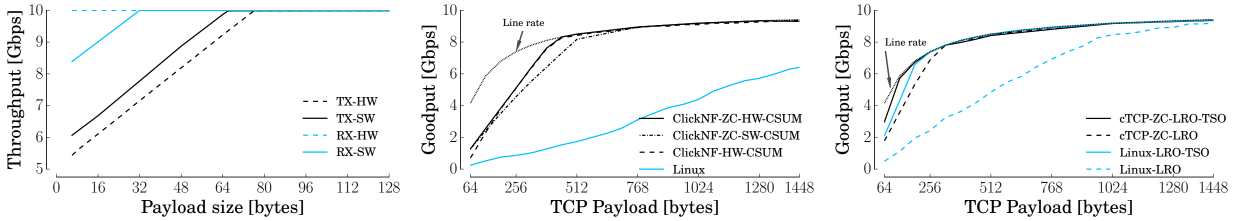
However, using packet batches between Click elements (Section 5.1) reduces the cost of modularity by improving instruction and data cache utilization. Indeed, when processing batches instead of single packets we experimentally evaluate that ClickNF to sustain line rate with up to 150 *PushNull* elements in RX, TX, and FW configurations. In ClickNF we adopt batch processing with batches of 32 packets to improve performance.

Checksum offloading: To evaluate hardware checksum offloading in our DPDK module, we measure the throughput using software or hardware checksum computation-verification. As in the previous tests, we run the DPDK-TG on one side and ClickNF on the other. We then use two different configurations for transmitting (TX) and receiving (RX) packets belonging to a single TCP flow. For transmissions, ClickNF computes header checksums before transmitting the packets to the traffic generator. For receptions, ClickNF verifies whether the checksums are correct before discarding the packet. Both operations are performed in hardware or in software.

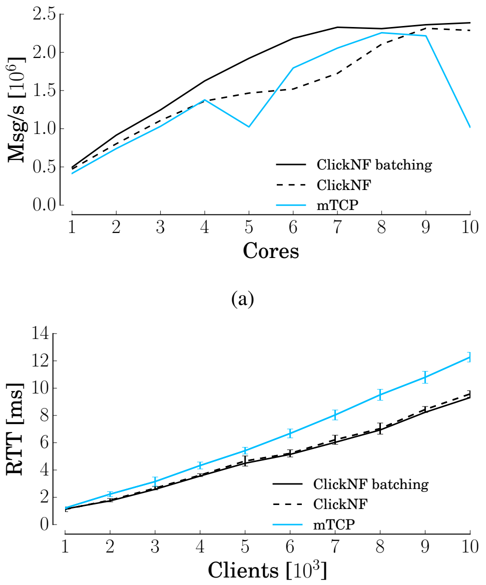
Figure 8a shows the results for TX and RX with increasing payload size (6–128 bytes). As expected, offloading checksum verification provides significant performance benefits and allows ClickNF to sustain line rate even when receiving small packets. Surprisingly, TX checksum computation in software is significantly better than in hardware. This is because modern CPUs are very efficient when performing sequential operations on cached memory, and sometimes even faster than dedicated hardware. However, as we see in the next experiments, this only holds because the CPU is underloaded.

Bulk transfer: To validate ClickNF in a more realistic scenario we execute a bulk transfer of a 20 GB file from a client to a server. Moreover, we evaluate the performance of TCP segment offloading (TSO) and large received offloading (LRO), as well as equivalent implementations in software Click elements. For comparison, we use iperf [4] running on top of Linux network.



(a) (b) (c)

Figure 8: (a) TCP throughput with and without TCP/IP checksum offloading. (b) TCP goodput in a bulk transfer with increasing TCP payload size. (c) TCP goodput in a bulk transfer with TSO and LRO enabled.



(a)

(b)

Figure 9: Comparison between ClickNF and mTCP. (a) Echo server message rate with increasing number of cores. (b) RTT with increasing number of TCP clients.

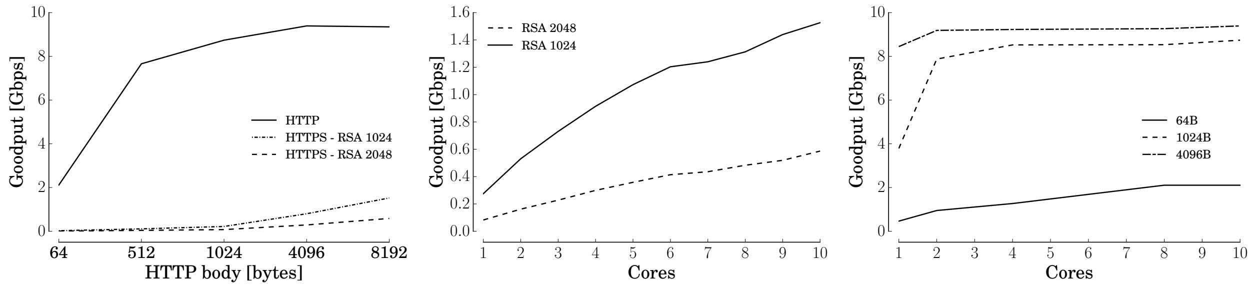
Figure 8b shows the TCP goodput for increasing payload sizes for ClickNF and Linux. For ClickNF, we use the socket API with HW checksum computation-verification (ClickNF-HW-CSUM), the zero-copy API with either software checksum computation-verification (ClickNF-ZC-SW-CSUM) or hardware checksum offloading (ClickNF-ZC-HW-CSUM). For Linux, we use iperf for tests with hardware checksum enabled. ClickNF significantly outperforms Linux and achieves line rate for TCP payloads larger than 448 bytes when the packet header overhead is smaller. For 64-byte payload, the zero-copy API provides roughly 50% throughput improvement over the socket API. This occurs because, with larger packets, the number of calls to memcopy and recv decreases, limiting the advantage of zero copy. In the following tests, we use the zero-copy API, as it delivers better performance with respect to the socket API.

Unlike what is observed in reception, TX checksum offloading (ClickNF-ZC-HW-CSUM) provides significant benefits with respect to software (ClickNF-ZC-SW-CSUM). For computationally intensive workloads, TX checksum offloading prevents the CPU from spending precious cycles in checksum computation-verification.

Figure 8c presents the results with TSO and LRO enabled. ClickNF outperforms Linux, specially for small payloads suggesting that the Linux stack is particularly inefficient for small packets, as reported in [20, 35, 10]. ClickNF achieves line rate for TCP payloads larger than 128 bytes while Linux have similar performance with TSO and LRO for TCP payloads larger than 192 bytes. In the following, we always enable LRO and TSO to amortize segmentation and reassembly cost.

Echo server: We also evaluate ClickNF in the presence of short TCP connections and compare its performance against mTCP [20], a user-space network stack with particular focus on performance and with similar goals to ClickNF. To evaluate multicore scalability, we run an echo server on top of both stacks. Clients running in two separate 8-core ClickNF instances connect to the server, send a 64-byte message, and wait for the echo reply. When the client receives the message back, it resets the connection to avoid port exhausting. The client then repeats the operation and measures the message rate. To provide a fair comparison against mTCP, we disable delayed ACKs that, when enabled, decrease the overhead and increase the overall throughput. Figure 6 depicts the configuration graph of the echo server used in this test, except for the *SSLServer* element that is not included.

First we measure the rate obtained by ClickNF and mTCP with a single core. ClickNF provides high throughput, 0.5×10^6 Msg/s, when using DPDK packet I/O. Compared to legacy Click elements for packet I/O, 0.169×10^6 Msg/s, (*i.e.,* using PCAP library linked to *FromDevice*), ClickNF provides 4x higher throughput. This shows how important kernel bypass is when enabling zero-copy packet processing at user space. Additionally, ClickNF outperforms mTCP, 0.415×10^6 Msg/s, by approximately 20%.



(a) HTTP cache - 10 cores with/without SSL/TLS (b) HTTP cache - with SSL/TLS (c) Proxy

Figure 10: Average goodput of the ClickNF modular HTTP(S) cache server.

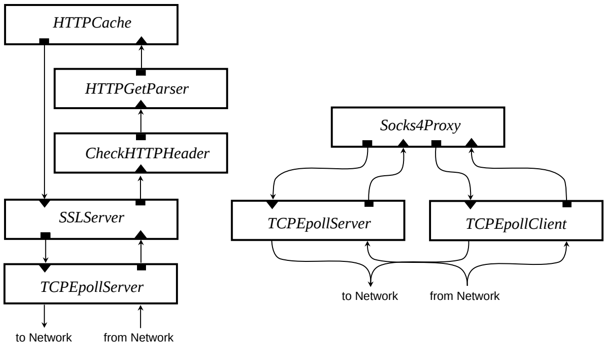


Figure 11: Configuration graphs for an HTTP cache server with SSL/TLS and for a SOCKS4 Proxy.

Figure 9a presents the message rate obtained with ClickNF and with mTCP for increasing number of cores. Despite its modularity, ClickNF provides equivalent performance to mTCP up to 4 cores, and scales slower for more cores. As observed earlier, modularity has a cost, but can be amortized with packet batches. In this case, Click elements receives packet batches instead of single packets hence optimizing CPU instruction and data cache usage. We enable batching in ClickNF for L2–L3 operations to avoid packet reordering issues at L4 and repeated the echo server experiment. Figure 9a shows that, ClickNF outperforms mTCP and achieves line rate with 7 cores. Results with hyperthreading (not reported here) show higher throughput, reducing the number of cores required to saturate the link to 4.

Since ClickNF employs batching at all levels, the risk is that RTT might be undesirably long. Figure 9b shows the RTT experienced by ClickNF and mTCP in the single core echo server test with increasing number of concurring clients. Due to the usage of batch timeouts, the latency introduced with increasing number of clients is limited and lower when compared to mTCP.

6.2 Modular Network Functions

To evaluate ClickNF performance and show the benefits of its modularity, we build two sample applications.

HTTP(S) cache: Figure 11 depicts the configuration graph used to deploy an HTTP cache server. Using the basic building blocks provided by ClickNF, application logic is implemented with three simple elements.

To evaluate the performance of our modular HTTP cache server, we run tests with SSL/TLS termination using self-signed certificates for 1024- or 2048-byte RSA keys. Clients running in two 8-core ClickNF instances first connect to the server and then issue HTTP GET requests for web pages of size 64–8192 bytes, stored in the HTTP cache server's main memory. The server responds to the requests and then closes the TCP connection.

Figure 10a,10b presents the goodput of the ClickNF HTTP cache server with and without SSL/TLS termination. With unencrypted HTTP traffic running on 10 cores (cf. Figure 10a), ClickNF achieves high goodput for small HTTP pages, and scales linearly with bigger page size. With SSL/TLS termination, the goodput drops to a maximum of $\approx$ 1.6 Gbps for 1024-byte keys and 10 cores. This is due to the complexity of public-key RSA cryptographic operations during SSL/TLS handshake [15]. This overhead, however, can be alleviated by delegating such operations to GPUs [27, 48].

SOCKS4 proxy: Socket Secure (SOCKS) is a protocol for enabling client-server communication through a proxy. Starting from a basic SOCKS4 proxy implementation written in C, we built a modular SOCKS4 proxy composed by three elements namely *Socks4Proxy*, and ClickNF building blocks *TCPEpollServer* and *TCPEpollClient*. Figure 11 depicts the high-level configuration graph for the proxy. Notice that, due to ClickNF L7 modularity, the SOCKS4 proxy graph can be easily modified to introduce additional functions (e.g., firewall, SSL encryption) right before the paths connecting *TCPEpollServer* and *Socks4Proxy*.

To evaluate the performance of our modular SOCKS4 proxy, we run a simple test similar to the one presented for the HTTP cache. In this case, clients connect to the SOCKS4 proxy which opens a new connection toward the HTTP cache. Once the connection is established, the client requests an HTTP page of fixed size and then resets the connection. Figure 10c presents the goodput of the ClickNF SOCKS4 proxy with increasing number of cores and variable HTTP body sizes. Similarly to the HTTP cache experiment, when the HTTP message is small the overhead (connection establishment and SOCKS protocol) is significant and prevents the system from achieving a higher goodput. For larger page sizes, the overhead decreases and the proxy is able to achieve close to line rate using just two CPU cores.

7 Related Work

Click [29] and its modular data plane have been improved and extended in multiple directions over almost two decades. For instance, Routebricks [18] parallelizes routing functionality across and within software routers building on top of Click to scale its performance. Recently, Fastclick [9] introduced high-speed packet I/O such as DPDK and netmap [33, 44] in Click.Moreover, GPU offloading is also proposed in [28, 46] to increase throughput beyond CPU capabilities. Similarly, ClickNP [32] provides Click-like programming abstractions to enable the construction of FPGA-accelerated network functions. ClickNF is orthogonal to such extensions and enables the modular composition of L2–L7 stacks, bridging Click's L2-L3 packet processing with L4 flow processing and L7 modular applications.

Click inspired other modular network function frameworks [8, 12, 40]. These systems mainly focus on control plane operations, such as data plane element placement, network function scaling, and traffic steering. For the data plane, FlowOS [11] is proposed as a middlebox platform that enables flow processing, but without TCP support. CoMb [45] and xOMB [7] use Click to consolidate middleboxes through the composition of different L7 elements. Both rely on the OS for packet I/O and transport layer, reducing customization and performance. Frameworks to enable stack customization of L2–L7 are proposed in [42, 26]. In [42], authors introduce an overview of the control and data planes of a modular architecture, with focus on hardware acceleration. In [26], the design of a modular middlebox platform based on mTCP [20] is presented. Instead of redesigning a framework with Click-like abstractions and/or providing new event-driven domain-specific APIs, ClickNF introduces L2–L7 modularity in Click to expose and exploit its modularity, as well as benefiting from existing Click extensions and contributions by the community.

Network stacks were proposed to overcome the I/O inefficiencies of OS [10, 43, 20, 35, 23, 49, 16]. IX [10] separates the control plane and data plane processing. Arrakis [43] is a customized OS that provide applications with direct access to I/O devices, allowing kernel bypass for I/O operations. mTCP [20] is a user-level TCP implementation proposed for multicore systems. It provides a socket API for application development supporting L2–L4 zero copy. In a different spirit, Stackmap [49] provides packet I/O acceleration to TCP kernel implementation obtaining better performance compared to Linux TCP. Sandstorm [35] proposes a specialized network stack with zero-copy APIs merging application and network logics. Similarly to ClickNF, Modnet [41] has a modular approach for providing customizable networking stack, but modularity is limited to L2–L4. Few other efforts [3, 5, 2, 16, 13] also provide efficient, sometimes modular, networking stacks but cannot completely benefit of L2–L7 modularity provided by ClickNF.

Our previous workshop paper [31] focused on providing an initial architecture for a modular TCP implementation in Click. ClickNF extends it in several directions. For instance, ClickNF takes advantage of hardware offloading, multicore scalability, timing wheels, and an epoll-based API to improve performance. Application level modularity and SSL/TLS termination provide building blocks for novel network functions to be deployed with little effort. We hereby propose a more comprehensive picture of ClickNF's performance, flexibility, and ease of use.

8 Conclusions

The advent of NFV gives us a different perspective on the way application servers and middleboxes can be implemented. ClickNF enables the composition of high-performance network functions at all layers of the network stack and opens up its inner workings for the benefit of developers. In this paper, we illustrated and benchmarked several concrete examples where ClickNF can be used to accelerate network function development by enabling fine-grained code reuse, and highlighted ClickNF's good scaling properties and a reasonable price of modularity, which arguably outweigh many of the hurdles in network function development. The ClickNF source code is available for download at [21].

Selecta: Heterogeneous Cloud Storage Configuration for Data Analytics

Ana Klimovic

Heiner Litz
UC Santa Cruz

Christos Kozyrakis
Stanford University

Abstract

Data analytics are an important class of data-intensive workloads on public cloud services. However, selecting the right compute and storage configuration for these applications is difficult as the space of available options is large and the interactions between options are complex. Moreover, the different data streams accessed by analytics workloads have distinct characteristics that may be better served by different types of storage devices.

We present Selecta, a tool that recommends near-optimal configurations of cloud compute and storage resources for data analytics workloads. Selecta uses latent factor collaborative filtering to predict how an application will perform across different configurations, based on sparse data collected by profiling training workloads. We evaluate Selecta with over one hundred Spark SQL and ML applications, showing that Selecta chooses a near-optimal performance configuration (within 10% of optimal) with 94% probability and a near-optimal cost configuration with 80% probability. We also use Selecta to draw significant insights about cloud storage systems, including the performance-cost efficiency of NVMe Flash devices, the need for cloud storage with support for fine-grain capacity and bandwidth allocation, and the motivation for end-to-end storage optimizations.

1 Introduction

The public cloud market is experiencing unprecedented growth, as companies move their workloads onto platforms such as Amazon AWS, Google Cloud Platform and Microsoft Azure. In addition to offering high elasticity, public clouds promise to reduce the total cost of ownership as resources can be shared among tenants. However, achieving performance and cost efficiency requires choosing a suitable configuration for each given application. Unfortunately, the large number of instance types and configuration options available make selecting the right resources for an application difficult.

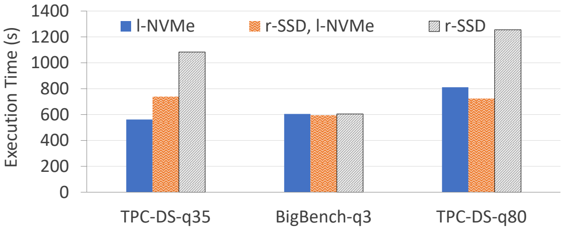

Figure 1: Performance of three applications on eight `i3.xl` instances with different storage configurations.

The choice of storage is often essential, particularly for cloud deployments of data-intensive analytics. Cloud vendors offer a wide variety of storage options including object, file and block storage. Block storage can consist of hard disks (*HDD*), solid-state drives (*SSD*), or high bandwidth, low-latency NVMe Flash devices (*NVMe*). The devices may be local (*l*) to the cloud instances running the application or remote (*r*). These options alone lead to storage configuration options that can differ by orders of magnitude in terms of throughput, latency, and cost per bit. The cloud storage landscape is only becoming more diverse as emerging technologies based on 3D X-point become available [35, 16].

Selecting the right cloud storage configuration is critical for both performance and cost. Consider the example of a Spark SQL equijoin query on two 128 GB tables [53]. We find the query takes 8.7× longer when instances in an 8-node EC2 cluster access *r*-HDD compared to *l*-NVMe storage. This is in contrast to a recent study, conducted with a prior version of Spark, which found that faster storage can only improve the median job execution time by at most 19% [50]. The performance benefits of *l*-NVMe lead to 8× lower execution cost for this query, even though NVMe storage has higher cost per unit time. If we also consider a few options for the number of cores and memory per instance, the performance gap between the best and worst performing VM-storage configurations is over 30×.

Determining the right cloud configuration for analytics applications is challenging. Even if we limit ourselves to a single instance type and focus on optimizing performance, the choice of storage configuration for a particular application remains non-trivial. Figure 1 compares the performance of three Spark applications using 8 `i3.xl` AWS instances with *l*-NVMe, *r*-SSD, and a hybrid (*r*-SSD for input/output data, *l*-NVMe for intermediate data). The first application is I/O-bound and benefits from the high throughput of NVMe Flash. The second application has a CPU bottleneck and thus performs the same with all three storage options. The third application is I/O-bound and performs best with the hybrid storage option since it minimizing interference between read and write I/Os, which have asymmetric performance on Flash [40]. This result should not be surprising. Analytics workloads access multiple data streams, including input and output files, logs, and intermediate data (e.g., shuffle and broadcast). Each data stream has distinct characteristics in terms of access frequency, access patterns, and data lifetime, which make different streams more suitable for different types of storage devices. For example, for TPC-DS query 80 in Figure 1, storing input/output data on *r*-SSD and intermediate data on *l*-NVMe Flash outperforms storing all data on *l*-NVMe as it isolates streams and eliminates interference.

We present *Selecta*, a tool that learns near-optimal VM and storage configurations for analytics applications for user-specified performance-cost objectives. Selecta targets analytics jobs that are frequently or periodically rerun on newly arriving data [1, 25, 55]. A configuration is defined by the type of cloud instance (core count and memory capacity) along with the storage type and capacity used for input/output data and for intermediate data. To predict application performance for different configurations, Selecta applies latent-factor collaborative filtering, a machine-learning technique commonly used in recommender systems [10, 57, 11, 22, 23]. Selecta uses sparse performance data for training applications profiled on various cloud configurations, as well as performance measurements for the target application profiled on only two configurations. Selecta leverages the sparse training data to learn significantly faster and more cost-effectively than exhaustive search. The approach also improves on recent systems such as CherryPick and Ernest whose performance prediction models require more information about the target application and hence require more application runs to converge [3, 69]. Moreover, past work does not consider the heterogeneous cloud storage options or the varying preferences of different data streams within each application [71].

We evaluate Selecta with over one hundred Spark SQL and ML workloads, each with two different dataset scaling factors. We show that Selecta chooses a near-optimal performance configuration (within 10% of optimal) with 94% probability and a near-optimal cost configuration with 80% probability. We also analyze Selecta's sensitivity to various parameters such as the amount of information available for training workloads or the target application.

A key contribution of our work is our analysis of cloud storage systems and their use by analytics workloads, which leads to several important insights. We find that in addition to offering the best performance, NVMe-based configurations also offer low execution cost for a wide range of applications. We observe the need for cloud storage options that support fine-grain allocation of capacity and bandwidth, similar to the fine-grain allocation of compute and memory resources offered by serverless cloud services [7]. Disaggregated NVMe Flash can provide the substrate for such a flexible option for cloud storage. Finally, we showcase the need for end-to-end optimization of cloud storage, including application frameworks, operating systems, and cloud services, as several storage configurations fail to meet their potential due to inefficiencies in the storage stack.

2 Motivation and Background

We discuss current approaches for selecting a cloud storage configuration and explain the challenges involved.

2.1 Current Approaches

Conventional configurations: Input/output files for data analytics jobs are traditionally stored in a distributed file system, such as HDFS or object storage systems such as Amazon S3 [62, 6]. Intermediate data is typically read/written to/from a dedicated local block storage volume on each node (i.e., *l*-SSD or *l*-NVMe) and spilled to *r*-HDD if extra capacity is needed. In typical Spark-as-a-service cloud deployments, two remote storage volumes are provisioned by default per instance: one for the instance root volume and one for logs [19].

Existing tools: Recent work focuses on automatically selecting an optimal VM configuration in the cloud [71, 69, 3]. However, these tools tend to ignore the heterogeneity of cloud storage options, at best distinguishing between 'fast' and 'slow'. In the next section, we discuss the extent of the storage configuration space.

2.2 Challenges

Complex configuration space: Cloud storage comes in multiple flavors: object storage (e.g., Amazon S3 [6]), file storage (e.g., Azure Files [45]), and block storage (e.g., Google Compute Engine Persistent Disks [29]). Block and object storage are most commonly used for data analytics. Block storage is further sub-divided into hardware options: cold or throughput-optimized hard drive disk, SAS SSD, or NVMe Flash. Block storage can be local (directly attached) or remote (over the network) to an instance. Local block storage is ephemeral; data persists only as long as the instance is running. Remote volumes persist until explicitly deleted by the user.

Table 1 compares three block storage options available in Amazon Web Services (AWS). Each storage option provides a different performance, cost, and flexibility trade-off. For instance, *l*-NVMe storage offers the highest throughput and lowest latency at higher cost per bit. Currently, cloud providers typically offer NVMe in fixed capacity units directly attached to select instance types, charged per second or hour. AWS currently charges $0.023 more per hour for an instance with 475 GB of NVMe Flash compared to without NVMe. In contrast, S3 fees are based on capacity ($0.023 per GB/month) and bandwidth ($0.004 per 10K GET requests) usage.

In addition to the storage configuration, users must choose from a variety of VM types to determine the right number of CPU cores and memory, the number of VMs, and their network bandwidth. These choices often affect storage and must be considered together. For example, on instances with 1 Gb/s network bandwidth, the network limits the sequential throughput achievable with *r*-HDD and *r*-SSD storage volumes in Table 1.

Performance-cost objectives: While configurations with the most CPU cores, the most memory, and fastest storage generally provide the highest performance, optimizing for runtime cost is much more difficult. Systems designed to optimize a specific objective (e.g., predict the configuration that maximizes performance or minimizes cost) are generally not sufficient to make recommendations for more complex objectives (e.g., predict the configuration that minimizes execution time within a specific budget). By predicting application execution time on candidate configurations, our approach remains general. Unless otherwise specified, we refer to cost as the cost of executing an application.

Heterogeneous application data: We classify data managed by distributed data analytics frameworks (e.g., Spark [74]) into two main categories: *input/output data* which is typically stored long-term and *intermediate data* which lives for the duration of job execution. Examples of intermediate data include shuffle data exchanged between mappers and reducers, broadcast variables, and cached dataset partitions spilled from memory. These streams typically have distinct access frequency, data lifetime, access type (random vs. sequential), and I/O size. For example, input/output data is generally long-lived and sequentially accessed, whereas intermediate data is short-lived and most accesses are random.

Storage	Seq Read MB/s	Seq Write MB/s	Rand Read IOPS	Rand Write IOPS	Rand Rd/Wr IOPS
r-HDD	135	135	132	132	132
r-SSD	165	165	3,068	3,068	3,068
l-NVMe	490	196	103,400	35,175	70,088

Table 1: Block storage performance for 500GB volumes. Sequential IOs are 128 KB, random IOs are 4 KB.

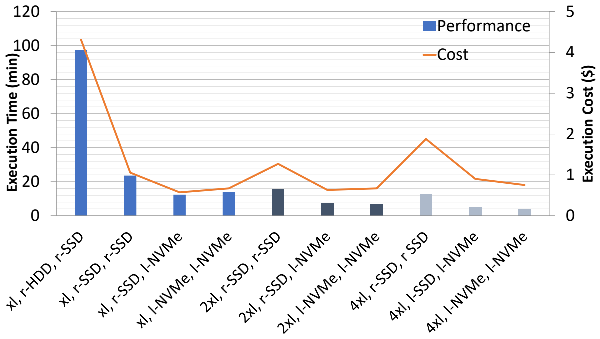

Figure 2: Comparison of execution time and cost for TPC-DS query 64 on various VM and storage configurations, defined as <VM size, storage for input/output data, storage for intermediate data>.

Storage decisions are complex: Selecting the right configuration for a job significantly reduces execution time and cost, as shown in Figure 2, which compares a Spark SQL query (TPC-DS query 64) on various VM and storage configurations in an 8-node cluster. We consider 3 `i3` VM instance sizes in EC2 (`xl, 2xl, and 4xl`) and heterogeneous storage options for input/output and intermediate data. The lowest performing configuration has 24× the execution time of the best performing configuration. Storing input/output data on *r*-SSD and intermediate data on *l*-NVMe (the lowest cost configuration) has 7.5× lower cost than storing input/output data on *r*-HDD and intermediate data on *r*-SSD.

3 Selecta Design

3.1 Overview

Selecta is a tool that automatically predicts the performance of a target application on a set of candidate configurations. As shown in Figure 3, Selecta takes as input: i) execution time for a set of training applications on several configurations, ii) execution time for the target application on two reference configurations, and iii) a performance-cost objective for the target application. A configuration is defined by the number of nodes (VM instances), the CPU cores and memory per node, as well as the storage type and capacity used for input/output data and for intermediate data. Selecta uses latent factor collaborative filtering (see §3.2) to predict the performance

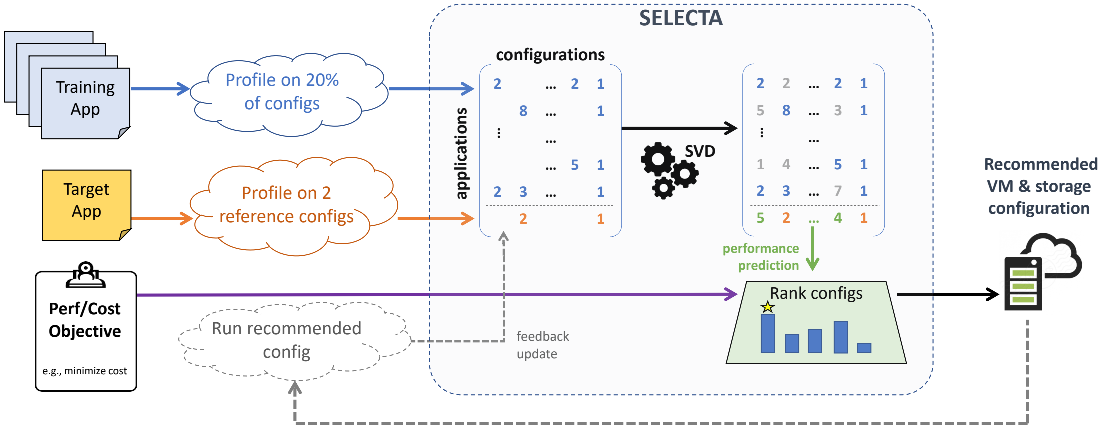

Figure 3: An overview of performance prediction and configuration recommendation with Selecta.

of the target application on the remaining (non-reference) candidate configurations. With these performance predictions and the per unit time cost of various VM instances and storage options, Selecta can recommend the right configuration for the user's performance-cost objective. For example, Selecta can recommend configurations that minimize execution time, minimize cost, or minimize execution time within a specific budget.

As new applications are launched over time, these performance measurements become part of Selecta's growing training set and accuracy improves (see § 4.4). We also feed back performance measurements after running a target application on a configuration recommended by Selecta — this helps reduce measurement noise and improve accuracy. Since Selecta takes ∼1 minute to generate a new set of predictions (the exact runtime depends on the training matrix size), a user can re-run Select when re-launching the target application with a new dataset to get a more accurate recommendation. In our experiments, the recommendations for each target application converge after two feedback iterations. The ability to grow the training set over time also provides Selecta with a mechanism for expanding the set of configurations it considers. Initially, the configuration space evaluated by Selecta is the set of configurations that appear in the original training set. When a new configuration becomes available and Selecta receives profiling data for applications on this configuration, the tool will start predicting performance for all applications on this configuration.

3.2 Predicting Performance

Prediction approach: Selecta uses collaborative filtering to predict the performance of a target application on candidate configurations. We choose collaborative filtering as it is agnostic to the details of the data analytics framework used (e.g., Spark vs. Storm) and it allows us to leverage *sparse* training data collected *across applications* and configurations [56]. While systems such as CherryPick [3] and Ernest [69] build performance models based solely on training data for the target application, Selecta's goal is to leverage training data available from multiple applications to converge to accurate recommendations with only two profiling runs of a target application. We discuss alternatives to collaborative filtering to explain our choice.

Content-based approaches, such as as linear regression, random forests, and neural network models, build a model from features such as application characteristics (e.g., GB of shuffle data read/written) and configuration characteristics (e.g., I/O bandwidth or the number of cores per VM). We find that unless inputs features such as the average CPU utilization of the target application *on the target configuration* are used in the model, content-based predictors do not have enough information to learn the compute and I/O requirements of applications and achieve low accuracy. Approaches that require running target applications on all candidate configurations to collect feature data are impractical.

Another alternative is to build performance prediction models based on the structure of an analytics framework, such as the specifics of the map, shuffle, and reduce stages in Spark [36, 75]. This leads to framework-specific models and may require re-tuning or even remodeling as framework implementations evolve (e.g., as the CPU efficiency of serialization operations improves).

Latent factor collaborative filtering: Selecta's collaborative filtering model transforms applications and configurations to a latent factor space [10]. This space characterizes applications and configurations in terms of latent (i.e., 'hidden') features. These features are *automatically inferred* from performance measurements of training applications [56]. We use a matrix factorization technique known as Singular Value Decomposition (SVD) for the latent factor model. SVD decomposes an input matrix P, with rows representing applications and columns representing configurations, into the product of three matrices, U, λ, and V. Each element p_{ij} of P represents the normalized performance of application i on configuration j. The latent features are represented by singular values in the diagonal matrix λ, ordered by decreasing magnitude. The matrix U captures the strength of the correlation between a row in P and a latent feature in λ. The matrix V captures the strength of the correlation between a column in P and a latent feature in λ. Although the model does not tell us what the latent features physically represent, a hypothetical example of a latent feature is random I/O throughput. For instance, Selecta could infer how strongly an application's performance depends on random I/O throughput and how much random I/O throughput a configuration provides.

One challenge for running SVD is the input matrix P is sparse, since we only have the performance measurements of applications on certain configurations. In particular, we only have two entries in the target application row and filling in the missing entries corresponds to predicting performance on the other candidate configurations. Since performing SVD matrix factorization requires a fully populated input matrix P, we start by randomly initializing the missing entries and then run Stochastic Gradient Descent (SGD) to update these unknown entries using an objective function that minimizes the mean squared error on the *known* entries of the matrix [13]. The intuition is that by iteratively decomposing and updating the matrix in a way that minimizes the error for known entries, the technique also updates unknown entries with accurate predictions. Selecta uses the Python sci-kit `surprise` library for SVD [33].

3.3 Using Selecta

New target application: The first time an application is presented to Selecta, it is profiled on two reference configurations which, preferably, are far apart in their compute and storage resource attributes. Selecta requires that reference configurations remain fixed across all applications, since performance measurements are normalized to a reference configuration before running SVD. Profiling application performance involves running the application to completion and recording execution time and CPU utilization (including iowait) over time.

Defining performance-cost objectives: After predicting application performance across all configurations, Selecta recommends a configuration based on a user-defined ranking function. For instance, to minimize runtime cost, the ranking function is min(runtime × cost/hour). While choosing a storage technology (e.g., SSD vs. NVMe Flash), Selecta must also consider the application's storage capacity requirements. Selecta leverages statistics from profiling runs available in Spark monitoring logs to determine the intermediate (shuffle) data and and input/output data capacity [63].

Adapting to changes: Recurring jobs and their input datasets are likely to evolve. To detect changes in application characteristics that may impact the choice of optimal configuration, Selecta relies on CPU utilization information from both initial application profiling and subsequent executions rounds. When an application is first introduced to the system, Selecta assigns a unique ID to store application specific information such as iowait CPU utilization. Whenever an application is re-executed, Selecta compares the current iowait time to the stored configuration. Depending on the difference in iowait time, Selecta will either compute a refined prediction based on available measurements or treat the workload as new application, starting a new profiling run.

Dealing with noise in the cloud: An additional challenge for recommending optimal configurations is noise on public cloud platforms, which arises due to interference with other tenants, hardware heterogeneity, or other sources [59]. To account for noise, Selecta relies on the feedback of performance and CPU utilization measurements. Initially, with few profiling runs, Selecta's performance predictions are affected by noise. As more measurements are fed into the system, Selecta averages performance and CPU utilization and uses reservoir sampling to avoid high skew from outliers [70]. Selecta keeps a configurable number of sample points for each entry in the application-configuration matrix (e.g., three) to detect changes in applications as described above. If a particular run is heavily impacted by noise such that the compute and I/O bottlenecks differ significantly from previous runs, Selecta's mechanism for detecting changes in applications identifies the outlier.

4 Selecta Evaluation

Selecta's collaborative filtering approach is agnostic to the choice of applications and configurations. We evaluate Selecta for data analytics workloads on a subset of the cloud configuration space with the goal of understanding how to provision cloud storage for data analytics.

4.1 Methodology

Cloud configurations: We deploy Selecta on Amazon EC2 and consider configurations with the instance and storage options shown in Tables 2 and 3. Among the possible VM and storage combinations, we consider seventeen candidate configurations. We trim the space to stay within our research budget and to focus on experiments that are most likely to uncover interesting insights about cloud storage for analytics. We choose EC2 instance families that are also supported by Databricks, a popular Spark-as-a-service provider [18]. `i3` is currently the only instance family available with NVMe Flash and

Instance	CPU cores	RAM (GB)	NVMe
`i3.xlarge`	4	30	1 x 950 GB
`r4.xlarge`	4	30	-
`i3.2xlarge`	8	60	1 x 1.9 TB
`r4.2xlarge`	8	60	-
`i3.4xlarge`	16	120	2 x 1.9 TB
`r4.4xlarge`	16	120	-

Table 2: AWS instance properties

Storage	Type	Locality	Use for Input/Output Data?	Use for Intermediate Data?
r-HDD	Block	Remote	✓	-
r-SSD	Block	Remote	✓	✓
l-NVMe	Block	Local	✓	✓
S3	Object	Remote	✓	-

Table 3: AWS storage options considered

`r4` instances allow for a fair comparison of storage options as they have the same memory to compute ratio. We only consider configurations where the intermediate data storage IOPS are equal to or greater than the input/output storage IOPS, as intermediate data has more random accesses. Since we find that most applications are I/O-bound with *r*-HDD, we only consider *r*-HDD for the instance size with the least amount of cores. We limit our analysis to *r*-HDD because our application datasets are up to 1 TB whereas instances with *l*-HDD on AWS come with a minimum of 6 TB disk storage, which would not be an efficient use of capacity. We do not consider local SAS/SATA SSDs as their storage capacity to CPU cores ratio is too low for most Spark workloads. We use Elastic Block Store (EBS) for remote block storage [5].

We use a cluster of 9 nodes for our evaluation. The cluster consists of one master node and eight executor nodes. The master node runs the Spark driver and YARN Resource Manager. Unless input/output data is stored in S3, we run a HDFS namenode on the master server as well. We configure framework parameters, such as the JVM heap size and number of executors, according to Spark tuning guidelines and match the number of executor tasks to the VM's CPU cores [15, 14].

Applications: We consider Spark [74] as a representative data analytics framework, similar to previous studies [50, 68, 3]. We use Spark v2.1.0 and Hadoop v2.7.3 for HDFS. We evaluate Selecta with over one hundred Spark SQL and ML applications, each with two different dataset scales, for a total of 204 workloads. Our application set includes 92 queries of the TPC-DS benchmark with scale factors of 300 and 1000 GB [67]. We use the same scale factors for Spark SQL and ML queries from the TPC-BB (BigBench) benchmark which has of structured, unstructured and semi-structured data modeled after the retail industry domain [27]. Since most BigBench queries are CPU-bound, we focus on eight queries which have more substantial I/O requirements: queries 3, 8, 14, 16, 21, 26, 28, 29. We also run 100 and 400 GB sort jobs [52]. Finally, we run a SQL equijoin query on two tables with 16M and 32M rows each and 4KB entries [53]. For all input and output files, we use the uncompressed Parquet data format [26].

Experiment methodology: We run each application on all candidate configurations to obtain the ground truth performance and optimal configuration choices for each application. To account for noise in the cloud we run each experiment (i.e., each application on each candidate configuration) three times and use the average across runs in our evaluation. Two runs are consecutive and one run is during a different time of day. We also validate our results by using data from one run as input to Selecta and the average performance across runs as the ground truth. To train and test Selecta, we use leave-one-out cross validation [58], meaning one workload at a time serves as the target application while the remaining workloads are used for training. We assume training applications are profiled on all candidate configurations, except for the sensitivity analysis in §4.4 where we investigate training matrix density requirements for accurate predictions.

Metrics: We measure the quality of Selecta's predictions using two metrics. First, we report the relative root mean squared error (RMSE), a common metric for recommender systems. The second and more relevant metric for Selecta is the probability of making an accurate configuration recommendation. We consider a recommendation accurate if the configuration meets the user's cost-performance objective within a threshold T of the true optimal configuration for that application. For example, for a minimum cost objective with T = 10%, the probability of an accurate prediction is the percentage of Selecta's recommendations (across all tested applications) whose true cost is within 10% of the true optimal cost configuration. Using a threshold is more robust to noise and allows us to make more meaningful conclusions about Selecta's accuracy, since a second-best configuration may have similar or significantly worse performance than the best configuration. Our performance metric is execution time and cost is in US dollars.

4.2 Prediction Accuracy

We provide a matrix with 204 rows as input to Selecta, where one row (application) is designated as the target application in each test round. We run Selecta 204 times, each time considering a different application as the target. For now, we assume all remaining rows of training data in the matrix are dense, implying the user has profiled training applications on all candidate configurations. The single target application row is sparse, containing only two entries, one for each of the profiling runs on reference configurations.

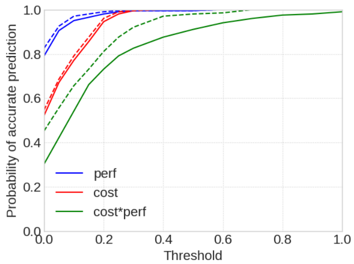

Figure 4: Probability of accurate recommendations within a threshold from optimal. Dotted lines are after one feedback iteration.

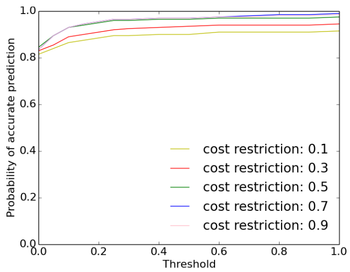

Figure 5: Probability of accurate configuration recommendation for performance within threshold, given strict cost restrictions.

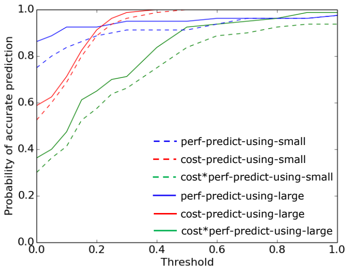

Figure 6: Accuracy with large datasets using predictions from small dataset vs. re-computing prediction with large dataset.

Selecta predicts performance with a relative RMSE of 36%, on average across applications. To understand how Selecta's performance predictions translate into recommendations, we plot accuracy in Figure 4 for performance, cost and cost*performance objectives. The plot shows the probability of near-optimal recommendations as a function of the threshold T defining what percentage from optimal is considered close enough. When searching for the best performing configuration, Selecta has a 94% probability of recommending a configuration within 10% of optimal. For a minimum cost objective, Selecta has a 80% probability of recommending a configuration within 10% of optimal. Predicting cost*performance is more challenging since errors in Selecta's relative execution time predictions for an application across candidate configurations are squared: cost*performance = (execution_time)^2 * config_cost_per_hour.

The dotted lines in Figure 4 show how accuracy improves after a single feedback round. Here, we assume the target application has the same dataset in the feedback round. This provides additional training input for the target application row (either a new entry if the recommended configuration was not a reference configuration, or a new sample to average to existing data if the recommended configuration was a reference configuration). The probability of near-optimal recommendations increases most noticeably for the cost*performance objective, from 52% to 65% after feedback, with T=10%.

Figure 5 shows the probability of accurate recommendations for objectives of the form "select the best performing configuration given a fixed cost restriction C." For this objective, we consider Selecta's recommendation accurate if its cost is less than or equal to the budget and if its performance is within the threshold of the true best configuration for the objective. Selecta achieves between 83% and 94% accuracy for the cost restrictions in Figure 5 assuming T=10%. The long tail is due to performance prediction errors that lead Selecta to underestimate the execution cost for a small percentage of configurations (i.e., cases where Selecta recommends a configuration that is actually over budget).

In Figure 7, we compare Selecta's accuracy against four baselines. The first baseline is a random forest predictor, similar to the approach used by PARIS [71]. We use the following features: the number of CPU cores, disk IOPS and disk MB/s the configuration provides, the intermediate and input/output data capacity of the application, and the CPU utilization, performance, and total disk throughput measured when running the application on each of the two reference configurations. Although the random forest predictor leverages more features than Selecta, it has lower accuracy. Collaborative filtering is a better fit for the sparse nature of the training data. We find the most important features in the random forest model are all related to I/O (e.g., the I/O throughput measured when running the application on the reference configurations and the read/write IOPS supported by the storage used for intermediate data), which emphasizes the importance of selecting the right storage.

The second baseline (labeled 'default') in Figure 7 uses the recommended default configurations documented in Databricks engineering blog posts: *l*-NVMe for intermediate data and S3 for input/output data [19, 21, 20]. The 'max cost per time' baseline uses the simple heuristic of always picking the most expensive instance per unit time. The 'min cost per time' baseline chooses the least expensive instance per unit time. Selecta outperforms all of these heuristic strategies, confirming the need for a tool to automate configuration selection.

4.3 Evolving Datasets

We study the impact of dataset size on application performance and Selecta's predictions using the small and large dataset scales described in §4.1. We train Selecta using all 102 workloads with small datasets, then evaluate Selecta's prediction accuracy for the same workloads with large datasets. The dotted lines in Figure 6 plots Se-

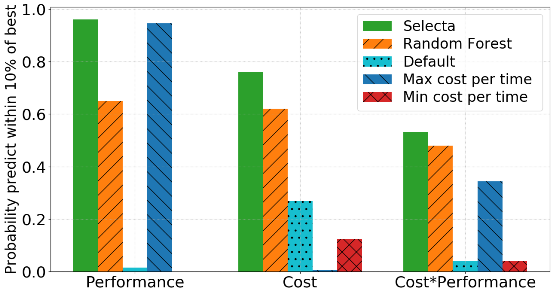

Figure 7: Selecta's accuracy compared to baselines.

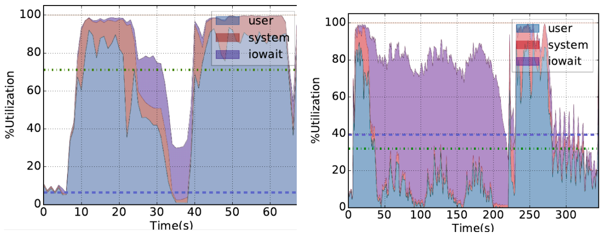


(a) Query on 300GB is CPU-bound. (b) Query on 1TB is IO-bound.

Figure 8: CPU utilization over time for TPC-DS query 89 on `r4.xlarge` cluster with *r*-SSD. For this query, performance with a small dataset is not indicative of performance with a larger dataset. Selecta detects difference in average iowait percentage (blue dotted line).

lecta's accuracy when recommending configurations for applications with large datasets solely based on profiling runs of the application with a smaller dataset. The solid lines show accuracy when Selecta re-profiles applications with large datasets to make predictions. For approximately 8% of applications, profiling runs with small datasets are not sufficient indicators of performance with large datasets.

We find that in cases where the performance with a small dataset is not indicative of performance with a large dataset, the relationship between compute and I/O intensity of the application is affected by the dataset size. As described in §3.3, Selecta detects these situations by comparing CPU utilization statistics for the small and large dataset runs. Figure 8 shows an example of a workload for which small dataset performance is not indicative of performance with a larger dataset. We use the Intel Performance Analysis Tool to record and plot CPU utilization [34]. When the average iowait percentage for the duration of the run changes significantly between the large and small profiling runs on the reference configuration, it is generally best to profile the application on the reference configurations and treat it as a new application.

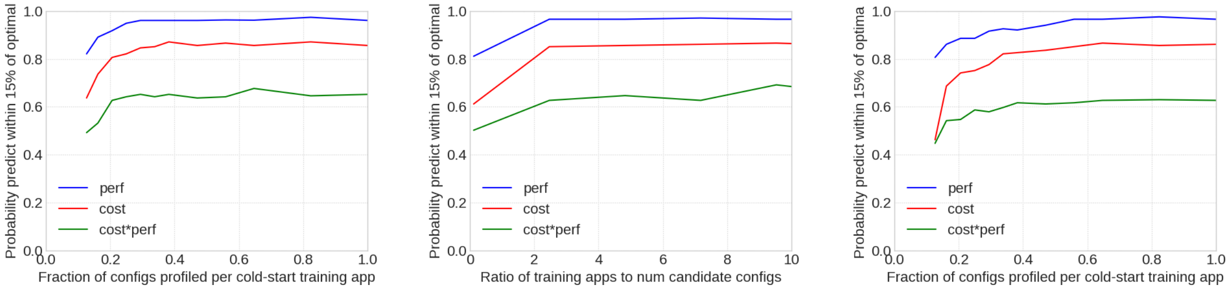
4.4 Sensitivity Analysis

We perform a sensitivity analysis to determine input matrix density requirements for accurate predictions. We look at both the density of matrix rows (i.e., the percentage of candidate configurations that training applications are profiled on) and the density of matrix columns (i.e., the number of training applications used). We also discuss sensitivity to the choice of reference configurations.

Figure 9a shows how Selecta's accuracy for performance, cost and cost*performance objectives varies as a function of input matrix density. Assuming 203 training applications have accumulated in the system over time, we show that, on average across target applications, rows only need to be approximately 20 to 30% dense for Selecta to achieve sufficient accuracy. This means that at steady state, users should profile training applications on about 20-30% of the candidate configurations (including reference configurations). Profiling additional configurations has diminishing returns.

Next, we consider a cold start situation in which a user wants to jump start the system by profiling a limited set of training applications across all candidate configurations. Figure 9b shows the number of training applications required to achieve desired accuracy. Here, for each target application testing round, we take the 203 training applications we have and randomly remove a fraction of the rows (training applications). We ensure to drop the row corresponding to the different dataset scale factor run of the target application, to ensure Selecta's accuracy does not depend on a training application directly related to the target application. Since the number of training applications required to achieve desirable accuracy depends on the size of the configuration space a user wishes to explore, the *x*-axis in Figure 9b represents the ratio of the number of training applications to the number of candidate configurations, *R*. We find that to jump start Selecta with dense training data from a cold start, users should provide 2.5× more training applications than the number of candidate configurations to achieve desirable accuracy. In our case, jump starting Selecta with more than $43 = \lceil 2.5 \times 17 \rceil$ training applications profiled on all 17 configurations reaches a point of diminishing returns.

Finally, we investigate whether, a cold start requires profile training applications on all configurations. We use *R*=2.5, which for 17 candidate configurations corresponds to using 43 training applications. Figure 9c plots accuracy as we vary the percentage of candidate configurations on which the training applications are profiled (including reference configurations, which we assume are always profiled). The figure shows that for a cold start, it is sufficient for users to profile the initial training applications on 40% to 60% of candidate configurations. As Selecta continues running and accumulates more training applications, the percentage of configura-



(a) Sensitivity to input matrix density in *steady state*: 20% density per row suffices for accurate predictions.

(b) Sensitivity to number of training applications, profiled on all configurations: 2.5× the number of configs suffices.

(c) Sensitivity to input matrix density for *cold start*: ∼50% density per row (training application) required.

Figure 9: Sensitivity analysis: accuracy as a function of input matrix density

tions users need to profile for training applications drops to 20-30% (this is the steady state result from Figure 9a).

We experimented with different reference configurations for Selecta. We find that accuracy is not very sensitive to the choice of references. We saw a slight benefit using references that have different VM and storage types. Although one reference configuration must remain fixed across all application runs since it is used to normalize performance, we found that the reference configuration used for the second profiling run could vary without significant impact on Selecta's accuracy.

5 Cloud Storage Insights

Our analysis of cloud configurations for data analytics reveals several insights for cloud storage configurations. We discuss key takeaways and their implications for future research on storage systems.

NVMe storage is performance and cost efficient for data analytics: We find that configurations with NVMe Flash tend to offer not only the best performance, but also, more surprisingly, the lowest cost. Although NVMe Flash is the most expensive type of storage per GB/hr, its high bandwidth allows applications to run significantly faster, reducing the overall job execution cost.

On average across applications, we observe that *l*-NVMe Flash reduces job completion time of applications by 27% compared to *r*-SSD and 75% compared to *r*-HDD. Although we did not consider *l*-SSD or *l*-HDD configurations in our evaluation, we validate that local versus remote access to HDD and SDD achieves similar performance since our instances have sufficient network bandwidth (up to 10 Gb/s) and modern networking adds little overhead on top of HDD and SSD access latency [8]. In contrast, a previous study of Spark applications by Ousterhout et al. concluded that optimizing or eliminating disk accesses can only reduce job completion time by a median of at most 19% [50]. We believe the main reason for the increased impact of storage on end-to-end application performance is due to the newer version of Spark we use in our study (v2.1.0 versus v1.2.1). Spark has evolved with numerous optimizations targeting CPU efficiency, such as cache-aware computations, code generation for expression evaluation, and serialization [17]. With ongoing work in optimizing the CPU cycles spent on data analytics computations, for example by optimizing the I/O processing path [66], we expect the choice of storage to be of even greater importance.

The need for flexible capacity and bandwidth allocation: Provisioning storage involves selecting the right capacity, bandwidth, and latency. Selecta uses statistics from Spark logs to determine capacity requirements and applies collaborative filtering to explore performance-cost trade-offs. However, the cost-efficiency of the storage configuration selected is limited by numerous constraints imposed by cloud providers. For example, for remote block storage volumes, the cloud provider imposes minimum capacity limits (e.g., 500 GB for *r*-HDD on AWS) and decides how data in the volume is mapped to physical devices, which directly affects storage throughput (e.g., HDD throughput is proportional to the number of spindles). A more important restriction is for local storage, such as *l*-NVMe, which is only available in fixed capacities attached to particular instance types. The fixed ratio between compute, memory and storage resources imposed by cloud vendors does not provide the right balance of resources for many of the applications we studied. For example the SQL equijoin query on two 64 GB tables saturates the IOPS of the 500 GB NVMe device on a `i3.xl` instance, but leaves half the capacity underutilized. Furthermore, local storage is ephemeral, meaning instances must be kept on to retain data on local devices. Thus, although we showed it is cost-efficient to store input/output and intermediate data on *l*-NVMe for the duration of a job, storing input/output files longer term on *l*-NVMe would dramatically increase cost compared to using remote storage volumes or an object storage system such as S3.

We make the case for a fast and flexible storage option in the cloud. Emerging trends in cloud computing, such as serverless computing offerings like AWS Lambda, Google Cloud Functions and Azure Functions, provide fine-grain, pay-per-use access to compute and memory resources [31, 7, 28, 46]. Currently, there is no option that allows for fine-grain capacity and bandwidth allocation of cloud storage with low latency and high bandwidth characteristics [41]. Although S3 provides pay-per-use storage with high scalability, high availability and relatively high bandwidth, we show that data analytics applications benefit from even higher throughput (i.e., NVMe Flash). S3 also incurs high latency, which we observed to be a major bottleneck for short-running SQL queries that read only a few megabytes of data.

Disaggregated NVMe is a promising option for fast and flexible cloud storage: Disaggregating NVMe Flash by enabling efficient access to the resource over the network is a promising option for fast and flexible cloud storage. Recent developments in hardware-assisted [49, 44] and software-only [40] techniques enable access to remote NVMe devices with low latency overheads over a wide range of network options, including commodity Ethernet networking with TCP/IP protocols. These techniques allow us to build disaggregated Flash storage that allows fine-grain capacity and IOPS allocation for analytics workloads and independent scaling of storage vs. compute resources. Applications would allocate capacity and bandwidth on demand from a large array of remotely accessible NVMe devices. In this setting, Selecta can help predict the right capacity and throughput requirements for each data stream in an analytics workload to guide the allocation of resources from a disaggregated Flash system.

There are several challenges in implementing flexible cloud storage based on disaggregated Flash. First, networking requirements can be high. Current NVMe devices on AWS achieve 500 MB/s to 4 GB/s sequential read bandwidth, depending on the capacity. Write throughput and random access bandwidth is also high. The networking infrastructure of cloud systems must be able to support a large number of instances accessing NVMe Flash remotely with the ability to burst to the maximum throughput of the storage devices. An additional challenge with sharing remote Flash devices is interference between read and write requests from different tenants [40, 61]. We observed several cases where separating input/output data and intermediate data on *r*-SSD (or S3) and *l*-NVMe, respectively, led to higher performance (and lower cost) than storing all data on *l*-NVMe. This occurred for jobs where large input data reads overlapped with large shuffle writes, such as for TPC-DS query 80 shown in Figure 1. A disaggregated Flash storage system must address interference using either scheduling approaches [40, 47, 61, 51, 60] or device-level isolation mechanisms [12, 54, 38]. Finally, the are interesting trade-offs in the interfaces used to expose disaggregated Flash (e.g., block storage, key-value storage, distributed file system, or other).

The need for end-to-end optimization: In our experiments, remote HDD storage performed poorly, despite its cost effectiveness for long-living input/output data and its ability to match the sequential bandwidth offered by SSD. Using the Linux `blktrace` tool [37] to analyze I/O requests at the block device layer, we found that although each Spark task reads/writes input/output data sequentially, streams from multiple tasks running on different cores interleave at the block device layer. Thus, the access stream seen by a remote HDD volume consists of approximately 60% random I/O operations, dramatically reducing performance compared to fully sequential I/O. This makes solutions with higher throughput for random accesses (e.g., using multiple HDDs devices or Flash storage) more appropriate for achieving high performance in data analytics. Increasing random I/O performance comes at a higher cost per unit time. In addition to building faster storage systems, we should attempt to optimize throughout the stack for sequential accesses when these accesses are available at the application level. Of course, there will always be workloads with intrinsically random access patterns that will not benefit from such optimizations.

6 Discussion

Our work focused on selecting storage configurations based on their performance and cost. Other important considerations include durability, availability, and consistency, particularly for long-term input/output data storage [42]. Developers may also prefer a particular storage API (e.g., POSIX files vs. object interface). Users can use these qualitative constraints to limit the storage space Selecta considers. Users may also choose different storage systems for high performance processing versus long term storage of important data.

Our study showed that separating input/output data and intermediate data uncovers a richer configuration space and allows for better customization of storage resources to the application requirements. We can further divide intermediate data into finer-grained streams such as shuffle data, broadcast data, and cached RDDs spilled from memory. Understanding the characteristics of these finer grain streams and how they should be mapped to storage options in the cloud may reveal further benefits.

Compression schemes offer an interesting trade-off between processing, networking, and storage requirements. In addition to compressing input/output files, systems like Spark allow compressing individual intermediate data streams using a variety of compression algorithms (lz4, lzf, and snappy) [64]. In future work, we plan to extend Selecta to consider compression options in addition to storage and instance configuration.

We used Selecta to optimize data analytics applications as they represent a common class of cloud workloads. Selecta's approach should be applicable to other data-intensive workloads too, as collaborative filtering does not make any specific assumptions about the application structure. In addition to considering other types of workloads, in future work, we will consider scenarios in which multiple workloads share cloud infrastructure. Delimitrou et al. have shown that collaborative filtering can classify application interference sensitivity (i.e., how much interference an application will cause to co-scheduled applications and how much interference it can tolerate itself) [22, 23]. We also believe Selecta's collaborative filtering approach can be extended to help configure isolation mechanisms that limit interference between workloads, particularly on shared storage devices like NVMe which exhibit dramatically different behavior as the read-write access patterns vary [40].

7 Related Work

Selecting cloud configurations: Several recent systems unearth near-optimal cloud configurations for target workloads. CherryPick uses Bayesian Optimization to build a performance model that is just accurate enough to distinguish near-optimal configurations [3]. Model input comes solely from profiling the target application across carefully selected configurations. Ernest predicts performance for different VM and cluster sizes, targeting machine learning analytics applications [69]. PARIS takes a hybrid online/offline approach, using random forests to predict application performance on various VM configurations based on features such as CPU utilization obtained from profiling [71]. These systems do not consider the vast storage configuration options in the cloud nor the heterogeneous data streams of analytics applications which can dramatically impact performance.

Resource allocation with collaborative filtering: Our approach for predicting performance is most similar to Quasar [23] and Paragon [22], which apply collaborative filtering to schedule incoming applications on shared clusters. ProteusTM [24] applies collaborative filtering to auto-tune a transactional memory system. While these systems consider resource heterogeneity, they focus on CPU and memory. While Selecta applies a similar modeling approach, our exploration of the cloud storage configuration space is novel and reveals important insights.

Automating storage configurations: Many previous systems provide storage configuration recommendations [9, 65, 2, 48, 4, 30, 39]. Our work analyzes the trade-offs between traditional block storage and object storage available in the cloud. We also considering how heterogeneous streams in data analytics applications should be mapped to heterogeneous storage options.

Analyzing performance of analytics frameworks: While previous studies analyze how CPU, memory, network and storage resources affect Spark performance [50, 68, 66, 43], our work is the first to evaluate the impact of new cloud storage options (e.g., NVMe Flash) and provide a tool to navigate the diverse storage configuration space.

Tuning application parameters: Previous work auto-tunes data analytics framework parameters such as the number of executors, JVM heap size, and compression schemes [32, 73, 72]. Our work is complementary. Users set application parameters and then run Selecta to obtain a near-optimal hardware configuration.

8 Conclusion

The large and increasing number of storage and compute options on cloud services makes configuring data analytics clusters for high performance and cost efficiency difficult. We presented Selecta, a tool that learns near-optimal configurations of compute and storage resources based on sparse training data collected across applications and candidate configurations. Requiring only two profiling runs of the target application, Selecta predicts near-optimal performance configurations with 94% probability and near-optimal cost configurations with 80% probability. Moreover, Selecta allowed us to analyze cloud storage options for data analytics and reveal important insights, including the cost benefits of NVMe Flash storage, the need for fine-gain allocation of storage capacity and bandwidth in the cloud, and the need for cross-layer storage optimizations. We believe that, as data-intensive workloads grow in complexity and cloud options for compute and storage increase, tools like Selecta will become increasingly useful for end users, systems researchers, and even cloud providers (e.g., for scheduling 'serverless' application code).

Remote regions: a simple abstraction for remote memory

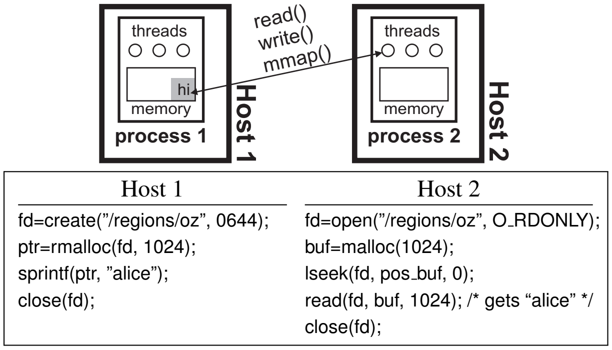
Abstract

We propose an intuitive abstraction for a process to export its memory to remote hosts, and to access the memory exported by others. This abstraction provides a simpler interface to RDMA and other remote memory technologies compared to the existing *verbs* interface. The key idea is that a process can export parts of its memory as files, called *remote regions*, that can be accessed through the usual file system operations (read, write, memory map, etc). We built this abstraction in the Linux kernel, and evaluated it. We show that remote regions are easy to use and perform close to RDMA. We demonstrate it via micro-benchmarks and by adapting two in-memory single-host applications to use remote memory: R and Metis. With R, using remote regions requires no changes to the code and allows R to run with remote memory that exceeds the physical memory of a host. With Metis, the modifications amount to ≈100 lines of code and they allow Metis to scale its performance across 8 hosts.

1 Introduction

Remote memory allows a process to read and write the memory of another process in a different host. This is an exciting idea whose time has come [1]. Remote memory is available now, using RDMA technology over Infiniband or Ethernet [49, 29], and other new technologies are emerging [28, 24, 47]. Many applications are being redesigned to use remote memory (key-value storage systems [43, 14, 30, 15], database systems [50, 6, 64], map-reduce [39], etc).

Unfortunately, remote memory faces two problems now. First, it has no standard interface. Current technology uses the RDMA verbs interface, but new hardware such as Gen-Z and OpenCAPI will have their own interfaces to control mapping, access, etc. Even RDMA is still changing with key innovations, such as DCT [18], that are offered in some implementations but not others. Second, remote memory today is hard to use. With RDMA, even the simplest program to access some data from a remote host requires a complex ritual: code is required to initialize contexts, register memory, establish RDMA connections, create queue-pairs, associate them with connections, transition the queues through various states, exchange RDMA keys, post commands on queues, and poll the queues for completions [7]. Furthermore, RDMA lacks naming and location services that applications need, forcing them to reimplement this functionality every time.



Host 1	Host 2
fd=create("/regions/oz", 0644);	fd=open("/regions/oz", O_RDONLY);
ptr=rmalloc(fd, 1024);	buf=malloc(1024);
sprintf(ptr, "alice");	lseek(fd, pos_buf, 0);
close(fd);	read(fd, buf, 1024); /* gets "alice" */
	close(fd);

Figure 1: Using regions, Host 1 creates a region named *oz* in REGIONFS, allocates a buffer in the region, and populates the buffer. Host 2 then reads host 1's string, similar to an RDMA-read operation, except that developers need not program with RDMA directly (which is complex).

In this paper, we propose a simple idea: to use files as the interface to remote memory, shedding the complexity of RDMA and providing a standard for new technologies. In particular, we propose *remote regions* or, in short, *regions*. With regions, a process exports parts of its memory as *files* in REGIONFS, a file system that a remote host can then access using the usual file operations (read, write, memory map, etc). In addition to a simple interface, regions draw features from file systems to provide functionality lacking in RDMA: name space, timestamps, access control, etc (§4).

Regions are simple because they replace low-level RDMA mechanisms with high-level controls that are operated through a familiar interface. Figure 1 shows how easily a host can use regions to read data in the memory of another host. By contrast, equivalent RDMA logic takes around 300 lines of hard-to-understand code [7].

The main challenge in designing regions is to find the right balance between elegance, expressiveness, and efficiency, while overcoming the limitations of the hardware. To find this balance, we address questions of file semantics, memory allocation, data sharing, memory mapping, page fault preemption, security, data-metadata separation, caching, cache coherence, and sharing granularity, while addressing RDMA limits on memory registration, connections, and keys. The current implementation of regions targets RDMA, but we believe region's interface will be applicable to new upcoming remote memory technologies [24, 28], providing a common abstraction with which applications can be written in a portable fashion across these new technologies.

We have built regions using RDMA in the Linux kernel v4.8, and we evaluated their cost on a cluster of 8 machines with RoCE. Using microbenchmarks, we see that accessing data via regions is reasonably close to RDMA. We have used regions to extend two applications, R [48] and Metis [41], to use remote memory. R is a system for statistical processing of data, while Metis is an in-memory implementation of map-reduce running on a single host. We use regions to adapt R to operate on large data sets in remote memory exceeding the available local memory capacity. We do this by using R's ff package to store objects in memory-mapped files, and placing these files in REGIONFS. We also use regions to produce a distributed version of Metis that runs across many hosts, sharing in-memory data. This change required only 82 lines of code, and allows Metis to scale to 8 hosts, giving it more memory and improving performance by 3.5× compared to a single host.

2 Related work

Same interface, different goal. The file interface is often used for *remote storage*, where the main goal is to provide durable storage capacity. Several such systems use RDMA to improve performance, such as Octopus [40], Crail [57], Ceph [11], and GlusterFS [25]. DAFS [13] is a file system protocol for RDMA, while [60] is a proposal to run NFS over RDMA. The file interface can also be used to manage large local memories [58]. All of the above works rely on a file interface but have a different goal from our goal of accessing the memory of remote applications.

Different interface, same goal. Prior work provides remote memory with a different interface. LITE [61] provides a kernel interface that offers more flexible protection, and better scalability and isolation than verbs on RDMA. There is much work in distributed shared memory (DSM) (e.g., [9, 33, 46, 2, 51, 53, 56, 8]) including recent work on persistence using non-volatile memory and replication [54]. FaRM [14, 15] provides transactions over RDMA with lock-free reads. All these systems provide a simpler interface than RDMA, but they do not support the well-known file interface, which has many advantages (§4).

Different interface, different goal. Many systems provide remote storage with an interface other than files, including key-value stores (e.g., [43, 14, 30, 15]), Linda tuples [10], distributed objects (e.g., [63, 27, 5]), and database systems. These systems offer a different abstraction from regions. For example, key-value stores provide GETs and PUTs on key-value pairs; Linda provides a tuple interface; distributed objects require applications to declare and manipulate the objects provided by the framework; and database systems use SQL.

Remote memory applications. Several works have proposed replacing disks with remote memory as a faster target for swapping or paging (e.g., [23, 12, 34, 21, 31, 22, 17]). CacheDM [36] uses remote memory as a cache for a network file system, while Infiniswap [26] uses remote memory as a cache for a local swap/paging device. Several of these applications are built with RDMA; they might have been simpler to develop with regions.

New hardware. Disaggregated memory proposes a new system architecture that detaches memory from machines and places it on a common fabric. The work includes academic papers [26, 37, 20, 4, 23, 45] and upcoming technologies to support it, such as Gen-Z [24] and Omni-Path [28]. Regions could provide an elegant interface to disaggregated memory, though the implementation of regions will differ from the RDMA implementation we give (that will depend on the details of these technologies, which are still work in progress).

3 Assumptions, goals, and motivation

We assume machines are connected to a network with low latency, high bandwidth, and reliable connectivity—such as, for example, machines in a few racks in a data center. We assume a single administrative, trust, and fault domain. We consider deployments with a couple to tens of machines. While some companies have large deployments with thousands of machines, the vast bulk of our customers are enterprises with deployments of 100 or fewer machines in a private facility, and that is our target environment. Network partitions are rare and, when they do occur, it is reasonable for the system to pause as the rest of the system will be unavailable anyways (e.g., network file systems and other servers are unreachable).

Our goal is to provide abstractions for applications to access the memory of other applications across the network. Currently, the standard way to do that is to employ one-sided read and write operations using the verbs library (libibverbs [35]). This interface has three issues that we want to overcome:

- *Complexity.* As we mentioned, verbs operations are complex, and we seek simple and intuitive alternatives.
- *Dependency on existing technology.* There are other remote memory technologies under development other than RDMA, such as Omni-Path [28] and Gen-Z [24]. We would like to find high-level abstractions so that applications can be portable across these technologies.
- *Resource limitations.* RDMA has limitations on resources at the network adapter, such as limited cache sizes for connections and memory translations [14]. We

want to design abstractions that can hide or overcome these limitations without concerning applications.

We expect a simpler interface to have performance costs but want them to be reasonable and we certainly want to understand them, much like a developer needs to understand the cost of other high-level features, such as garbage collection, lambdas, etc.

4 Why files?

By using a file interface, regions get many benefits:

- *Well-known.* All developers know files.
- *Utilities.* The file interface inherits a vast repertoire of utilities: editors, backup, grep, find, cp, cat, sed, awk, etc. Regions allow these to be used with remote memory.
- *Language support.* Most of the functionality of regions is in REGIONFS, and all major programming languages support files. There is only a small library (with synchronization and stub functions) that needs to be ported to a given language.
- *Interposition support.* There are many tools to interpose on file system calls, for tracing, debugging, auditing, and profiling (e.g., DFSTrace [44]). These tools all work with REGIONFS.
- *Name space.* Directories and files make it easy to find and organize data across applications in the network.
- *Users and access permissions.* Applications can use the notion of users from the operating system combined with access permissions to control who has access.

We get these benefits for free because the file interface is well matched to our problem. In contrast, other interfaces to remote memory, such as RDMA, provide none of these benefits.

5 The regions abstraction

We now explain how regions appear to users as an abstraction, and we explain how we arrived at this abstraction. We show how to provide the abstraction in §6.

In its simplest form, a (remote) region is a logically contiguous part of the memory of a process, called the *owner* process. The owner creates a region like a file, and can operate on it by memory mapping, reading, writing, or allocating variables using a special *rmalloc* function (§5.2); these operations refer to data in local memory. Processes in other hosts can also perform these operations, to access data in the memory of the owner.

5.1 Basic functions

Regions provide a file system called REGIONFS mounted in a known location, such as /regions. Each file in REGIONFS is a region stored in memory, either locally or remotely. REGIONFS supports the usual file operations (e.g., creat, unlink, open, close, read, write, chmod, stat) in addition to mmap (§5.7). By default, a region disappears when its creator process terminates or crashes (accessing it results in an I/O error).

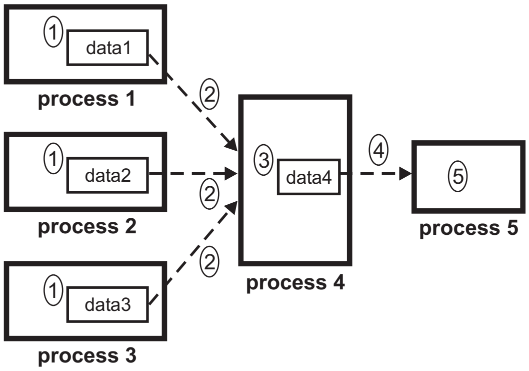


Figure 2: Example of the use of regions on a map-reduce style of computation. (1) Three mapper processes in different hosts create a region each, run some computation, and store the results in their region; (2) a fourth reducer process reads the data in the regions, and (3) creates a region and writes the result there; (4) a fifth process reads that region and (5) produces a graph in the display of a user.

A directory in REGIONFS is not a region but organizes regions, much like regular file systems; but unlike regular file systems, directories carry some special extended attributes that regions inherit upon creation (§5.4).

5.2 Memory allocation

An application often dynamically allocates and destroys many buffers in its lifetime. Rather than creating/deleting a region for each buffer, applications can dynamically allocate/free buffers *within* a region, using these functions:

```
void *rmalloc(int regionfd, size_t len)
int rfree(void *ptr)
```

where *regionfd* is a descriptor for a region open in write mode. Calling *rmalloc* is faster than creating a region: the former executes entirely in memory, while the latter requires contacting a metadata manager over the network (§6.6). In fact, an application might create just one region and then allocate its buffers within that region.

5.3 Example of usage

We illustrate the use of a region with an example with five processes that run a map-reduce style of computation (Figure 2). In existing map-reduce systems, processes exchange data using a distributed file system such as the Hadoop Distributed File System (HDFS) [3]. With regions, processes can exchange data directly in memory, as with RDMA, but with the simplicity of using files. Also, this is distinct from using an RDMA-enabled file system (e.g., [40, 11, 25]), where processes store data in a storage server and use RDMA to access the server; with regions, processes can directly export data in *their* memory and read data from the memory of other processes.

Attribute	Type	Description
OWNERPID	pid_t	pid of process owning region
PERSISTENT	bool	keep region when process ends (§5.5)
MULTIHOSTED	bool	store region across many hosts (§5.6)
FIXVADDR	uint64_t	fixed virtual address (§5.7)
ONEWRITER	bool	only one process can open for writing
HOSTALLOC	ip list	hosts storing region if MULTIHOSTED (§5.6)

Figure 3: Region-specific attributes.

5.4 Region attributes

Beyond the attributes of a typical file (access bits, uid, gid, etc), each region has some additional region-specific metadata that determine certain behaviors (Figure 3). The owner indicates the process who created the region; this is different from the owner uid of a region/file, which is a user. When this process ends, the region is automatically deleted unless the PERSISTENT attribute is set (§5.5). A region gets a fixed virtual address across hosts if FIXVADDR is set (§5.7). A region can be opened for writing by at most one process if ONEWRITER is set; this is enforced across hosts. When a region grows in size, new memory is typically allocated from the host of the owner, but it is possible to allocate it from remote hosts as well if MULTIHOSTED is set, in which case HOSTALLOC indicates the hosts to allocate from (§5.6).

Applications set these attributes when the region is created. Since we use the standard creat() call to create regions, which cannot specify attributes, we define an additional function

```
int rsetdefaultattr(int attr, char *val, int len) /* returns error flag */
```

that sets the default attributes of new regions for the calling thread.

5.5 Persistent regions

By default, a region is backed by the memory of a process. If the process terminates, its memory is deallocated and the region is automatically deleted. This could be undesirable in some cases: the process might wish to leave the data in memory for a short while until it is consumed by another process. One solution to this problem is for the process to defer its termination until its data has been consumed. This solution is complex because it requires the process to coordinate with other applications.

We provide a simpler solution: to retain the region contents after the process terminates. Upon termination, a process releases its memory but not the region. We call such regions *persistent* regions. Persistent regions should be deleted by the consuming process later. They are also deleted when the host reboots. To create a persistent region, a process sets the attribute PERSISTENT.

5.6 Multi-hosted regions

A multi-hosted region is a special type of region that is stored across many hosts. These regions can store large data that exceed the physical memory of any single host.

To create a multi-hosted region, a process sets attribute MULTIHOSTED and optionally chooses the hosts where the region will be allocated via attribute HOSTALLOC (§5.4); if this is not set, the default is to use all hosts.

5.7 Memory mapping

Processes can memory map a region using mmap(), so that the region can be accessed by memory operations instead of read() and write(). The function returns a pointer where the region is mapped. If a region is created with the FIXVADDR attribute, it is given a fixed virtual address [54]: it always maps to that address, no matter which process or host maps the region. This ensures that pointers to data in regions remain valid across hosts, allowing regions to store dynamic data structures and other data that require indirection. To implement this feature, we reserve virtual addresses across the cluster (§6.10).

5.8 Performance enhancing functions

Memory mapping of a region on a remote host is implemented using page faults. Page faults have two causes: (1) when a process first accesses a page, to fetch the page; (2) when the process first writes to the page, to mark it dirty. If the first access is a write, one page fault both fetches and marks it dirty. Because page faults are expensive, we provide two ways to prevent them: prefetch and mark-dirty. With prefetch, applications request the system to fetch pages immediately, by calling

```
int rprefetch(void *addr, size_t len, bool sync) /* ret: error flag */
```

which prefetches data in a region starting at *addr* with length *len*; if *sync* is set, it waits until the data it fetched. To avoid page faults due to writes, applications can request the system to mark the page dirty, by calling

```
int rmarkdirty(void *addr, size_t len, bool zero) /* ret: err flag */
```

before writing to a page. If parameter *zero* is true, this function zeroes the pages without reading their contents. This is useful to avoid the overhead of a read-modify-write cycle if the application intends to completely overwrite the pages (see §8.3).

Function rprefetch is just an optimization that does not change application semantics. Function rmarkdirty is also an optimization when parameter *zero* is false; if *zero* is true, rmarkdirty is equivalent to bzero().

5.9 Synchronization

When using regions, one might need to synchronize processes across hosts (e.g., to share data, as in §5.3). We provide several distributed synchronization primitives: barriers, mutexes, and door bells (Figure 4). These are

Function	Description
rbarrier_init(name, n)	Create barrier for *n* callers
rbarrier_wait(name)	Wait for barrier
rmutex_init(name)	Create mutex
rmutex_lock	Acquire mutex
rmutex_unlock	Release mutex
rbell_init(name)	Create door bell
rbell_ring(name)	Increment bell value
rbell_wait(name)	Wait for new value, return it
rdelete(name)	Deallocate

Figure 4: Available synchronization primitives.

offered in a user library, since a file system has no such functionality. A barrier has a parameter *n* and the caller blocks until the barrier has been called at least *n* times. This serves to synchronize a group of processes. A mutex ensures at most one caller gets the mutex at once. A door bell has an initial value 0; the ring function increments it; the wait function waits for it to be incremented since its last call, returning the current value.

5.10 Caching

When a process uses a region of a different host, the system locally maintains a page cache of data that has been recently read or that has been modified. The cache is a write-back cache (modifications are propagated back to the region in the background). The system does not provide cache coherence, because it is too expensive; rather applications can obtain coherence at the moments of their choice by explicitly using two mechanisms, flushing and clearing caches:

```
int msync(void *addr, size_t len, int flags) /* returns error flag */
int rclearcache(void *addr, size_t len) /* return error flag */
```

where addr is the address within one of the open regions. Flushing [msync] causes dirty pages to be written back to the region, so the owner can observe the modified data. Clearing pages [rclearcache] removes them from the cache, so that the calling process subsequently obtains fresh data from the owner. These functions produce an effect only at a process remote to the region or for multi-hosted regions, as the owner of single-hosted region does not have a cache. After clearing a page, a process might invoke rprefetch() to avoid a page fault (§5.8).

Processes sharing a region must follow some discipline on how to use these functions to avoid data corruption. We propose a simple and effective scheme in the next section.

5.11 Sharing data

To correctly share data, processes must flush and clear their caches carefully. Doing so is not easy in general, but we now describe a simple scheme that works well in the use cases that regions are designed for. To explain how this is done, we broadly classify sharing of data alongside two dimensions.

Type	Regions	RDMA
Owner-remote	Owner writes to region and remote process reads, or remote process writes to region and owner reads	One process writes locally and another RDMA-reads, or one process RDMA-writes and another reads locally
Remote-remote	A remote process writes to region and a remote process reads from region	One process RDMA-writes to third party's memory and another RDMA-reads

Figure 5: Two patterns of sharing data between processes in different hosts using regions and the analogue using RDMA.

The first dimension is who participates in the sharing relative to who owns the data. There are two possibilities: owner-remote sharing and remote-remote sharing (Figure 5). With owner-remote sharing, one of the processes sharing owns the region or the memory. With remote-remote, the process that owns the region or memory is a third party. Owner-remote sharing is simpler to deal with, because there is only one cache involved (the cache of the remote process), while remote-remote sharing involves two caches, one for each remote process.

The second dimension is what we call the *granularity of sharing*. With fine-grained sharing, processes interleave their execution often and share small bits of data (e.g., one or a few variables) at a time, with frequent coordination. For example, in a mutual exclusion algorithm, two processes frequently read and write common variables containing the state of flags or counters, often changing the role of who reads and writes the shared information. With coarse-grained sharing, one process produces a large chunk of data before another process consumes it; for example, in the map-reduce computation of Figure 2, the mappers produce large outputs that are later consumed by the reducer.

We anticipate that regions will be used for both owner-remote and remote-remote sharing alongside the first dimension, but only for coarse-grained sharing alongside the second dimension, because fine-grained sharing over the network is generally too costly. Coarse-grained sharing does not require the cache to be coherent very often: it suffices to be coherent in the instant after the producer has finished writing and before the consumer starts reading. Accordingly, processes can flush or clear their caches at that moment, as follows. With owner-remote sharing, the remote process either flushes or clear its cache, depending on whether it is producing or consuming data. With remote-remote sharing, the remote process that produces data flushes its cache, while the remote process that consumes data clears its cache.

5.12 Pseudo file system

Regions have more metadata than files. We expose this metadata to users in a pseudo file system /proc/regions,

File name	Description
hosts	List of hosts using regions
memusage	Aggregate memory usage of regions hosted locally
pools	List of pools (§6.7) with used/free space and daemon's logical address
daemon	pid of daemon process (§6.4)
procs	pid of local processes using regions
files/*pathname*	Metadata of region in *pathname*: vaddr, maximum size, pool, attributes

Figure 6: Region metadata stored in pseudo file system /proc/regions.

accessible only by root. Available Information includes local memory usage of regions, a list of local pools, and the local processes using regions (Figure 6). Moreover, for each region *r*, /proc/regions/files/*r* indicates the region's fixed virtual address, maximum size, pools from which memory is allocated, and attributes.

5.13 Limitations

Regions have a limitation: a process cannot use them to export data in its stack or static variables, because the process must allocate data in regions using rmalloc. However, these limitations may not matter: it is easy to change static variables to heap variables, and it is probably a bad idea for applications to export data in the stack, since that data disappears when its call frame is deleted.

6 Realizing regions using RDMA

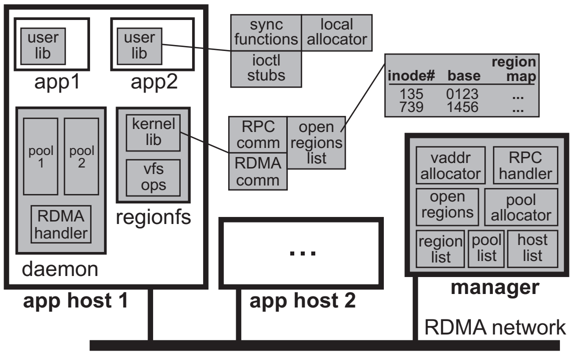
We now describe how we realize regions using RDMA. While the design is centered around RDMA, we expect that its key ideas will be applicable to future disaggregated memory hardware.

6.1 Basic architecture

Figure 7 shows the architecture of regions. There are four main logical components: REGIONFS file system, user library, daemon, and manager. Broadly, the REGIONFS file system component implements the VFS kernel operations required of a file system, while the user library implements synchronization and performance-enhancing functions. The first module is instantiated once per host; the second, once per application. The daemon (one per host) allocates and maintains large pools of memory in which regions are allocated, and shares these pools with both local and remote processes. The manager provides the control plane, handling every file system operation except reading and writing data. The manager has one instance but it is replicated for high availability using standard mechanisms, such as Paxos state machine replication [32, 52]. We provide more details in the next sections.

6.2 RegionFS file system component

This component is a kernel module that implements the file system for region, with functionality to drive the execution of file system operations, coordinating with the manager and the other hosts' daemons. The module keeps an important data structure, the open region list, which tracks all regions that the application has opened, with their virtual addresses, and map for locating the data within the region. We detail the VFS operations in §6.6 after some more background, but they fall into two categories: Data operations (read, write, readpage, etc) execute locally or over RDMA, depending on where a region resides. Metadata operations (directories, file attributes, etc) are similar to the implementation of a network file system (e.g., to create a directory, it calls the manager, which then records information about the directory).



Module	Description	Section
regionfs	file system for regions	§6.2
user lib	user-level file system	§6.3
daemon	holds and exports memory pools	§6.4
manager	handles control operations	§6.5
sync funcs	barrier, mutex, doorbell	§6.3
local alloc	kmalloc	§6.3
ioctl stubs	functions without VFS analogues	§6.3
kernel lib	communication library	§6.12
RPC comm	for communicating with manager	§6.12
RDMA comm	for communicating with daemons	§6.12
open regions list	list of regions that client has opened	§6.2
region map	tracks where a region is stored	§6.8
vfs ops	VFS interface to file system	§6.6
RDMA handler	accepts RDMA connections	§6.12
vaddr allocator	allocates virtual addresses	§6.10
RPC handler	handles requests from clients	§6.12
open regions	all open regions in the system	§6.5
pool allocator	allocates cluster memory	§6.9
region list	all regions in the system	§6.5
pool list	all pools in the system	§6.5
host list	keep track of hosts	§6.5

Figure 7: Architecture. Region components are in gray. The figure shows two application hosts, but we expect a few dozens of them. There is a single manager, and it is replicated for fault tolerance. The manager is involved only in infrequent control operations, staying out of the performance-critical data path.

6.3 User library component

The user library provides the synchronization functions (§5.9), an allocator for rmalloc (§5.2), and ioctl stubs. The synchronization functions issue an RPC to the manager, which implements the actual functionality. The RPC call blocks until the synchronization occurs (e.g., a barrier gets all its participants). For the rmalloc allocator, we memory map the region (if it has not been mapped already) and organize the space using a buddy allocator. The allocator uses a magic number at the beginning of the region to know if the allocator structures must be initialized. The ioctl stubs provide region-specific functions without a corresponding VFS operation (rsetdefaultattr (§5.4), rprefetch (§5.8), rmarkdirty (§5.8), rclearcache (§5.10)). The stubs translate these functions into ioctl's that get handled by VFS.

6.4 The daemon

The daemon serves three purposes. First, it overcomes resource limitations of the RDMA network adapter, which cannot keep many connections or export many buffers because its internal cache is small [14]. To address these problems, the daemon allocates big pools of physical memory (§6.7) and then allocates regions within these pools. Thus, a host exports a few pools (rather than many regions) and a remote process can connect just with the daemon to access the data of all applications in the host (instead of connecting to each application). Second, the daemon allows a host to offer memory to multi-hosted regions (§5.6) even if the host has no running applications. Third, the daemon supports persistent regions (§5.5) by holding the region's data when a process terminates.

6.5 Manager

A central manager handles all control operations: creation, opening, closing, deletion, and memory-mapping of regions; file system metadata operations (create and delete directories, set and get inode attributes); allocation of memory for regions; and allocation of global virtual addresses. To do that, the manager keeps track of the hosts in the system, file system metadata (inodes and directory contents), memory usage of all pools at each host, allocation of regions, allocation of virtual addresses, and list of all open regions. The manager is not involved in reading and writing data in regions—the performance critical operations—so it is not a bottleneck. However, a larger system might require distributing the manager.

6.6 VFS operations

To open a region [open()], the client calls the manager; if the region exists, the manager returns its starting virtual address and region map (§6.8); the client adds the region to its open regions list and stores its virtual address and region map. To create a region, the client calls the manager to check if the region already exists, to preallocate an initial set of pages to it, to allocate virtual addresses (§6.10), and to return the starting virtual address and region map, which the client stores.

To read a region [read()], the client consults the region map and issues RDMA read(s) to the proper host(s); it then copies the result to the user-provided buffer. To write a region [write()], the client checks if the write falls outside the preallocated space for the region; if it does, it contacts the manager to extend the region and the region map; then, the library copies the user-provided buffer into RDMA-registered memory, consults the region map to determine the host(s) to contact, and issues RDMA-write(s) to the proper host(s).

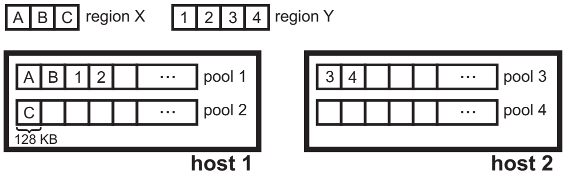


Figure 8: Four pools in two hosts. Region X stores its data in two pools of a host. Region Y is multi-hosted, spanning pools of two different hosts.

To prefetch data [ioctl for rprefetch()], the client consults the region map to determine where to read the data from, reads over RDMA, and places it in the file system cache. Similarly, to write back [msync()] a page, the client consults the region map, write-protects the page, writes the page over RDMA, and marks the page clean. To mark a page dirty [ioctl for rmarkdirty()], the client sets the dirty bit for the page. To clear a page from the cache [ioctl for rclearcache()], the client evicts it from the file system cache.

6.7 Pools

A *pool* is a chunk of physical memory, at one of the hosts, that is used to store a region or parts thereof (Figure 8). Pools are allocated by the daemon (§6.4) and are shared with local processes (using shared memory) and with remote processes (using RDMA). To share locally, the daemon allocates its pools using anonymous files [38], which are chunks of anonymous memory that can be memory mapped at many processes. More precisely, the daemon creates a pool using memfd_create; then, an application process can memory map the pool at the addresses that correspond to a region that the process needs. Regions need not be contiguous within a pool; however, to reduce the number of memory maps, the daemon allocates the region in large contiguous chunks.

To share its pools with remote hosts, the daemon RDMA-registers each pool so that it can be read and written over RDMA. RDMA provides access control through a key for each buffer that a host exports. Because a pool is a single buffer, this mechanisms is coarse-grained: it provides identical access to all data in the pool.

6.8 Finding region data

A *region map* tracks where a region is stored, by mapping offsets in a region to a host, a pool in that host, and an offset in that pool. The map has entries, each representing a fixed-length contiguous chunk of memory on one pool at one host. There are two aspects to this map: its granularity and how to represent hosts and pools.

Granularity. The granularity involves a trade-off between the size and the flexibility of the map. A small grain leads to a prohibitively large map; a large grain leads to internal fragmentation. A natural size might be the page size (4 KB), but that causes a significant 0.2% space overhead for the map (e.g., 2 GB for a 1 TB region). We chose the granularity to be 128 KB for an overhead of 64 KB for a 1 TB region.

Target representation. We want map entries to take at most 64 bits. We use 47 bits to represent a 64-bit address within a host, by dropping the lower 17 bits and aligning over 2^{17} =128 KB chunks, which coincides with the map granularity above. We use the remaining 17 bits as a global identifier that maps to a host and a pool in that host; this map is kept by the manager ("pool list" box in Figure 7) and cached by the user library.

6.9 Managing memory

There are two aspects to memory management: local and cluster allocation.

Local allocation. Each host has limited memory and one needs to decide how much to reserve for pools and regions. We make this determination locally at each host, where the daemon allocates and frees pools as needed.

Cluster allocation. When an application needs memory, one needs to decide which pool(s) to use; for multi-hosted regions, one needs to also decide which hosts will provide memory. We make this determination in a centralized fashion: the manager knows about all participating hosts, their pools, and the free space in each pool ("pool allocator" box in Figure 7). The manager receives requests to create new regions, with an initial space to preallocate for future region growth. It then decides from what pools to allocate the memory using some allocation policy. The current policy is as follows. For regions in a single host, the manager picks from the pools in that host; if the host does not have enough memory, it asks the daemon to create more pools; if the daemon is unable, the request to create or expand a region fails. For multi-hosted regions (§5.6), the manager picks memory from the hosts in a round-robin fashion, allocating ALLOCSIZE$\geq 2^{17}$ bytes at a time. Note that ALLOCSIZE becomes the maximum contiguous size that a client can transfer in one RDMA request. We pick ALLOCSIZE to be 2 MB—a value large enough to offset the initial fixed costs of an RDMA transfer (with a 40 Gbps network, the initial cost to transfer 2 MB is 0.3% of the total cost).

6.10 Allocating virtual addresses

Regions are assigned a fixed and unique virtual address (§5.7). Therefore, we must ensure that (a) different regions get assigned disjoint virtual addresses, even if they are created by different applications in different hosts, and (b) an application will not use a region's virtual addresses for other purposes. To ensure (a), we use centralization: region creation goes through the manager, who knows about all virtual addresses in use by regions. The manager assigns unique virtual addresses to each region ("vaddr allocator" box in Figure 7). To ensure (b), we reserve a range of virtual addresses for regions using the dynamic linker responsible for loading binaries. There are many ways to do that in Linux. First, we can specify an ET_EXEC object file type in the ELF binary and then create a program header with attributes p_vaddr and p_memsz, indicating the address and size of the virtual address to reserve [19]; this requires statically linking all libraries. Second, we can use a custom dynamic linker that avoids the virtual addresses reserved for regions; we do that by including in the ELF binary an INTERP program header with the path to the linker [16]. These approaches require modifying the application binary. A third approach, which requires no binary changes, is to modify the default dynamic linker, ld-linux.so.

Are there enough virtual addresses? Today, Intel processors use page tables with four levels, addressing 48 bits of addresses; one bit is used by the Linux kernel, leaving 47 bits for applications. If we reserve another bit for regions, that leaves 64 TB for each application and 64 TB for all regions. If that is not enough, Intel plans to support five-level page tables, which add 9 bits of virtual addressing [55]; reserving one bit for regions gives 32 PB for each application and 32 PB for all regions.

6.11 Security

We enforce access control using the file system, which assumes that the kernel is trusted. This provides reasonable security against damage from bugs and human errors, but an attacker of a host gets access to the regions in every host. Providing stronger security is future work.

6.12 Other modules

The kernel lib consists of two kernel modules: (1) RPC comm module implements RPC's to the manager, and (2) the RDMA comm modules establishes a reliable RDMA connection to remote hosts and implements one-sided RDMA read and write. The RPC handler module at the manager handles RPC requests from clients. The RDMA handler at the daemons registers the pools with RDMA, reports the RDMA key and pool address to the manager so that clients can later access the pool, and accepts reliable RDMA connections from remote daemons.

System	Description
rdma	RDMA read or write
nfs-tmpfs	NFS to a ramdisk
tmpfs	local ramdisk
rr	regions
rr+	regions with prefetching

Figure 9: Baselines (top) and systems under study (bottom).

6.13 User-level file interface

An earlier version of REGIONFS was implemented as a user-level file system [42] and a user-level page-fault handler [62]. We found that data operations were faster, because they could use RDMA's user-level interface. However, page fault handling was slower. As future research, it would be interesting to explore a hybrid design that provides both user-level and kernel interfaces to the *same* file system to get the best of both worlds.

7 Implementation

We implemented a prototype of regions for the Linux kernel v4.8 with 7700 lines of C/C++. Our current implementation differs from the design in a few significant ways: (1) we do not replicate the manager, (2) at each daemon, we have a fixed number of pools, hence a fixed amount of memory for regions, and (3) our VFS file system implements only the functionality needed to run our applications and benchmarks.

8 Evaluation

Our goal is to understand how well do regions perform, and how easy it is to use them in practice. To answer these questions, we use micro-benchmarks, examine code complexity, modify two applications to use regions, and measure their performance.

8.1 Testbed

Our testbed has 8 machines connected to a 100 Gbps RoCE switch. Each server has 128 GB RAM, a 800 GB SATA SSD, dual Intel Haswell-EP 2.4 GHz processors with a Mellanox ConnectX-4 NIC and Linux kernel 4.8.

8.2 Baselines

We compare the performance of regions against three baselines (Figure 9). RDMA offers a different interface to remote memory (RDMA verbs). Nfs-tmpfs and tmpfs provide a similar interface as regions (files), but without access to remote memory: nfs-tmpfs accesses files in a RAM disk of the NFS server, while tmpfs accesses files in a local RAM disk without network overheads, representing an upper bound on achievable performance.

We consider two variants of regions (rr and rr+) without and with performance enhancements that we describe in each experiment. In all experiments, we configure a region to be stored remotely from the benchmark or application operating on it, and so they access the region over the network rather than locally.

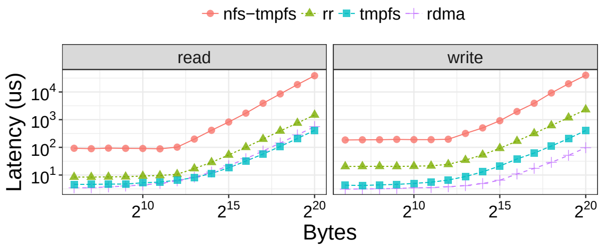

Figure 10: Latency for transferring data (no caching).

8.3 Performance of memory-mapped access

Setup. We study the time it takes for regions to read and write memory-mapped data. In an experiment, we memory map a file or region, and then sequentially read or write bytes. We choose an operation type (read or write), and operation size (number of bytes to read or write), and repeat the operation 100 times, measuring the latency of each operation. We compare regions against the baselines (nfs-tmpfs, tmpfs, rdma); RDMA does not support memory-mapping, so we instead read or write the data using one-sided RDMA verbs. We consider two variations of region. One variant (rr) performs raw operations without caching: we drop the cache after every operation, so that every operation must go over the network. The other variant (rr+) caches the most recently accessed page, so that consecutive operations on the same page access the cache, and writes to a page are buffered until the entire page is written. We also consider a variant of nfs-tmpfs that caches a page in the same way (nfs-tmpfs+).

Results. Figure 10 shows the results. For reads (left), we see that nfs-tmpfs and rr are flat from 64 bytes until 4K; this is because the file system operates at a page granularity, so it fetches an entire page even if the request needs fewer bytes. RDMA and tmpfs have the lowest latency, at 41% and 54% of rr's latency on 64 bytes, and 38% and 28% on 1MB. This is because rr suffers from overheads of page faults, 4KB-transfer granularity, and the file cache; tmpfs also incurs those overheads, but it compensates by avoiding the network latency. nfs-tmpfs is the worst due to higher network overheads. For writes (right), results are qualitatively similar; for rr and nfs-tmpfs, writes are slower than reads because the file system performs a read-modify-write operation, where it first reads the page before it writes it, requiring two network round trips. With RDMA, writes are faster than reads because RDMA writes complete as soon as they are posted on the PCIe bus at the remote host, whereas reads

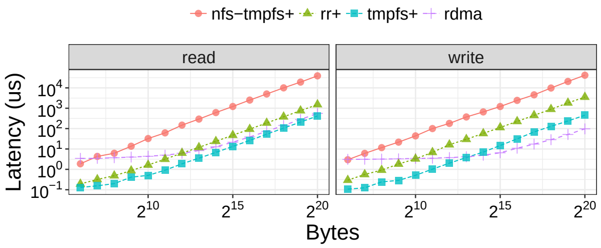

Figure 11: Latency for transferring data (caching).

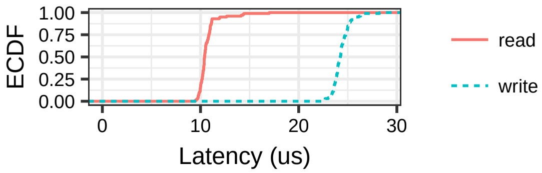

Figure 12: Distribution of latency for reading and writing 4 KB on a memory-mapped region using rr.

need to get data from memory.

These comparisons are unfair to file systems: unlike RDMA, they fetch full 4KB pages even for small requests, and cache them; doing so benefits applications that use the page later, but Figure 10 gives no credit for that. So, we now consider the effects of having a cache. Figure 11 shows the results with caching of the last page accessed. We see much improvement for small requests. Here, rr+ performs better than RDMA up to 4KB (reads) or 1KB (writes). We include RDMA in the graph for comparison, but it has no cache. Theoretically, an application can implement its own caching for RDMA, but doing so makes RDMA even more complex. In contrast, caching comes for free with a file system, without any application effort.

Figure 12 shows the cdf for reading or writing 4 KB of data using rr (no cache). We see a concentration from 10–11 us for reads, with the 95-percentile at 12 us; and a concentration from 23–26 us for writes, with the 95-percentile at 25.8 us. As we pointed out, writes are slower because the file system performs a read-modify-write operation (with memory-mapping, the system does not know that the application will eventually overwrite the entire page). This overhead is avoided by calling rmarkdirty (§5.8) prior to writing a page (not shown).

8.4 Performance of the file system

Setup. We run Sysbench, a standard file IO benchmark [59], to measure the performance of reading data from REGIONFS. We configure Sysbench with a single thread that reads from a 2GB file and reports throughput, average latency, and 95% latency. We study sequential and random reads of 16 KB chunks. We compare REGIONFS against nfs-tmpfs and local tmpfs.

System	Seq Tput (MB/s)	Seq LatAve (ms)	Seq Lat95 (ms)	Rnd Tput (MB/s)	Rnd LatAve (ms)	Rnd Lat95 (ms)
nfs-tmpfs	4871	0	0.01	4247	0	0.01
rr	5432	0	0.01	4821	0	0.01
tmpfs	6556	0	0	6048	0	0

Figure 13: Sysbench file IO benchmark results. Seq refers to sequential reads, Rnd to random reads.

Functionality	Description	regions loc	RDMA loc
Initialization	Code needed in every application	6	229
Producer-consumer	Simple message queue	29	103
Linked list	Traverse linked list	18	68
Hash table	Lookup operation of hash table	14	78
Access revocation	Remove access from a host	1	37

Figure 14: Equivalent functionality in regions and RDMA.

Results. Figure 13 shows the results. For throughput, tmpfs performs the best: 6.5 and 6.0 GB/s for sequential and random reads, respectively, while REGIONFS is within 83% and 80%—reasonably close to the in-memory performance of tmpfs, despite going to the network. Nfs-tmpfs is the worst at 4.9 and 4.2 GB/s. For latency, the resolution of the benchmark is 0.01ms, which is too large to reflect the difference between the different systems. (Please refer to the previous experiments, where we report other latency numbers.)

8.5 Code complexity

Setup. To study code complexity, we implement functionality that is commonly used in remote memory applications, and compare the number of lines of code (LOC) to implement them using REGIONFS and RDMA verbs.

Results. Figure 14 shows the complexity results. We see that region code has much fewer lines of code – 4.2 times on average, excluding initialization and revocation. For initialization, region requires just opening and memory mapping a file, while RDMA requires initializing contexts, memory registration, establishing connections, creating, transitioning and initializing queue pairs, key exchange, and more. For the other functionality, regions are similarly simpler, requiring just memory or file operations, while RDMA code must manually submit requests to queue pairs, monitor for completions, etc. In addition, RDMA verbs require explicit management of a partitioned global address space, which translates to more work at the application level. This complexity makes it hard for new developers to even get started on RDMA.

Next, we further study complexity, by using regions to adapt two applications to use remote memory.

8.6 Application: R

R is a statistical processing system for data in memory. Using regions, we adapt R to use remote memory. R

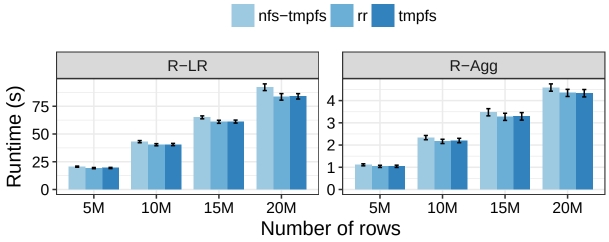

Figure 15: R application. Bars show total runtime (smaller is better). Error bars show std deviation.

has a large number of packages to extend its core functionality, including a package *ff* that extends R's memory capacity using memory-mapped files. ff provides objects that are each stored in a file; to limit memory consumption, small parts of the file called *sections* get memory mapped and unmapped as needed, with at most one section per file mapped at a time. We set up ff to use the files in REGIONFS, and to use sections that are 128KB wide.

Setup. In each experiment, we choose a workload for R and an input size. We use R to process the workload with an input of the given size, and we measure the time it takes. The workload mimics a data analyst that has a large data set and uses R to analyze parts of it. The data set is a large matrix stored in a host different from the one running R, representing data generated elsewhere in the network that does not fit in R's memory. The matrix is stored as several ff objects, one per column, with 200 columns and a number of rows that varies from 5 to 20 million. We consider two workloads:

- *R-Agg.* Compute an aggregation (mean) over ten columns of the matrix. This workload represents an extreme in terms of the ratio of computation to memory accesses: it almost entirely performs memory accesses, by reading data and only computing a sum.
- *R-LR.* Compute a linear regression over ten columns of the matrix. The algorithm accesses the rows of the matrix several times, but performs significant more computation than R-Agg, representing a balance between memory accesses and compute.

We consider three systems: rr, tmpfs, and nfs-tmpfs.

Results. Figure 15 (right) shows the R-Agg workload. Regions approach tmpfs within 1%, despite having to read the input from a remote host. In comparison, nfs-tmpfs is within 6% of tmpfs.

For the R-LR workload (Figure 15 left), we see a similar trend but with a larger running time incurred by linear regression. Regions are again within 1% of tmpfs, while nfs-tmpfs is within 9% of tmpfs.

While the performances of tmpfs and nfs-tmpfs are similar to rr, tmpfs and nfs-tmpfs do not permit R to run with a large memory because their capacity is limited by the available memory locally or in the nfs server. By contrast, regions can be multihosted (§5.4) to aggregate the memory of many machines.

We also ran R and placed the ff-generated files in an SSD rather than in REGIONFS, as a way to obtain more space. The running time of R increased by 2.5× (for R-agg) and 2.7× (for R-LR) relative to rr.

As for code complexity, we made no changes to R's ff package; we just set it up to use files in REGIONFS.

8.7 Applications: Metis

Metis is an in-memory map-reduce processing framework. Metis reads its initial input from a file, and launches many threads to run map-reduce. In map-reduce, the data is partitioned across a set of mappers, each producing an output; the outputs of all mappers are grouped based on a key, and the groups are partitioned across the reducers; each reducer produces some output, and all outputs are aggregated in the end. Metis runs on a single host, using work queues to distribute map and reduce tasks among many threads.

We modify Metis to run across many hosts, using regions to share its input and output. More specifically, the modified Metis does three things: (1) reads the initial input from remote hosts using regions, representing data produced by another computation, such as a previous map-reduce job[1], (2) runs threads across many hosts, with each host writing the output to a region to make it available to the other hosts, and (3) collects the regions with the results from all the hosts and aggregates the output. In effect, we produce a distributed version of Metis, while retaining its in-memory processing.

Setup. In each experiment, we run a map-reduce job to produce a histogram. In this job, each mapper processes a partition of the input and produces a partial histogram; the reducers then aggregate the bins, each reducer responsible for a disjoint set of bins; a final stage collects the bins from the reducers.

We consider two systems: the original Metis and our distributed version. We vary the number of threads in each system; for the distributed version, we vary the number of hosts. We measure the time to run the map-reduce computation. The input is a 2.6 GB image file, and the output produces 403 bins. Metis has an option called *prefault* to initially preload all input to memory.

Results. Figure 16 (left) shows the results for a single host as we increase the number of threads. We see that rr is faster because it reads the input from remote memory, while Metis reads from an SSD. For one host and one thread, rr is 2.0× faster than Metis; for 4 threads, it is 3.5× faster. By increasing the number of threads to 4,

[1] The motivation is that many map-reduce applications run a chain of map-reduce jobs, each consuming the output of the previous job.

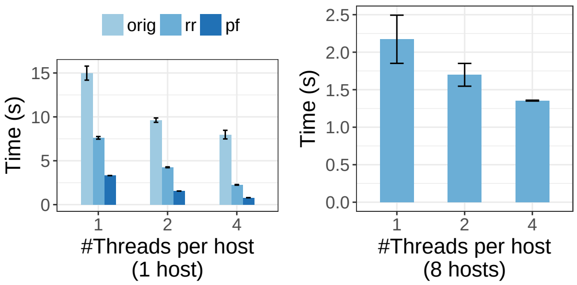

Figure 16: Metis application performance. On the left, there is a single host; *rr* refers to our distributed version of Metis, while *orig* and *pf* refer to the original Metis, where *pf* enables Metis's prefault option. On the right, we show our distributed version of Metis on 8 hosts (there are no bars for the original Metis since it runs only on 1 host). The y-axis is running time (smaller is better). Error bars show std deviation.

Metis and rr improve by 1.91× and 3.4×. If we exclude reading the input (with prefault), performance improves by 2.3–2.9× compared to rr.

Figure 16 (right) shows the results for our distributed version of Metis running on eight hosts and 1–4 threads per host. We see that performance improves compared to running with one host. Using 8 hosts, rr is 3.5, 2.5, 1.7× faster for 1, 2, 4 threads than rr using a single host with the same number of threads. The improvement comes from the hosts running the computation in parallel. The scalability is not linear because the running time is only a few seconds and so the overhead of synchronizing the hosts between phases is relatively high.

As for code complexity, the modifications to Metis consist of 82 lines. This is small, as the changes amount to changing a centralized system into a distributed one.

9 Conclusion

In this paper, we applied the Unix idea that "everything is a file" to remote memory, obtaining an abstraction in which a process exports parts of its memory as a file that remote processes can access. We studied the design behind this abstraction, described a prototype that achieves reasonable performance, and showed that applications can easily benefit from it.

Abstract

Serverless computing frameworks allow users to launch thousands of concurrent tasks with high elasticity and fine-grain resource billing without explicitly managing computing resources. While already successful for IoT and web microservices, there is increasing interest in leveraging serverless computing to run data-intensive jobs, such as interactive analytics. A key challenge in running analytics workloads on serverless platforms is enabling tasks in different execution stages to efficiently communicate data between each other via a shared data store. In this paper, we explore the suitability of different cloud storage services (e.g., object stores and distributed caches) as remote storage for serverless analytics. Our analysis leads to key insights to guide the design of an ephemeral cloud storage system, including the performance and cost efficiency of Flash storage for serverless application requirements and the need for a pay-what-you-use storage service that can support the high throughput demands of highly parallel applications.

1 Introduction

Serverless computing is an increasingly popular execution model in the cloud. With services such as AWS Lambda, Google Cloud Functions, and Azure Functions, users write applications as collections of stateless functions which they deploy directly to a serverless framework instead of running tasks on traditional virtual machines with pre-allocated resources [8, 14, 19, 2]. The cloud provider schedules user tasks onto physical resources with the promise of automatically scaling according to application demands and charging users only for the fine-grain resources their tasks consume.

While already popular for web microservices and IoT applications, the elasticity and fine-grain billing advantages of serverless computing are also appealing for a broader range of applications, including interactive data analytics. Several frameworks are being developed which leverage serverless computing to exploit high degrees of parallelism in analytics workloads and achieve near real-time performance [13, 17, 10].

A key challenge in running analytics workloads on serverless computing platforms is efficiently sharing data between tasks. In contrast to simple event-driven applications that consist of a single task executed in response to an event trigger, analytics workloads typically consist of multiple stages and require intermediate results to be shared between stages of tasks. In traditional analytics frameworks (e.g., Spark, Hadoop), tasks buffer intermediate data in local storage and exchange data between tasks directly over the network [25, 24]. In contrast, serverless computing frameworks achieve high elasticity and scalability by requiring tasks to be stateless [15]. In other words, a task's local file system and child processes are limited to the lifetime of the task itself. Furthermore, since serverless platforms do not expose control over task scheduling and placement, direct communication between tasks is difficult. Thus, the natural approach for inter-task communication is to store intermediate data in a common, remote storage service. We refer to data exchanged between tasks as *ephemeral data*.

There are several storage options for data sharing in serverless analytics jobs, each providing different cost, performance and scalability trade-offs. Managed object storage services like S3 offer pay-what-you-use capacity and bandwidth for storage resources managed by the provider [7]. Although primarily intended for long term data storage, they can also be used for ephemeral data. In-memory key-value stores like Redis and Memcached offer high performance, at the high cost of DRAM [21, 4]. They also require users to manage their own storage VMs. It is not clear whether existing storage options meet the demands of serverless analytics or how we can design a storage system to rule them all.

In this paper, we characterize the I/O requirements for data sharing in three different serverless applications including MapReduce sort, distributed software compilation, and video processing. Using AWS Lambda as our serverless platform, we analyze application performance using three different types of storage systems. We consider a disk-based, managed object storage service (Amazon S3), an in-memory key value store (ElastiCache Redis), and a Flash-based distributed storage system (Apache Crail with a ReFlex Flash backend [1, 23, 18]). Our analysis leads to key insights for the design of distributed ephemeral storage, such as the use of Flash to cost-efficiently support the throughput, latency and capacity requirements of most applications and the need for a storage service that scales to meet the demands of applications with abundant parallelism. We conclude with a discussion of remaining challenges such as resource auto-scaling and QoS-aware data placement.

2 Serverless Analytics I/O Properties

We study three different serverless analytics applications and characterize their throughput and capacity requirements, data access frequency and I/O size. We use AWS Lambda as our serverless platform and configure lambdas with the maximum supported memory (3 GB) [8]. Figure 1 plots each job's cumulative storage bandwidth usage over time. Figure 2 shows the I/O size distribution.

Parallel software build: We use a framework called gg to automatically synthesize the dependency tree of a software build system and coordinate lambda invocations for distributed compilation [12, 3]. Each lambda fetches its dependencies from ephemeral storage, computes (i.e., compiles, archives or links depending on the stage), and writes an output file. Compilation stage lambdas read source files which are generally up to 10s of KBs. While 55% of files are read only once (by a single lambda), others are read hundreds of times (by many lambdas in parallel), such as glibc library files. Lambdas which archive or link read objects up to 10s of MBs in size. We use gg to compile `cmake` which has 850 MB of ephemeral data.

MapReduce Sort: We implement a MapReduce style sort application on AWS Lambda, similar to PyWren [17]. Map lambdas fetch input files from long-term storage (S3) and write intermediate files to ephemeral storage. Reduce lambdas merge and sort intermediate data read from ephemeral storage and write output files to S3. Sorting is I/O-intensive. For example, we measure up to 7.5 cumulative GB/s when sorting 100 GB with 500 lambdas. Each intermediate file is written and read only once and its size is directly proportional to the dataset size and inversely related to the number of workers.

Video analytics: We use Thousand Island Scanner (THIS) to run distributed video processing on lambdas [20]. The input is an encoded video that is divided into batches and uploaded to ephemeral storage. First stage lambdas read a batch of encoded video frames from ephemeral storage and write back decoded video frames. Each lambda then launches a second stage lambda which reads a set of decoded frames from ephemeral storage, computes a MXNET deep learning classification algorithm and outputs a classification result. We use a video consisting of 6.2K 1080p frames and tune the batch size to optimize runtime (62 lambdas in the decode stage and 310 lambdas for classification). The total ephemeral storage capacity is 6 GB.

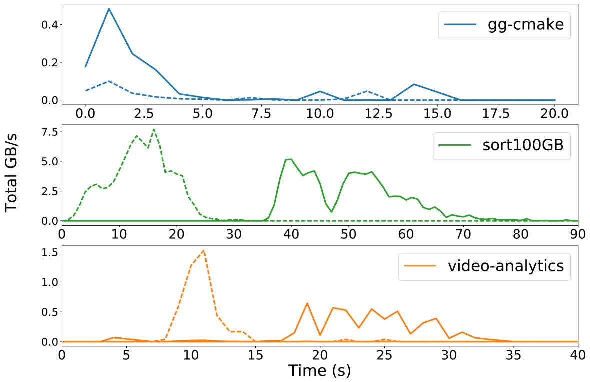

Figure 1: Cumulative throughput over time.

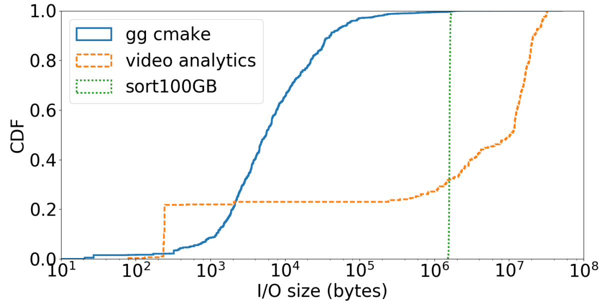

Figure 2: I/Os range from 100s of bytes to 100s of MBs.

3 Remote Storage for Data Sharing

We consider three different categories of storage systems for ephemeral data sharing in serverless analytics: fully managed cloud storage (e.g., S3), in-memory key-value storage (e.g., Redis), and distributed Flash storage (e.g., Crail-ReFlex). We focus on ephemeral storage as the original input and final output data of analytics jobs typically has long-term availability requirements that are well served by various existing cloud storage systems.

Simple Storage Service (S3): Amazon S3 is a fully managed object storage system that achieves high availability and scalability by replicating data across multiple nodes with eventual consistency [9]. Users pay only for the storage capacity and bandwidth they use, without ex-

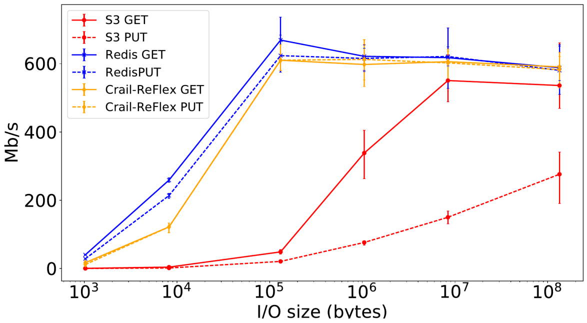

Figure 3: Peak storage throughput per lambda

	Read	Write	Metadata lookup
S3	12.1 ms	25.8 ms	–
Redis	230 μs	232 μs	–
Crail-ReFlex	283 μs	386 μs	185 μs

Table 1: Average unloaded latency for 1KB requests.

plicitly managing storage resources. S3 has significant overhead, particularly for small requests. As shown in Table 1, it takes on average over 25 ms to write 1KB. For requests smaller than 100 KB, Figure 3 shows that a single lambda achieves less than 5 MB/s (40 Mb/s) throughput. For requests 10 MB or larger, throughput goes up to 70 MB/s. With up to 2500 concurrent lambda clients, S3 scales to 80 GB/s with each client achieving approximately 30 MB/s (not shown in the figure).

Elasticache Redis: DRAM is a viable storage media for ephemeral data, which is short-lived. We use ElastiCache Redis with cluster mode enabled as an example in-memory key-value store [21, 6]. Table 1 shows that Redis latency is ∼240 μs, two orders of magnitude lower than S3 latency. We find that AWS Lambda infrastructure introduces some overhead as the same `c4.8xlarge` Redis cluster has ∼ 115μs lower round-trip latency from a `r4.8xlarge` EC2 client (10 GbE). We also confirm the 640 Mb/s peak per-lambda throughput in Figure 3 is an AWS Lambda limitation; the EC2 client achieves up to 5 Gb/s for the same, single TCP connection test. Since we occasionally observe lambda throughput burst above 640 Mb/s, we suspect AWS throttles a 1 Gb/s link.

Crail-ReFlex: Finally, we consider a Flash-based distributed storage system as Flash offers a medium ground between disk and DRAM for both performance and cost. In particular, NVM Express (NVMe) Flash devices are becoming increasingly popular in the cloud, offering high performance and capacity per dollar [5]. We choose to use the Apache Crail distributed storage system as it is designed for high performance access to data with low durability requirements, which matches the properties of ephemeral data. While Crail is originally designed for RDMA networks which are not available on AWS, its modular architecture supports pluggable storage tiers. We implement a NVMe Flash storage tier for Crail based on ReFlex, an open-source software system for low-latency, high throughput access to Flash over commodity networks [18]. We deploy Crail-ReFlex on `i3` EC2 nodes. Table 1 shows that from a lambda client, remote access to Flash (using Crail-ReFlex) has similar read latency as remote access to DRAM (using Redis). However, while Redis uses a simple hash to assign keys to storage servers, Crail relies on metadata servers to route client requests and manage data placement across nodes for more control over load balancing and quality of service. Thus, Crail requires an extra round-trip for metadata lookup which takes 185 μs.

4 Serverless Analytics Storage Analysis

We compare three different storage systems for ephemeral data sharing in serverless analytics and discuss how application latency sensitivity, parallelism, and I/O intensity impact ephemeral storage requirements.

Latency-sensitive jobs: We find that jobs in which lambdas mostly issue fine-grain I/O operations are latency-sensitive. Out of the applications we study, only gg shows some sensitivity to storage latency since the majority of files accessed are under 100 KB. Figure 4 shows the runtime for a parallel build of `cmake` as a function of the number of concurrent lambdas (gg allows users to set the maximum lambda concurrency, similar to `-j` in `make`). The job benefits from the lower latency of Redis storage compared to S3 with up to 100 concurrent lambdas. The runtime with S3 and Redis converges as we increase concurrency because the job eventually becomes compute-bound on AWS Lambda.

Jobs with limited parallelism: While serverless platforms allow users to exploit high application parallelism by launching many concurrent lambdas, individual lambdas are wimpy. Hence, we find that jobs with inherently limited parallelism (e.g., due to dependencies between lambdas) are likely to experience lambda resource bottlenecks (e.g., memory, compute and/or network bandwidth limits) rather than storage bottlenecks. This is the case for gg . The first stage of the software build process has high parallelism as each file can be pre-processed, compiled and assembled independently. However, subsequent lambdas which archive and link files depend on the outputs of earlier stages. Figure 5 plots the per-lambda read, compute and write times when using gg to compile `cmake` with up to 650 concurrent lambdas (650 is the highest degree of parallelism in the job's dependency graph). Using Redis (Figure 5b) compared to S3 (Figure 5a) reduces the average time that lambdas spend on I/O from 51% to 11%. However, the job takes approx-

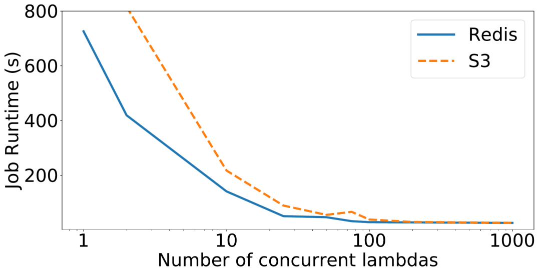

Figure 4: Distributed compilation of `cmake` is latency-sensitive at low concurrency and becomes compute-bound when run with ∼100 or more concurrent lambdas.

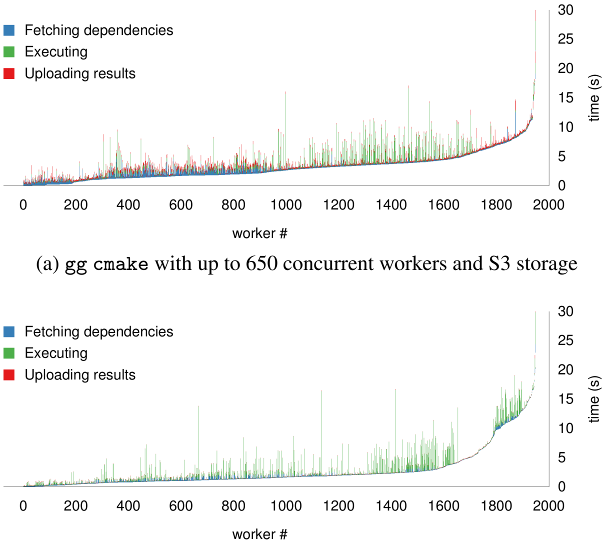
imately 30 seconds to complete, regardless of the storage system. This is because optimizing I/O does not affect the lambdas with particularly high compute latency which become the bottleneck.

Throughput-intensive jobs: MapReduce sort is an I/O-intensive application with abundant parallelism. Figure 6 shows the average time each lambda spends on I/O and compute to sort a 100 GB dataset [16]. We use S3 for input/output files and compare performance with S3, Redis (12 `cache.r4.2xlarge` nodes), Crail-ReFlex (12 `i3.2xlarge` nodes) as ephemeral storage. Storing ephemeral data in remote DRAM (Redis) or remote Flash (Crail-ReFlex) gives similar end-to-end performance, since we provision sufficient bandwidth in the storage clusters and the bottleneck becomes lambda CPU usage. Performance scales linearly as we increase the number of lambdas. S3 achieves lower throughput than Redis and Crail-ReFlex with 250 lambdas, leading to higher execution time. However, S3 outperforms a *single* node Redis or Crail-ReFlex cluster since a single node's network link becomes a bottleneck (not shown in the figure). Using S3 for ephemeral data shuffling with more than 250 lambdas in the 100 GB sort job results in I/O rate limit errors, preventing the job from completing.

Video analytics is another application with abundant parallelism. Figure 7 shows the average time lambdas in each stage spend reading, computing, and writing data. Reading and writing ephemeral data to/from S3 increases execution time compared to Redis and Crail-ReFlex. Stage 2 read time is higher with Crail-ReFlex than Redis due to read-write interference on Flash. Some lambdas in the first stage complete and launch second stage lambdas sooner than others. Thus read I/Os for some second stage lambdas interfere with the write requests from first stage lambdas that are still running. This interference can be problematic on Flash due to asymmetric read-write latency [18]. However, this does not noticeably affect overall performance as stage 2 lambdas are compute-bound. Stage 2 has low write time as its output (a list of objects detected in the video) is small.



(a) gg `cmake` with up to 650 concurrent workers and S3 storage

(b) gg `cmake` with up to 650 concurrent workers and Redis storage

Figure 5: Redis reduces I/O time compared to S3, but compute is the bottleneck. Based on Figure 6 from [12].

5 Discussion

Our analysis leads to several insights for the design of ephemeral storage for serverless analytics. We summarize the properties an ephemeral storage system should provide to address the needs of serverless analytics applications, make recommendations for the choice of storage media, and outline areas for future work.

Desired ephemeral storage properties: To meet the I/O demands of serverless applications, which can consist of thousands of lambdas in one execution stage and only a few lambdas in another, the storage system should have *high elasticity*. The system should also support *high IOPS* and *high throughput*. Since the granularity of data access varies widely (Figure 2), storing both small and large objects should be cost and performance efficient. To relieve users from the difficulty of managing storage clusters, the storage service should *auto-scale resources* based on load and charge users for the bandwidth and capacity used. This effectively extends the serverless abstraction to storage. Finally, the storage system can leverage the unique characteristics of ephemeral data. Namely, ephemeral data is short-lived and can easily be re-generated by re-running a job's tasks. Thus, unlike traditional long-term storage, an ephemeral storage system can provide low data durability guarantees. Furthermore, since the majority of ephemeral data is written and read only once (e.g., a mapper writes intermediate results for a particular reducer), the storage system can optimize capacity usage with an API that allows users to hint when data should be deleted right after it is read.

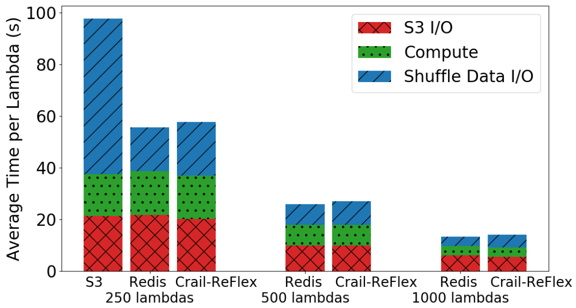


Figure 6: Average time per lambda for 100GB sort. S3 gives I/O rate limit errors with over 250 lambdas.

Choice of storage media: A storage system can support arbitrarily high throughput by scaling resources up and/or out. The more interesting question is which storage technology allows the system to cost effectively satisfy application throughput, latency and capacity requirements. Figure 1 plots cumulative GB/s over time for gg cmake, sort, and video analytics which have 0.85, 100, and 6 GB ephemeral datasets, respectively. Considering typical throughput-capacity ratios for each storage technology (DRAM: $\frac{20\text{GB/s}}{64\text{GB}} = 0.3$, Flash: $\frac{3.2\text{GB/s}}{500\text{GB}} = 0.006$, HDD: $\frac{0.7\text{GB/s}}{6\text{TB}} = 0.0001$), we conclude that the sort application is best suited for Flash-based ephemeral storage. The throughput-capacity ratios of the gg-cmake and video analytics jobs fall into the DRAM regime. However we observed that using Flash gives similar end-to-end performance for these applications at lower cost per GB, as lambda CPU is the bottleneck. I/O intensive applications with concurrent ephemeral read and write I/Os are likely to prefer DRAM storage as Flash tail read latency increases significantly with concurrent writes [18].

Future research directions: The newfound elasticity and fine resource granularity of serverless computing platforms motivates many systems research directions. Serverless computing places the burden of resource management on the cloud provider, which typically has no upfront knowledge of user workload characteristics. Hence, building systems that dynamically and autonomously rightsize cluster resources to meet elastic application demands is critical. The challenge involves provisioning resources across multiple dimensions (e.g., compute resources, network bandwidth, memory and storage capacity) in a fine-grain manner to find low cost allocations that satisfy application performance requirements. With multiple tenants sharing serverless computing infrastructure to run jobs with high fan-out, another challenge is providing predictable performance. Interference often leads to high variability, yet a job's runtime often depends on the slowest lambda [11]. Developing *fine-grain* isolation mechanisms and QoS-aware resource sharing policies is an important avenue to explore.

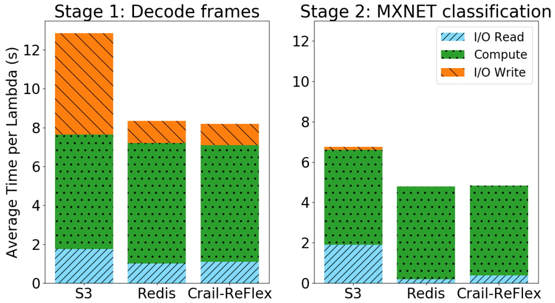

Figure 7: Video analytics I/O vs. compute breakdown, storing ephemeral data in S3, Redis and Crail-ReFlex.

6 Related Work

Fouladi et al. leverage serverless computing for distributed video processing and overcome the challenge of lambda communication by implementing the mu software framework to orchestrate lambda invocations with a long lived coordinator that is aware of each worker's state and execution flow [13]. While their system uses S3 to store ephemeral data, we study the suitability of three different types of storage systems for ephemeral data storage. Jonas et al. implement PyWren to analyze the applicability of serverless computing for generic workloads, including MapReduce jobs, and find storage to be a bottleneck [17]. We build upon their work, provide a more thorough analysis of ephemeral storage requirements for analytics jobs, and draw insights to guide the design of future systems. Singhvi et al. show that current serverless infrastructure does not support network intensive functions like packet processing [22]. Among their recommendations for future platforms, they also identify the need for a scalable remote storage service.

7 Conclusion

To support data-intensive analytics on serverless platforms, our analysis motivates the design of an ephemeral storage service that supports automatic and fine-grain allocation of storage capacity and throughput. For the three different applications we studied, throughput is more important than latency and Flash storage provides a good balance for performance and cost.

Abstract

Efficient transaction processing over large databases is a key requirement for many mission-critical applications. Though modern databases have achieved good performance through horizontal partitioning, their performance deteriorates when cross-partition distributed transactions have to be executed. This paper presents Solar, a distributed relational database system that has been successfully tested at a large commercial bank. The key features of Solar include: 1) a shared-everything architecture based on a two-layer log-structured merge-tree; 2) a new concurrency control algorithm that works with the log-structured storage, which ensures efficient and non-blocking transaction processing even when the storage layer is compacting data among nodes in the background; 3) fine-grained data access to effectively minimize and balance network communication within the cluster. According to our empirical evaluations on TPC-C, Smallbank and a real-world workload, Solar outperforms the existing shared-nothing systems by up to 50x when there are close to or more than 5% distributed transactions.

1 Introduction

The success of NoSQL systems has shown the advantage of the scale-out architecture for achieving near-linear scalability. However, it is hard to support transaction in them, an essential requirement for large databases, due to the distributed data storage. For example, Bigtable [5] only supports single-row transactions, while others like Dynamo [6] do not support transactions at all. In response to the need for transaction support, NewSQL systems are designed for efficient OnLine Transaction Processing (OLTP) on a cluster with distributed data storage.

Distributed transaction processing is hard because of the need of efficient synchronization among nodes to ensure ACID properties and maintain good performance. Despite the significant progress and success achieved by many recently proposed systems [12, 27, 29, 19, 9, 23, 8, 37, 33], they still have various limitations. For example, the systems relying on shared-nothing architecture and 2PC (two-phase commit) heavily suffer from cross-partition distributed transactions, and thus require careful data partitioning with respect to given workloads. On the other hand, distributed shared-data systems like Tell [19] require specific hardware supports that are not commonly available yet at large scale.

That said, when no prior assumption can be made regarding the transaction workloads, and with no special hardware support, achieving high performance transaction processing on a commodity cluster is still a challenging problem. Meanwhile, prior studies have also shown it is possible to design high performance transaction engines on a single node by exploring the multi-core and multi-socket (e.g, NUMA) architecture. Both Silo [30] and Hekaton [7] have used a single server for transaction processing and demonstrated high throughput. However, such systems may not meet the needs of big data applications whose data cannot fit on a single node, hence requiring the support for a distributed data storage.

Inspired by these observations, our objective is to design a transactional database engine that *combines the benefits* of scalable data storage provided by a cluster of nodes and the simplicity for achieving efficient transaction processing on a single server node, *without* making any apriori assumptions on the transactional workloads *and without* requiring any special hardware support.

Bank of Communications, one of the largest banks in China, has faced these challenges. On one hand, new e-commerce applications from its own and its partners' mobile and online apps have driven the need for the support of ad-hoc transactions over large data, where little or no knowledge/assumptions can be made towards the underlying workloads as new apps emerge constantly. On the other hand, the bank has a strong interest towards better utilization of its *existing* hardware infrastructures to avoid costly new hardware investment if possible.

With that in mind, Solar is designed using a *shared-everything* architecture, where a server node (called *T-node*) is reserved for in-memory transaction processing and many storage nodes (called *S-nodes*) are used for data storage and read access. In essence, the S-nodes in Solar form a *distributed storage engine* and the T-node acts as *a main-memory transaction engine*. The distributed storage engine takes advantage of a cluster of nodes to achieve scalability in terms of the database capacity and the ability to service concurrent reads. The transaction engine provides efficient transaction processing and temporarily stores committed updates through its *in-memory committed list*. Periodically, *recently committed data items* on T-node are merged back into S-nodes through a *data compaction* procedure running in the background, *without* interrupting ongoing transactions. Overall, Solar is designed to achieve high performance transaction processing and scalable data storage.

To speed up update operations in the system, the in-memory committed list on T-node and the disk storage from all S-nodes *collectively form a distributed two-layer log-structured merge-tree* design [22]. Furthermore, a processing layer called *P-unit* is introduced to carry out *both* data access from S-nodes *and* any computation needed in a transaction so that the T-node can be freed from the burden of coordinating data access and performing business logic computation. This separation of storage and computation also enables the system to leverage all CPU resources for transaction scheduling and validation. Towards realizing the above design principle, we also design and implement a number of optimizations and algorithms to minimize the overhead in the system. Our contributions are summarized as follows:

- A distributed shared everything architecture with a T-node, a set of S-nodes and P-units is proposed for achieving high performance transaction processing.
- A hybrid concurrency control scheme called *MVOCC* is explored that combines the OCC (optimistic concurrency control) and the MVCC (multi-version concurrency control) schemes.
- A data compaction algorithm, as part of MVOCC, is designed to efficiently merge the *committed list* on T-node back to S-nodes periodically, *without interrupting* transaction processing on T-node.
- Several optimizations are investigated to improve the overall performance, e.g., separation of computation and storage through P-units, grouping multiple data access operations in one transaction, maintaining a bitmap for avoiding unnecessary data access to the distributed storage engine.

In our empirical evaluation on TPC-C, Smallbank and a real-world workload, Solar outperforms existing shared-nothing systems by 50x when the transactions requiring distributed commits are close to or more than 5%.

2 Solar Architecture

Solar is a distributed shared-everything relational database that runs concurrent transactions on a cluster of commodity servers. Figure 1 shows its architecture.

2.1 Design considerations

Shared-everything architecture. Shared-nothing architecture [12, 27] places data in non-overlapping partitions on different nodes in the hope that it can avoid expensive 2PC among nodes when almost all of the transactions only need to touch data on one partition and thus can run independently. For distributed transactions, multiple partitions with data involved need to be locked, blocking all other transactions that need to touch those partitions, which greatly increases system latency. Even worse, it only takes merely a handful of distributed transactions to always have locks on all the partitions and, as a result, system throughput can be reduced to nearly zero.

Instead, Solar employs a shared-everything architecture, where a transaction processing unit can access any data. ACID can be enforced at a finer granularity of individual records rather than at partitions. It also avoids expensive 2PC by storing updates on a single high-end server, enabling a higher transaction throughput.

In-memory transaction processing and scalable storage. Traditional disk-based databases rely on buffering mechanisms to reduce the latency of frequent random access to the data. However, this is several magnitudes slower than accessing in-memory data due to the limited size of the buffers and complication added to recovery.

In-memory transaction processing proves to be much more efficient than disk-based designs [7, 12]. Limited memory is always a key issue with in-memory transaction processing. Databases must have mechanisms to offload data to stable storage to free up memory for an unbounded stream of transactions. A key observation is that transactions typically only touch a very small subset of the whole database, writing a few records at a time in a database of terabytes of data. Thus, Solar reduces transaction processing latency by writing completely in memory while having an unbounded capacity by storing a consistent snapshot on a distributed disk-based storage, which can be scaled out to more nodes if needed.

Fine-grained data access control. In Solar, processing nodes directly access data stored in remote nodes via network, which can lead to overheads. Existing studies have shown that it is advantageous to use networks such as InfiniBand and Myrinet [19]. However, they are far from widely available. They require special software and hardware configurations. It is still unclear how to do that on a cluster of hundreds of off-the-shelf machines.

Solar is designed to work on a cluster of commodity servers, and thus uses a standard networking infrastructure based on Ethernet/IP/TCP. But network latency is significant because of the transition and data copying into and out of kernel. It also consumes more CPU than Infiniband, where data transport is offloaded onto NIC. To address the issue, we designed fine-grained data access to reduce network overhead, including caching, avoiding unnecessary reads and optimizing inter-node communication via transaction compilation. Fine-grained data access brings the transaction latency on par with the state-of-the-art systems and improves throughput by 3x.

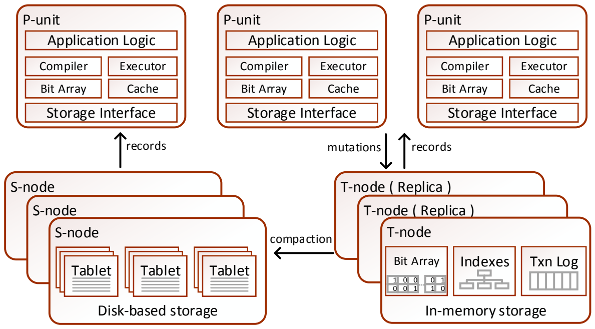

Figure 1: Architecture of Solar

2.2 Architecture overview

Figure 1 provides an overview of Solar's architecture. Solar separates transaction processing into *computation, validation and commit* phases using a *multi-version optimistic concurrency control protocol*. A transaction can be initiated on any one of the P-units, which do not store any data except several small data structures for data access optimization (Section 4). The P-unit handles all the data fetches from either T-node or S-nodes as well as transaction processing. The writes are buffered at the P-unit until the transaction commits or aborts. When the transaction is ready to commit, the P-unit sends the write set to T-node for validation and commit. Once T-node completes the validation, it writes the updates to its in-memory storage, and also a Write-Ahead Log to ensure durability. Finally, T-node notifies the P-unit if the transaction is successfully committed. P-units can be instantiated on any machine in or outside the cluster (typically on S-nodes or at client side). They offload most of the computation burden from T-node so that T-node can be dedicated to transaction management. Cluster information (e.g. states of all nodes, data distribution) are maintained by a manager node, and cached by other nodes.

Solar adopts a two-layer distributed storage that mimics the *log-structured merge tree (LSM-tree)* [22]. The storage layer consists of 1) a consistent database snapshot; and 2) all committed updates since the last snapshot. The size of the snapshot can be arbitrarily large and thus is stored in a distributed structure called SSTable across the disks of the S-nodes. Records in a table are dynamically partitioned into disjoint ranges according to their primary keys. Each range of records is stored in a structure called tablet (256 MB in size by default), which is essentially a B-tree index. The committed updates are stored in Memtable on T-node, which are from recent transactions and are typically small enough to fit entirely in memory. Memtable contains both a hash index and a B-tree index on the primary keys. The data entry points to all the updates (updated columns only) since the last snapshot, sorted by their commit timestamp. To access a specific record, a P-unit first queries Memtable. If there's no visible version in Memtable, it then queries SSTable for the version from the last snapshot.

The size of Memtable increases as transactions are committed. When it reaches certain memory threshold or some scheduled off-peak time (e.g. 12:00 am - 4:00 am for Bank of Communications), Solar performs a data compaction operation to merge the updates in Memtable into SSTable to free up the memory on T-node. At the end of data compaction, a new consistent snapshot is created in SSTable and Memtable drops all the committed updates prior to the start of the data compaction.

During data compaction, a new Memtable is created to handle new transactions arriving after the start of the data compaction. Then the old Memtable is merged into SSTable in a way similar to LSM-tree, namely merging two sorted lists from the leaf level of B-Tree index. Instead of overwriting the data blocks with new contents, we make new copies and apply updates on the copies. As we will explain in Section 3, transactions that have already started at the start of data compaction might still need to access the old SSTable. Thus, this approach minimizes the interruption to ongoing transactions.

Note that the function of T-node is twofold: it works as a transaction manager that performs timestamp assignment, transaction validation as well as committing updates; on the other hand, it serves as the *in-memory portion of the log-structured storage layer*. This architecture allows low-latency and high-throughput insertion, deletion and update through the in-memory portion. The log-structured storage also enables fast data compaction, which has a very small impact on the system performance because it mainly consumes network bandwidth instead of T-node's CPU resource.

Finally, Solar uses data replication to provide high availability and resistance to node failures. In SSTable, each tablet has at least 3 replicas and they are assigned to different S-nodes. Replication also contributes to achieve better load balancing among multiple S-nodes: a read request can access any one of the replicas. Memtable is replicated on two backup T-nodes. Details of data replication and node failures are discussed in Section 3.2.

3 Transaction Management

Solar utilizes both Optimistic Concurrency Control (OCC) and Multi-Version Concurrency Control (MVCC) to provide *snapshot isolation* [2]. Snapshot isolation is widely adopted in real-world applications, and many database systems (e.g. PostgreSQL prior to 9.1, Tell [19]) primarily support snapshot isolation, although it admits the write-skew anomaly that is prevented by serializable isolation. This paper focuses on Solar's support for snapshot isolation, and leave the discussion of serializable isolation to a future work. To ensure durability and support system recovery, redo log entries are persisted into the durable storage on T-node before transaction commits (i.e., write-ahead logging).

3.1 Supporting snapshot isolation

Solar implements snapshot isolation through combining OCC with MVCC [15, 2]. More specifically, MVOCC is used by T-node over Memtable. Recall that each record in Memtable maintains multiple versions. A transaction t_x is allowed to access versions created before its start time, which is called the *read-timestamp* and can be any timestamp before its first read. At the commit time, a transaction obtains a *commit-timestamp*, which should be larger than any existing *read-timestamp* or *commit-timestamp* of other transactions. Transaction t_x should also verify that no other transactions ever write any data, between t_x's *read-timestamp* and *commit-timestamp*, that t_x has also written. Otherwise, t_x should be aborted to avoid lost-update anomaly [2]. When a transaction is allowed to commit, it updates a record by creating a new version tagged with its *commit-timestamp*.

With MVOCC, SSTable contains, for all records in the database, the latest versions created by transactions with *commit-timestamps* are smaller than the *last data compaction time* (*compaction-timestamp*). Memtable contains newer versions created by transactions with *commit-timestamps* larger than *compaction-timestamp*.

T-node uses a global, monotonically increasing, counter to allocate timestamps for transactions. Transaction processing in Solar is decomposed into three phases: processing, validating and writing/committing.

Processing. In the processing phase, a worker thread of a P-unit executes the user-defined logic in a transaction t_x and reads records involved in t_x from both T-node and S-nodes. A transaction t_x obtains its *read-timestamp* (rt_x for short) when it first communicates with T-node. The P-unit for processing t_x reads the latest version of each record involved in t_x, whose timestamp is smaller than rt_x. In particular, it first retrieves the latest version from Memtable. If a proper version (i.e., timestamp less than rt_x) is not fetched, it continues to access the corresponding tablet of SSTable to read the record. During this process, t_x buffers its writes in a local memory space on the P-unit. When t_x has completed all of its business logic code, it enters the second phase. The P-unit sends a commit request for t_x containing t_x's write-set to T-node. T-node would then validate and commit the transaction.

Validating. The validation phase is conducted on T-node, which aims to identify potential write-write conflicts between t_x and other transactions. During the validation phase, T-node attempts to lock all records in t_x's write-set (denoted as w_x) on Memtable and checks, for any record $r \in w_x$, whether there is any newer version of r in Memtable whose timestamp is larger than rt_x. When all locks are successfully held by t_x and no newer version for any record in w_x is found, T-node guarantees that t_x has no write-write conflict and can continue to commit. Otherwise, T-node will abort t_x due to the lost update anomaly. Hence, after validation, T-node determines whether to commit or abort a transaction t_x. If it decides to abort t_x, T-node sends the abort decision back to the P-unit who sent in the commit request for t_x. The P-unit will simply remove the write-set w_x. Otherwise, the transaction t_x continues to the third phase.

Writing/Committing. In this phase, a transaction t_x first creates a new version for each record from its write-set w_x in Memtable, and temporarily writes its transaction ID x into the header field of each such record. Next, T-node obtains a *commit-timestamp* for t_x by incrementing the global counter. T-node then replaces the transaction identifier with t_x's *commit-timestamp* for each record with transaction ID x in Memtable (i.e., those from w_x). Lastly, T-node releases all locks held by t_x.

Correctness. Given a transaction t_x with *read-timestamp* (rt_x) and *commit-timestamp* (ct_x), Solar guarantees that t_x reads a consistent snapshot of the database and there is no lost update anomaly.

Consistent snapshot read: Firstly, t_x sees the versions written by all transactions committed before rt_x because those transactions have finished creating new versions for their write-sets and obtained their commit-timestamps before t_x is assigned rt_x as its read-timestamp. Secondly, the remaining transactions in the system always write a new data version using a commit-timestamp that is larger than rt_x. Hence, their updates will not be read by t_x. Hence, t_x always operates on a consistent snapshot.

Prevention of Lost Update: Lost update anomaly happens when a new version of record r is created by another transaction for $r \in w_x$, and the version's timestamp is in the range of (rt_x, ct_x). Assume the version is created by t_y. There are two cases:

1) t_y acquired the lock on record r prior to t_x's attempt to lock r. Thus, t_x only gets the lock after t_y has committed and created a new version of r. Hence, t_x will see the newer version of r during validation and be aborted.

2) t_y acquires the lock on r after t_x has secured the lock. In this case, t_y will not be able to obtain a commit timestamp until it has acquired the lock released by t_x, which means $ct_y > ct_x$. This contradicts with the assumption that the new version of r has a timestamp within (rt_x, ct_x). Recall that the timestamp of a new version for a record $r \in w_y$ is assigned the commit-timestamp of t_y.

3.2 System recovery

Failure of P-unit. When a P-unit fails, a transaction may still be in the processing phase if it has not issued the commit request. Such a transaction is treated as being aborted. For transactions in either the validation or the committing phase, they can be terminated by T-node without communicating with the failed P-unit. T-node will properly validate a transaction in this category and decide whether to commit or to abort. Both the snapshot isolation and durability are guaranteed, and all affected transactions are properly ended after a P-unit fails.

Failure of T-node. T-node keeps its Memtable in main memory. To avoid data loss, it uses WAL and forces redo log records to its disk storage for all committed transactions. When T-node fails, it is able to recover committed data by replaying the redo log. Moreover, to avoid being the single point of failure, Solar also synchronizes all redo log records to two replicas of T-node using a primary-backup scheme. Each replica catches up the content of T-node by replaying the log. When the primary T-node crashes, all actively running transactions are terminated; and further transaction commit requests are redirected to a secondary T-node quickly. As a result, Solar is able to recover from T-node failure and resume services in just a few seconds.

Failure of S-node. An S-node failure does not lead to loss of data as an S-node keeps all tablets on disk. The failure of a single S-node does not negatively impact the availability of system because all tablets have at least three replicas on different S-nodes. When one S-node has crashed, a P-unit can still access records of a tablet from the copy on another S-node.

3.3 Snapshot isolation in data compaction

Data compaction recycles memory used for Memtable. It produces a new SSTable by merging the current Memtable from T-node into the SSTable on S-nodes.

Data compaction. Let m_0 and s_0 be the current Memtable and SSTable respectively. Data compaction creates a new SSTable s_1 by merging m_0 and s_0. An empty Memtable m_1 replaces m_0 on T-node to service future transaction writes. Note that s_1 contains the latest version of each record originally stored in either m_0 or s_0, and is a consistent snapshot of the database. It indicates that there is a timestamp t_{dc} for the start of compaction such that transactions committed before t_{dc} store their updates in s_1 and transactions committed after t_{dc} keep new versions in m_1.

When data compaction starts, T-node creates m_1 for servicing new write requests. A transaction is allowed to write data into m_0 *if and only if* its validation phase occurred before data compaction started. T-node waits till all such transactions have committed (i.e., no more transaction will update m_0 any more). At this point, S-nodes start to merge m_0 with their local tablets. An S-node does not overwrite an existing tablet directly. Rather, it writes the new tablet using the copy-on-write strategy. Thus, ongoing transactions can still read s_0 as usual. An S-node acknowledges T-node when a tablet on that S-node involving some records in m_0 is completely merged with the new versions of those records from m_0. Data compaction completes when all new tablets have been created. T-node is now allowed to discard m_0 and truncate the associated log records.

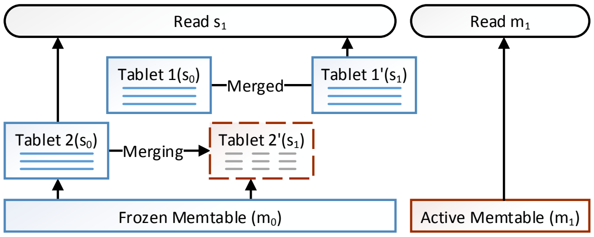

Figure 2: Data access during data compaction.

Figure 2 illustrates how to serve read access during data compaction. A read request for any newly committed record versions (after t_{dc}) is served by m_1; otherwise it is served by s_1. There are two cases when accessing s_1: if the requested record is in a tablet that has completed the merging process, only the new tablet in s_1 needs to be accessed (e.g., Tablet 1' in Figure 2); if the requested record is in a tablet that is still in the merging process (e.g., Tablet 2 in Figure 2), we need to access both that tablet from s_o and m_0.

Concurrency control. Snapshot isolation needs to be upheld during data compaction. The following concurrency control scheme is enforced. 1) If a transaction starts its validation phase before a data compaction operation is initiated, it validates and writes on m_0 as described in Section 3.1. 2) A data compaction operation can acquire a timestamp t_{dc} only when each transaction that started validation before the data compaction operation is initiated either aborts or acquires a commit-timestamp. 3) The data compaction can actually be started once all transactions with a commit-timestamp smaller than t_{dc} finish. 4) If a transaction t_x starts its validation phase after a data compaction operation is initiated, it can start validation only after the data compaction operation obtains its timestamp t_{dc}. The transaction t_x validates against *both* m_0 and m_1 but *only writes* to m_1. During validation, t_x acquires locks on both m_0 and m_1 for each record in its write set w_x, and verifies that no newer version is created relative to t_x's read-timestamp. Once passing validation, t_x writes its updates into m_1, after which t_x is allowed to acquire its commit-timestamp. 5) If a transaction acquires a read-timestamp which is larger than t_{dc}, it validates against and writes to m_1 only.

Correctness. Consistent snapshot read is guaranteed by assigning a read-timestamp to each transaction. Its correctness follows the same analysis as discussed for the normal transaction processing. The above procedure also prevents lost update during data compaction. Consider a transaction t_x with read timestamp rt_x and commit-timestamp ct_x. Assume that another transaction t_y exists, which has committed between rt_x and ct_x, i.e., $rt_x < ct_y < ct_x$, and t_y has written some records that t_x will also write later after t_y has committed. We only need to consider the case where $ct_y < t_{dc} < ct_x$, since, otherwise, lost update anomaly is guaranteed not to happen because both t_x and t_y will validate against the same set of Memtables (m_0 and/or m_1). This leads to the situation where $rt_x < ct_y < t_{dc} < ct_x$. Thus, t_x will be validated against both m_0 and m_1, and it will guarantee to see the committed updates made by t_y. As a result, t_x will be aborted since it will find at least one record with timestamp greater than its read timestamp rt_x. Hence, lost update anomaly still never happens even when data compaction runs concurrently with other transactions.

Recovery. The recovery mechanism is required to correctly restore both m_0 and m_1 when a node fails during an active data compaction. Data compaction acts as a boundary for recovery. Transactions committed before the start of the latest data compaction (that was actively running when a crash happened) should be replayed into m_0 while those committed after that should be replayed into m_1. Furthermore, we do *not* need to replay any transactions committed before the completion of the latest *completed* data compaction, since they have already been successfully persisted to SSTable through the merging operation of that completed data compaction. To achieve that, a compaction start log entry (CSLE) is persisted into the log on disk storage, when a data compaction starts, to document its t_{dc}. A compaction end log entry (CELE) is persisted when a data compaction ends with its t_{dc} serving as a unique identifier to identify this data compaction.

That said, failure of any P-unit does not lead to data loss or impact data compaction. When T-node fails, the recovery procedure replays the log from the CSLE with timestamp t_{dc}, which can be found in the last CELE. Initially, it replays the log into the Memtable m_0. When a CSLE is encountered, it creates a new Memtable m_1 and replays subsequent log entries into m_1. The merging into S-nodes continues after m_0 is restored from the recovery.

If an S-node fails during a data compaction, no data is lost since S-nodes use disk storage. But an S-node β may still be in the process of creating new tablets when it fails. Thus, when β recovers and rejoins the cluster, it contains the tablets of old SSTable and incomplete tablets produced during merging. If the system has already completed the data compaction (using other replicas for the failed node), there is at least one replica for each tablet in the new SSTable. The recovered node β simply copies the necessary tablets from a remote S-node. If data compaction has not completed, β would continue merging by reading records in m_0 from T-node.

Storage management. During data compaction, m_0 and s_0 (the existing SSTable before the current compaction starts) remain read only while s_1 and m_1 are being updated. When compaction completes, m_0 and s_0 are to be truncated. But they can only be truncated when no longer needed for any read access. In summary, m_0 and s_0 can be truncated when the data compaction has completed *and* no transaction has a read timestamp smaller than t_{dc}.

4 Optimization

It is important for Solar to reduce the network communication overhead among P-units, S-nodes and T-node. To achieve better performance, we design fine-grained data access methods between P-units and the storage nodes.

4.1 Optimizing data access

The correct data version that a transaction needs to read is defined by the transaction's read-timestamp, which could be stored either in SSTable on S-nodes or in Memtable on T-node. Thus, Solar does not know where a record (or columns of a record) should be read from, and P-units have to access both SSTable on S-nodes and Memtable on T-node to ensure read consistency (though one of which will turn out to be an incorrect version).

Here, we first present an SSTable cache on P-units to reduce data access between P-units and S-nodes. Then, an asynchronous bit array is designed to help P-units identify potentially useless data accesses to T-node.

4.1.1 SSTable cache

A P-unit needs to pull records from SSTable. These remote data accesses can be served efficiently using a data cache. The immutability of SSTable makes it easy to build a cache pool on a P-unit. The cache pool holds records fetched from SSTable and serves data accesses to the same records.

The cache pool is a simple *key-value store*. The *key* stores the primary key and the *value* holds the corresponding record. All entries are indexed by a hash map. A read request on a P-unit first looks for the record from its cache pool. Only if there is a cache miss, the P-unit pulls the record from an S-node and adds it to its cache pool. The cache pool uses a standard buffer replacement algorithm to satisfy a given memory budget constraint.

Since SSTable is immutable and persisted on disk, Solar does not persist the cache pools. Entries in a cache pool do expire when the SSTable they were fetched from is obsolete after a data compaction operation. A P-unit builds a new cache pool when that happens.

4.1.2 Asynchronous bit array

SSTable is a consistent snapshot of the whole database. In comparison, Memtable only stores the newly created data versions after the last data compaction, which must be a small portion of the database. As a result, most likely a read request sent to a T-node would fetch nothing from T-node. We call this phenomenon *empty read*. These requests are useless and have negative effects. They increase latency and consume T-node's resources.

To avoid making many empty reads, T-node uses a succinct structure called *memo structure* to encode the existence of items in Memtable. The structure is periodically synchronized to all P-units. Each P-unit examines its local memo to identify potential empty reads.

The memo structure is a bit array. In the bit array, each bit is used to represent whether a column of a tablet has been modified or not. That is to say, if any record of a tablet T has its column C modified, the bit corresponding to (T,C) is turned on. Otherwise, the bit is turned off. Other design choices are possible, e.g., to encode the record-level information, but that would increase the size of the bit-array dramatically.

Solar keeps two types of bit arrays. The first type is a real-time bit array on T-node, denoted as b. The second type is an asynchronous bit array on each P-unit, which is a copy of b at some timestamp t, denoted as $b' = b_t$ where b_t is the version of b at time t. A P-unit queries b' to find potential empty reads without contacting T-node.

On T-node, b is updated when a new version is created for any column of a record for the first time. Note that when a version is created for a data item (a column value) that already exists in Memtable, it is not necessary to update b, as that has already been encoded in b. Each P-unit pulls b from T-node periodically to refresh and synchronize its local copy b'.

During query processing for a transaction t_x on a P-unit p, p examines its local b' to determine whether T-node contains newer versions for the columns of interest of any record in t_x's read set. If (T,C) is 0 in b' for such a column C, p treats the request as an empty read and does not contact T-node; otherwise, p will send a request to pull data from T-node.

Clearly, querying b' leads to false positives due to the granularity of the encoding, and such false positives will lead to empty reads to T-node. Consider in tablet T, row r_1 has its column C updated and row r_2 has not updated its column C. When reading column C of r_2, a P-unit may find the bit (T,C) in b' is set while there is no version for $r_2.C$ on T-node. In fact, the above method is most effective for read-intensive or read-only columns. They seldom have their bits turned on in the bit array.

Querying b' may also return false negatives because it is not synchronized with the latest version of b on T-node. Once a false negative is present, a P-unit may miss the latest version of some values it needs to read and end up using an inconsistent snapshot. To address this issue, a transaction must check all potential empty reads during its validation phase. If a transaction sees the bit for (T,C) is 0 in b' during processing, it needs to check whether the bit is also 0 in b during validation. If any empty read previously identified by b' cannot be confirmed by b, a transaction has to be re-processed by reading the latest versions in Memtable. False negatives are rare because b does not see frequent update: it is only updated at the first time any row in tablet T has its column C modified.

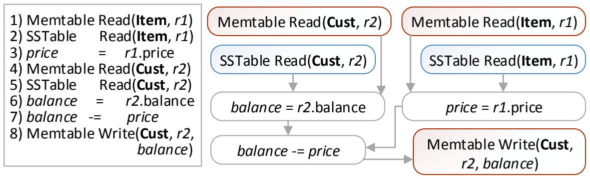
4.2 Transaction compilation

Solar supports JDBC/ODBC connections, as well as stored procedures. The latter takes the one-shot execution model [26] and avoids client-server interaction. This poses more processing burden on the DBMS, but enables server-side optimizations [33, 39, 40]. Solar designs a compilation technique to optimize inter-nodes communication by generating an optimized physical plan.

read	Memtable read
	SSTable read
write	update local buffer on P-unit **(local operation)**
process	expression, project, sort, join ... **(local operation)**
compound	loop, branch

Table 1: Possible operations in a physical plan.

Execution graph. The physical plan, to be executed by a P-unit, of a stored procedure is represented as a sequence of operations in Table 1 (nested structures, such as branch or loop, can be viewed as a compound operation). Reads are implemented via RPC while write and process/computation are *local operations*. Hence, reads are the key to optimizing network communication.



1) Memtable Read(**Item**, *r1*)
2) SSTable Read(**Item**, *r1*)
3) *price* = *r1*.price
4) Memtable Read(**Cust**, *r2*)
5) SSTable Read(**Cust**, *r2*)
6) *balance* = *r2*.balance
7) *balance* -= *price*
8) Memtable Write(**Cust**, *r2*, *balance*)
Memtable Read(**Cust**, *r2*)
Memtable Read(**Item**, *r1*)
SSTable Read(**Cust**, *r2*)
SSTable Read(**Item**, *r1*)
balance = *r2*.balance
price = *r1*.price
balance -= *price*
Memtable Write(**Cust**, *r2*, *balance*)

Figure 3: Example of operation sequence and execution graph.

Two operations have to be executed in order if they have 1) *procedure constraint*: two operations contain data/control dependence [21]; or 2) *access constraint*: two operations access the same record and one operation is a write. In practice, we cannot always determine two database records are the same during compilation, so we treat it as a potential access constraint if two operations are accessing the same table. Then, we can represent an operation sequence as an *execution graph*, where the nodes are operations and edges are the constraints and represent the execution order (Figure 3).

We also support branches and loops as compound operations. A compound operation is a complex operation if it contains multiple reads. If it only contains one read, the compound operation is viewed as the same type of read (defined in Table 1) as that single read. Otherwise, a compound operation is viewed as a local operation. We adopt loop distribution [14] to split a large loop into multiple smaller loops so that they can be categorized more specifically. For a read operation in a branch block, it can be moved out for speculative execution since reads do not have side effect and thus are safe to execute *even if* the corresponding branch is not taken.

Grouping Memtable **Reads.** To reduce the number of RPCs to T-node, we can group multiple Memtable reads together in one RPC to T-node if they do not have constraints between them. This is done in two passes over the physical plan. The first pass finds all the Memtable reads not constrained by any other reads via a BFS over the execution graph. The second pass starts from the unconstrained Memtable reads and marks all *local operations* that precede them. Before executing transaction logics, all those local operations marked in pass 2 get executed first. Then the Memtable reads marked in pass 1 are sent in a single RPC request to T-node.

Pre-executing SSTable **Reads.** SSTable reads can be issued even before a transaction obtains its read-timestamp from T-node and we concurrently execute them with other operations, since there is only one valid snapshot in SSTable at a time. This requires that the SSTable reads are not constrained by other operations. During execution, the result of a SSTable read might or might not be used depending on if there is update to the same record in Memtable. Though this optimization might introduce unused SSTable reads, the problem can be mitigated by the SSTable cache pool. The main benefit of pre-executing SSTable reads is reducing wait time and thus reducing latency. The SSTable reads that can be pre-executed can be found using a similar algorithm to the one that finds Memtable reads that can be grouped.

Remarks. The optimizations described in this section are desgined for short transactions. Other workloads, such as bulk loading, OLAP, require additional optimizations. For bulk loading, it is possible to skip the T-node and directly load data into S-nodes. For OLAP queries, they can be executed upon a consistent database snapshot, and some relational operators can be pushed down into storage nodes to reduce inter-node data exchange.

5 Experiment

We implemented Solar by extending the open-sourced version of Oceanbase (OB) [1]. In total, 58,281 lines were added or modified on its code base. Hence, Solar is a full-fledged database system, implemented in 457,206 lines of C++ code. In order to compare it to other systems that require advanced networking infrastructures, we conducted all experiments using 11 servers on Emulab [38], which allows configuring different network topologies and infrastructures. Each server has two 2.4 GHz 8-Core E5-2630 processors (32 threads in total when hyper-threading enabled) and 64GB DRAM, *connected through a 1 Gigabits Ethernet by default. By default ten servers* are used to deploy the database system. One server is used to simulate clients. We compared Solar with MySQL-Cluster 5.6, Tell (shared-everything) [19], and VoltDB Enterprise 6.6 (shared-nothing) [27]. Though Tell is designed for InfiniBand, we used a simulated InfiniBand over Ethernet to have a fair comparison. We use Tell-1G (Tell-10G) to represent the Tell system using 1-Gigabits (10-Gigabits) network respectively.

Solar is not compared with lightweight prototype systems that aim at verifying the performance of new concurrency control scheme, such as Silo [30]. These systems achieve impressive throughput, but their implementations lack many important features, such as durable logging, disaster recovery and a SQL engine. These features often introduce significant performance overhead, but are ignored by these lightweight system prototypes.

Solar deploys the T-node on a single server. It deploys both an S-node and a P-unit on each of the remaining nodes. Tell deploys a commit manager on a single server. It uses two servers for storage node deployment and the rest for processing nodes. We tested different combinations of processing node and storage node instances and chose the best configuration. Tell uses more processing node instances and fewer storage nodes. MySQL-Cluster deploys both a mysqld and a ndbmtd instance on each server. VoltDB creates 27 partitions on each server, which is based on the officially recommended strategy [32]. It was determined by adjusting partition numbers to achieve the best performance on a single server.

We used three different benchmarks. Performance of different systems are evaluated by transaction processed per second (TPS). In each test instance, we adjusted the number of clients to get the best throughput.

5.1 TPC-C benchmark

We use a standard TPC-C workload with 45% NewOrder, 43% Payment, 4% OrderStatus, 4% Delivery and 4 % StockLevel requests. Request parameters are generated according to the TPC-C specification. *By default, 200 warehouses* are populated in the database. Warehouse keys are used for horizontal partitioning. Initially, Solar stores 1.6 million records (2.5 GB) in the Memtable and 100 million records (42GB) in the SSTable (with 3x replication enabled). After the benchmark finishes, there are 11 GB data in the Memtable and the size of SSTable is about 655 GB.

Figure 4 shows the performance of different systems when we vary the number of warehouses. Solar achieves about 53k TPS on 50 warehouse, and increases to about 75k TPS with 350 warehouses. When more warehouses are populated, there are less access contention in the workload, leading to fewer conflicts and higher concurrency. Solar clearly outperforms the other systems. Its throughput is 4.8x of that of Tell-10G (about 15.6k TPS) with 350 warehouses. Note that Tell-1G, which uses the same network infrastructure as Solar, performs even worse than Tell-10G. VoltDB exhibits the worst performance due to distributed transactions. Lastly, Oceanbase is primarily designed for processing very short transactions and thus is inefficient on general transaction workloads. Solar always achieves at least 10x throughput improvement over Oceanbase. Therefore, we skip Oceanbase in other benchmarks.

Figure 5 evaluates the scalability when using different number of nodes. The throughputs of Solar, Tell and MySQL-Cluster increase with more nodes. In contrast, the throughput of VoltDB deteriorates for the following

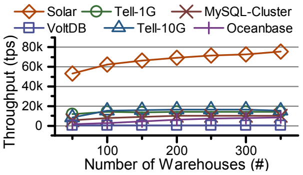


Figure 4: TPC-C: vary number of warehouses.

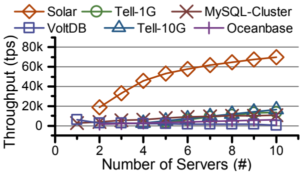

Figure 5: TPC-C: vary number of servers.

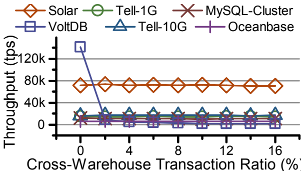

Figure 6: TPC-C: vary ratio of cross-warehouse transactions.

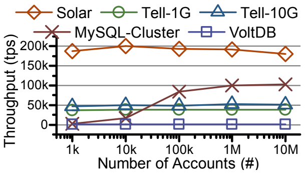

Figure 7: Smallbank: vary number of accounts.

reason. Distributed transactions are processed by a single thread in VoltDB. They block all working threads of the system. With more servers being used, it becomes more expensive for such request to be processed. The throughput growth in Solar slows down with more than 7 servers. As there are more access conflicts with a higher number of client requests, more transactions fail in the validation phase. Another reason is that T-node receives more loads when working with more P-units, *and* in our experimental setting, T-node uses the same type of machine as that used for P-units. Hence, the overall performance increases sub-linear with the number of P-units. However, in the real deployment of Solar, a high-end server is recommended for T-node, whereas P-units (and S-nodes) can be served with much less powerful machines.

Figure 6 shows the results when we vary the ratio of cross-warehouse transactions. If a transaction accesses records from multiple warehouse, it is a distributed transaction. VoltDB achieves the best performance (141k TPS) when there are no distributed transactions, which is about 2.0x of Solar (about 70k TPS). But as the ratio of distributed transactions increase, VoltDB's performance drops drastically as it uses horizontal partitioning to scale out. The other systems are not sensitive to this ratio.

Latency(ms)	Solar	Tell -1G	Tell -10G	MySQL-Cluster	VoltDB	OB
Payment	6	17	7	17	15619	38
NewOrder	15	28	12	103	30	60
OrderStatus	6	20	8	23	14	30
Delivery	40	160	53	427	14	174
StockLevel	9	14	7	17	14	60
Overall	12	30	12	95	2751	54

Table 2: 90th Latency, TPC-C workload.

Table 2 lists the 90th latency. Solar has a short latency for each transaction. Tell benefits from the better network. It gets better latency with the 10-Gbit network than the 1-Gbit one. The long latency of MySQL-Cluster comes from the network interaction between the database servers and clients because it uses JDBC instead of stored procedures. VoltDB is slow on distributed transactions. Under the standard TPC-C mix, about 15.0% Payment and 9.5% NewOrder requests are distributed transactions. Hence, the 90th latency of Payment is long. Though the 90th latency of NewOrder is small, its 95th latency reaches 15,819 ms.

5.2 Smallbank benchmark

Smallbank simulates a banking application. It contains 3 tables and 6 types of transactions. The workload contains 15% Amalgamate transactions, 15% Balance transactions, 15% DepositChecking transactions, 25% SendPayment transactions, 15% TransactSavings transactions and 15% WriteCheck transactions. Amalgamate and SendPayment operate on two accounts at a time. The other transactions access only a single account. We populated 10 million users into the database. Initially, there are 8M records (3 GB) in Memtable and 30M records (1.1 TB) in SSTable. After execution, Memtable has 5.2 GB data, and SSTable has about 1.1 TB data.

Figure 7 evaluates different systems by populating different number of accounts in the database. Note that *x-axis is shown in log-scale*. Solar has the best overall performance. Its throughput initially increases as the number of accounts increases, because less contention when there are more accounts. Due to the drop of SSTable's cache hit ratio as the number accounts further increases to 10M, P-units need to issue remomte data access to S-nodes. As a result, its throughput slightly drops.

Latency(ms)	Solar	Tell-1G	Tell-10G	MySQL-Cluster	VoltDB
Amalgamate	5	5	4	8	100
Balance	3	3	3	4	5
Deposit	4	4	4	3	5
SendPayment	7	4	4	12	102
Xact Savings	3	4	4	6	5
WriteCheck	5	4	4	5	6
Overall	5	4	4	8	92

Table 3: 90th Latency, Smallbank workload.

Tell shows a fairly stable performance, but 10G Ethernet only improves its throughput slightly. MySQL Cluster also has a better performance initially with more accounts, but stabilizes once it has maxed out all hardware resources. The performance of VoltDB is limited by cross-partition transactions. Table 3 lists the 90th latency number. It takes VoltDB much longer time than others to process *Amalgamate* and *SendPayment* and there are 40% such transactions in this workload.

Figure 8 evaluates each systems with different number of servers. Here, we populated 1M accounts in the database. Solar shows the best performance and scalability with respect to the number of servers. The throughputs of Solar, Tell and MySQL-Cluster scale linearly with the number of servers. The throughput of VoltDB is still quite limited by distributed transaction processing.

5.3 E-commerce benchmark

E-commerce is a workload from an e-business client of Bank of Communications. It includes 7 tables and 5 transaction types. There are two user roles in this application: buyer and seller. There are 4 tables for buyers:

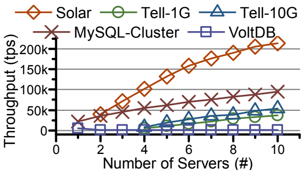

Figure 8: Smallbank: vary number of servers.

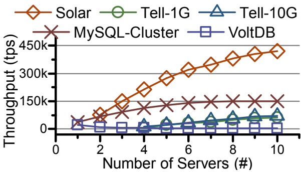

Figure 9: E-commerce: vary number of servers.

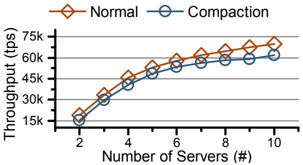

Figure 10: TPC-C: data compaction.

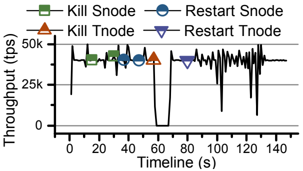

Figure 11: Solar: throughput under node failures.

User, *Cart*, *Favorite* and *Order* and 3 tables for sellers: *Seller*, *Item* and *Stock*. These tables are partitioned by *user_id* and *seller_id* respectively. At the start of the experiment, Solar has 11M records (5GB) in Memtable, and 25M records (815GB) in SSTable. When all experiments are completed, the Memtable has 8.6 GB data and the size of SSTable is 881GB.

The workload has 88% OnClick transactions, 1% AddCart transactions, 6% Purchase transactions and 5% AddFavorite transactions. The OnClick request is a *r*ead-only transaction while the others are *r*ead-write ones. OnClick reads an item and accesses *Item* and *Stock*. AddCart inserts an item into a buyer's cart and accesses *User* and *Cart*. AddFavorite inserts an item into a buyer's favorite list and updates the item's popular level. It accesses *User*, *Favorite* and *Item*. Purchase creates an order for a buyer and decrements the item's quantity. It accesses *User*, *Order*, *Item* and *Stock*.

Latency(ms)	Solar	Tell-1G	Tell-10G	MySQL-Cluster	VoltDB
OnClick	1	8	4	4	4
AddFavorite	2	12	5	6	47
AddCart	2	2	14	4	4
Purchase	4	12	4	6	49
Overall	1	8	4	4	19

Table 4: 90th Latency, E-commerce workload.

Figure 9 shows the performance of each system using different number of servers. The throughput of Solar increases with the number of servers used. It has achieved about 438k TPS when 10 servers are used, and is at least 3x that of any other system. As shown in Table 4 for the 90th latency, most transactions completed within 1ms by Solar. MySQL-Cluster and Tell also see performance improvement when more servers are used. But they have higher latency as shown in Table 4. VoltDB is highly inefficient on AddFavorite and Purchase because tables accessed by these transactions use different partition keys. These transactions may visit multiple partitions which block other single-partition transactions. As a result, OnClick and AddCart also have longer latency.

5.4 Data compaction

During transaction processing, Solar may initiate a data compaction in the background. Figure 10 shows the impact of data compaction on the performance, when Solar is processing the standard TPC-C workload. As shown in Figure 10, data compaction has little negative effect on the performance when 5 or less servers are used. It is because the performance is mainly limited by the number of P-units in these cases, and compaction would not influence the operation of P-units. When more servers are used, there is about 10% throughput loss. This is because at this point T-node has more impact on the overall system performance when more servers are introduced. Data compaction consumes part of the network bandwidth and CPU resources, which are also required by transaction processing on T-node.

5.5 Node failures

We next investigate the impact of node failures in Solar. In this experiment, 3 servers were used to deploy T-nodes, and 7 servers were used to deploy S-nodes and P-units. One T-node acts as the primary T-node, and the other two are secondary T-nodes. The TPC-C benchmark was used with 200 warehouses populated, and we terminated some servers at some point during execution. Figure 11 plots the changes of throughput against the time.

Removing 2 S-nodes does not impact the performance, as the SSTable keeps 3 replicas for each tablet and each P-unit also caches data from SSTable. Thus, losing 2 S-nodes does not influence performance. We then terminated the primary T-node. Immediately after it went down, the throughput drops to 0 because no T-node can service write requests now. After about 7 seconds, a secondary T-node becomes the primary and the system continues to function. After the failed T-node re-joins the cluster, the new primary T-node has to read redo log entries from the disk and send them to the T-node in recovery. Thus, the performance fluctuates and drops a little bit due to this overhead. It takes about 40 seconds for the failed T-node to catch up with the new primary, after which the system throughput returns to the normal level.

5.6 Access optimizations

Figure 12 evaluates the performance improvement brought by different access optimizations. The *y-axis shows the normalized performance to a baseline system without using any optimization.* The figure shows the improvement brought by enabling each individual optimization, as well as all of them, using the TPC-C workload. Other workloads share the similar performance trends. With more P-units and S-nodes deployed in system, the individual optimizations show different trends of improvement. The effectiveness of SSTable cache drops because the overall data access throughput increases when more S-nodes are deployed. However, the accesses to T-node are more contentious as more P-units communicate with the single T-node. With transaction compilation enabled, small data accesses to T-node are

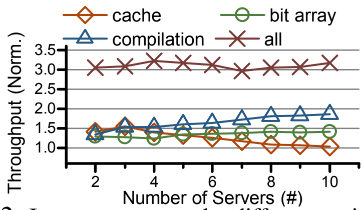

Figure 12: Improvements under different optimizations.

combined, which improves the overall throughput when there are more P-units. The bit array shows a relatively stable impact to the throughput because it prunes data access to T-node at the column level, which is related to the workload rather than the number of servers. As long as a column is not read-only in any row in a tablet, it cannot prune the data access to T-node. When all optimizations are used together, they bring about 3x throughput improvement regardless of the number of servers used.

6 Related Work

Single-node system. Single-node in-memory systems have exploited NUMA architectures, RTM, latch-free data structures, and other novel techniques to achieve high performance transaction processing, such as Silo [30], Hekaton [7], Hyper [13, 24], DBX [34], and others. The usage of these systems are subject to the main memory capacity on a single node as they require all data stored in the memory. Deuteronomy's [17] transaction component (TC) uses pessimistic, timestamp-based MVCC with decoupled atomic record stores. It can manage data sharded over multiple record stores, but Deuteronomy is not itself networked or distributed; instead stores are on different CPU sockets. It ships updates to the data storage via log replaying and all reads have to go through TC. In contrast, Solar uses MVOCC and a cluster of data storage, and it can potentially skip T-node access using its asynchronous bit arrays.

Shared-nothing systems. Horizontal partitioning is widely used to scale out. Examples include HStore [12, 26], VoltDB [27], Accordion [25], E-Store [28]. We have discussed their limitations in Section 2.1. Calvin [29] takes advantage of deterministic execution to maintain high throughput even with distributed transactions. However, it requires a separate reconnaissance query to predict unknown read/write set. Oceanbase [1] is Alibaba's distributed shared-nothing database designed for short transactions. In shared-nothing systems, locking happens at partition level. To get subpartition locking, distributed locks or a central lock manager must be implemented, which goes against the principle for strict partitioning (i.e., get rid of distributed locking/latching), and reintroduces (distributed) locking and latching coordination overheads and defeats the gains of shared nothing. That said, new concurrency control schemes can improve the performance of distributed transactions (e.g., [20]), when certain assumptions are made (e.g., knowing the workload apriori, using offline checking, deterministic ordering, and dependency tracking).

Shared-everything systems. The shared-everything architecture is an alternative choice to enable high scalability and high performance, where any node can access and modify any record in the system. Traditional shared-everything databases, like IBM DB2 Data Sharing [11] and Oracle RAC [4], suffer from expensive distributed lock management. Modern shared-everything designs exploit advanced hardware to improve performance, such as Tell [19], DrTM [37] and DrTM+B [36] (with live reconfiguration and data repartitioning), HANA SOE [10]. Solar, on the other hand, uses commodity servers and does not rely on special hardwares.

Log-structured storage. The log-structured merge tree [22] is optimized for insertion, update and deletion. It is widely adopted by many NoSQL vendors, such as LevelDB [18], BigTable [5], Cassandra [16] and etc. However, none of these supports multi-row transactions. LogBase [31] is a scalable log-structured database with a *log file only storage* where the objective is to remove the write bottleneck and to support fast system recovery, rather than optimizing OLTP workloads. Hyder II optimizes OCC for tree-structured, log-structured databases [3] which Solar may leverage for further improving its concurrency control scheme. vCorfu [35] implements materialized streams on a shared log to support fast random reads. But, it increases transaction latency as committing requires at least four network roundtrips.

7 Conclusion

This work presents Solar, a high performance and scalable relational database system that supports OLTP over a distributed log-structured storage. Extensive empirical evaluations have demonstrated the advantages of Solar compared to other systems on different workloads. Solar has been deployed at Bank of Communications to handle its e-commerce OLTP workloads. We plan to open source Solar on GitHub. Current and future works include designing a more effective query optimizer and task processing module, by leveraging the NUMA architecture, improving its concurrency control scheme, and designing an efficient and scalable OLAP layer.

Toward Coordination-free and Reconfigurable Mixed Concurrency Control

Aaron J. Elmore
University of Chicago

Abstract

Recent studies show that mixing concurrency control protocols within a single database can significantly outperform a single protocol. However, prior projects to mix concurrency control either are limited to specific pairs of protocols (e.g mixing two-phase locking (2PL) and optimistic concurrency control (OCC)) or introduce extra concurrency control overhead to guarantee their general applicability, which can be a performance bottleneck. In addition, due to unknown and shifting access patterns within a workload, candidate protocols should be chosen dynamically in response to workload changes. This requires changing candidate protocols online without having to stop the whole system, which prior work does not fully address. To resolve these two issues, we present CormCC, a general mixed concurrency control framework with no coordination overhead across candidate protocols while supporting the ability to change a protocol online with minimal overhead. Based on this framework, we build a prototype main-memory multicore database to dynamically mix three popular protocols. Our experiments show CormCC has significantly higher throughput compared with single protocols and state-of-the-art mixed concurrency control approaches.

1 Introduction

With an increase in CPU core counts and main-memory capacity, concurrency control has become a new bottleneck in multicore main-memory databases due to the elimination of disk stalls [8, 34]. New concurrency control protocols and architectures focus on enabling high throughput by fully leveraging available computation capacity, while supporting ACID transactions. Some protocols try to minimize the overhead of concurrency control [10], while other protocols strive to avoid single contention points across many cores [27, 35]. However, these single protocols are typically designed for specific workloads, may only exhibit high performance under their optimized scenarios, and have poor performance in others. Consider H-Store's concurrency control protocol that uses coarse-grained exclusive partition locks and a simple single-threaded executor per partition [10]. This approach is ideal for partitionable workloads that have tuples partitioned such that a transaction is highly likely to access only one partition. But this approach suffers decreasing throughput with increasing cross-partition transactions [34, 27, 20]. Here, an optimistic protocol may be preferred if the workload mainly consists of read operations or a pessimistic protocol may be ideal if the workload exhibits high conflicts. An appealing solution to this tension is to combine different protocols such that each protocol can be used to process a part of workload that they are optimized for, and avoid being brittle to scenarios where single protocols suffer.

Efficiently mixing multiple concurrency control protocols is challenging in several ways. First, it should not be limited to a specific set of protocols (e.g. OCC and 2PL [22, 28]), but be able to extend to new protocols with reasonable assumptions. Second, the overhead of mixing multiple protocols should be minimized such that the overhead is not a performance bottleneck in any scenario. A robust design should ensure that in any case the mixed execution does not perform worse than any single candidate protocol involved. Finally, as many transactional databases back user-facing applications, dynamically switching protocols online in response to workload changes is necessary to maintain performance.

While several recent studies focus on mixed concurrency control, they only address a part of the above challenges. For example, MOCC [28] and HSync [22] are designed to mix OCC and 2PL with minimal mixing overhead but fails to extend to other protocols; Callas [31] and Tebaldi [23] provide a general framework that can cover a large number of protocols, but their overhead of mixing candidate protocols is non-trivial in some scenarios and do not support online protocol switch thus failing to address the workload changes. Our prior work [25] envisions an adaptive database that mixes concurrency control, but does not includes a general framework to address these challenges.

In this paper, we present a general mixed concurrency control scheme **CormCC** (*Coordination-free and Reconfigurable Mixed Concurrency Control*) to systematically address all the aforementioned challenges. CormCC decomposes a database into partitions according to workload access patterns and assigns a specific protocol to each partition, such that a protocol can be used to process the parts of a workload they are optimized for. We then develop several criteria to regulate the mixed execution of multiple forms of concurrency control to maintain ACID properties. We show that under reasonable assumptions, this method allows correct mixed execution without coordination across different protocols, which minimizes the mixing overhead. In addition, we develop a general protocol switching method (i.e. reconfiguration) to support changing protocols online with multiple protocols running together; the key idea is to compose a *mediated* protocol compatible with both the old and new protocol such that switch process does not have to stop all transaction workers while minimizing the impact on throughput and latency. To validate the efficiency and effectiveness of CormCC, we develop a prototype main-memory database on multi-core systems that supports mixed execution and dynamic switching of three widely-used protocols: a single-threaded partition based concurrency control (*PartCC*) from H-Store [10], an optimistic concurrency control (*OCC*) based on Silo [27], and a two-phase locking based on VLL (*2PL*) [21]. [1]

The main contributions of this paper over our vision paper [25] are the following:

- A detailed analysis of mixed concurrency control design space, a general framework that is not limited to a specific set of protocols to mix multiple forms of concurrency control without introducing extra overhead of coordinating conflicts across protocols.

- A general protocol switching method to reconfigure a protocol for parts of a workload without stopping the system or introducing significant overhead.

- A thorough evaluation of state-of-the-art mixed concurrency control approaches, CormCC's end-to-end performance over varied workloads, and the performance benefits and overhead of CormCC's mixed execution and online reconfiguration.

2 Related Work

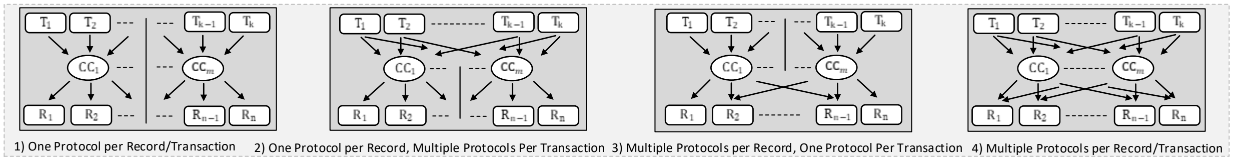
With the increase of main memory capacity and the number of cores for a single node, recent research focuses on improving traditional concurrency control protocols on modern hardware. We classify these works into optimizing single protocols, mixing multiple protocols, and adaptable concurrency control.

Optimizing Single Protocols Many recent projects consider optimizing a single protocol, which we believe are orthogonal to this project. H-Store [8, 10] developed a partitioned based concurrency control (PartCC) to minimize concurrency control overhead. The basic idea is to divide databases into disjoint partitions, where each partition is protected by a lock and managed by a single thread. A transaction can execute when it has acquired the locks of all partitions it needs to access. Exploiting data partitioning and the single-threaded model is also adopted by several research systems [8, 10, 32, 18, 19, 11]. Other projects propose new concurrency controls optimized for multi-core main-memory databases [6, 14, 27, 17, 35, 20, 13, 29, 30, 36, 12, 37, 16] or new data structures to remove the bottlenecks of traditional concurrency control [34, 21, 15, 9].

Mixing Multiple Protocols Callas [31] and its successive work Tebaldi [23] provide a modular concurrency control mechanism to group stored procedures and provide an optimized concurrency control protocol for each group based on offline workload analysis; for transaction conflicts across groups, Callas and Tebaldi introduce one or multiple protocols in addition to protocols for each group to resolve them. While stored procedure oriented protocol assignment can process conflicts within the same group more efficiently, the additional concurrency control overhead from executing both in-group and cross-group protocols can become the performance bottleneck for a main-memory database on a multi-core server. Section 3 shows a detailed discussion. In addition, the grouping based on offline analysis assumes workload conflicts are known upfront, which may not be true in real applications. Our work differs from Callas and Tebaldi in that our mixed concurrent control execution does not introduce any extra concurrency control overhead, which greatly reduces the mixing overhead. Additionally, we do not assume a static workload or require any knowledge about workload conflicts in advance, but allow protocols are chosen and reconfigured online in response to dynamic workloads. Some other projects exploit the mixed execution of 2PL or OCC [33, 6, 28, 22]. CormCC differs in that our framework is more general and can be extended to more protocols.

Adaptable Concurrency Control Adaptable concurrency control has been studied in several research works.

[1] Note that we use strong 2PL (SS2PL), but refer to it as 2PL



1) One Protocol per Record/Transaction 2) One Protocol per Record, Multiple Protocols Per Transaction 3) Multiple Protocols per Record, One Protocol Per Transaction 4) Multiple Protocols per Record/Transaction

Figure 1: Design choices of mixed concurrency control

At the hardware level, ProteusTM [7] is proposed to adaptively switch across multiple transaction memory algorithms for different workloads, but cannot mix them to process different parts of a workload. Tai et al. [24] shows the benefits of adaptively switching between OCC and 2PL. RAID [4, 3] proposes a general way to change a single protocol online. CormCC differs in that it allows multiple protocols running in the same system and supports to reconfigure a protocol for parts of workload. In this scenario, the presence of multiple protocols during the reconfiguration presents new challenges we are addressing.

3 Design Choices

While combining multiple protocols into a single system can potentially allow more concurrency to improve the overall throughput, it comes with the cost of higher concurrency control overhead. In this section, we discuss two key design choices to explore this trade-off and show how this trade-off motivates the design of CormCC. Specifically, we consider whether a record can be accessed (i.e. read/write) by multiple protocols and whether a single transaction involves multiple protocols. Based on the design choices, the overhead can be defined as *the cost of executing more than one protocol for each transaction plus the cost of synchronizing the concurrent read/write operations across different protocols for each record in the database*. Note that in this paper, we assume all the transaction logic and the corresponding concurrency control logic of a transaction are executed by a single thread (i.e. transaction worker), which is a common model in the design of mixed concurrency control [31, 23, 28, 22, 6]. We now discuss the four possible designs that are shown in Figure 1.

One Protocol per Record and per Transaction This is the simplest case, which is the left most part of Figure 1. We see that each transaction (denoted by `T`) can only choose one protocol (i.e. `CC` in Figure 1) and each record (denoted by `R`) can be accessed via one protocol. While the mixing overhead is minimal (based on our overhead definition), this design has very limited applicability since each transaction can only access the partition of records managed by a specific protocol. To the best of our knowledge, no previous work adopts it.

One Protocol per Record, Multiple Protocols per Transaction This design further allows that one transaction executes multiple protocols (shown in the second design in Figure 1); it provides the flexibility that transactions can access any record and allows a specific protocol to process all access to each record according to their access patterns. On the other hand, the execution of a single transaction may involve a larger set of instructions from multiple protocols, which makes CPU instruction cache less efficient. However, according to our experiment in Section 6.5 this mixing overhead is very low. MOCC [28] adopts this design to mix OCC and 2PL, but does not have a general framework.

Multiple Protocols per Record, One Protocol per Transaction An alternative design (the third one in Figure 1) is that each record can be accessed via multiple protocols and each transaction executes one protocol. This design is useful when the semantics of a subset of transactions (e.g. from stored procedures) can be leveraged by an optimized protocol. It raises a problem, however, that co-existence of multiple protocols on the same set of records should be carefully synchronized. One solution is to let all protocols share the same set of concurrency control metadata and carefully design each protocol such that all concurrent access to the same records can be synchronized without introducing additional coordination. This solution requires specialized design for all protocols and thus is limited in its applicability. Prior works Hekaton [6] and HSync [22] adopt this design, but can only combine 2PL and OCC.

Multiple Protocols per Record and per Transaction This design (the fourth one in Figure 1) provides the most fine-grained and flexible mixed concurrency control; each transaction can mix multiple protocols and each record can be accessed via different protocols. To process the concurrent access from different protocols over the same records, additional protocols are introduced. For example, Callas [31] and its successive work Tebaldi [23] organized protocols into a tree, where the protocols in leaf nodes process conflicts of the assigned transactions and the protocols in interior nodes process conflicts across its children. The overhead here is that for each record access, multiple concurrency control logic should be executed to resolve the conflicts across different protocols over that record. Such overhead, as we show in Section 6.3, can become a performance bottleneck in the multi-core main-memory database.

Summary The above discussion (and our experiments) show that the second design, which lets each pro-

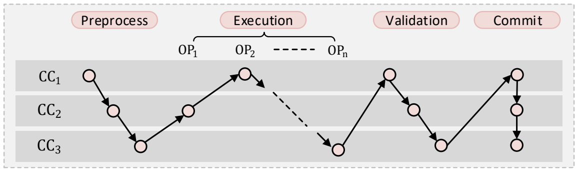


Figure 2: An Example of CormCC execution

tocol exclusively process the access of a subset of records to minimize synchronization cost and allows protocols are mixed within a transaction to provide mixing flexibility, strikes a good trade-off between leveraging the performance benefits of single protocols and minimizing mixing overhead. CormCC draws its spirit and builds a general and coordination-free framework.

4 CormCC Design

We consider a main-memory database with multiple forms of concurrency control on a multi-core machine. Each table includes one primary index and zero or more secondary indices. A transaction can be composed into read, write (i.e. update), delete, and insert operations to access the database via either primary or secondary indices in a key-value way. The database is (logically) partitioned with respect to candidate protocols within the system, that is, each partition is assigned a single protocol. Each protocol maintains an independent set of metadata for all records. For all operations on the records of a partition, the associated protocol executes its own concurrency control logic to process these operations (e.g. preprocess, reading/writing, commit), which we denote as *a protocol managing this partition*. We use a concurrency control lookup table to store the mapping from primary keys to the protocol. The lookup table maintains the mapping for the whole key space and is shared by all transaction workers. Prior work [26] shows that such a lookup table can be implemented in a memory-efficient and fast way, and thus will not be the performance bottleneck of CormCC. CormCC regards secondary indices as logically additional tables storing entries to primary keys (not pointers to records); it adopts a dedicated protocol (e.g. OCC) to process all concurrent operations over secondary indices. Transactions are routed to a global pool of transaction workers, each of which is a thread or a process occupying one physical core. This worker executes the transaction to the end (i.e. commit or abort) without interruption. We additionally use a coordinator to manage the online protocol reconfiguration for all transaction workers. It collects statistical information periodically from all workers, builds a new lookup table accordingly, and finally lets all workers use it. We first outline the CormCC protocol and then show the correctness of CormCC. After that, we discuss online protocol reconfiguration within CormCC.

4.1 CormCC Protocol

CormCC divides a transaction's life cycle into four phases: Preprocess, Execute transaction logic (Execution), Validation, and Commit. We adopt this four-phase model because most concurrency control protocols can fit into it. We use a transaction execution example in Figure 2 to explain the four phases.

Preprocess The preprocess phase executes concurrency control logic that should be executed before the transaction logic. Figure 2 shows that CormCC iterates over all candidate protocols (denoted as CC) and executes their preprocess phases respectively. Typical preprocess phase includes initializing protocol-specific metadata. For example, 2PL Wait-die needs to acquire a transaction timestamp to determine the relative order to concurrent transactions, or partition-based single-thread protocol (e.g. PartCC) acquires locks in a predefined order for partitions the transaction needs to access.

Execution Transaction logic is executed in this phase. As shown in Figure 2, for each operation (denoted as OP) issued from the transaction, CormCC first finds the protocol managing the record using the concurrency control lookup table. Then, CormCC utilizes the protocol's concurrency control logic to process this operation. For example, if the transaction reads an attribute of a record managed by 2PL, it acquires its read lock and returns the attribute's value. Note that insert operations can find the corresponding protocol in the lookup table even though the record to be inserted is not in the database because the table stores the mapping of the whole key space.

Validation Each validation phase of all protocols are executed sequentially in this phase. If the transaction passes all validation, it enters the Commit phase; otherwise, CormCC aborts it. For example, if OCC is involved, CormCC executes its validation to verify whether records read by OCC during Execution have been modified by other transactions. If yes, the transaction is aborted; otherwise, it passes this validation.

Commit Finally, CormCC begins an atomic Commit phase by executing commit phases of all protocols. For example, one typical commit phase, like OCC, will apply all writes to the database and make them visible to other transactions via releasing all locks. Note that an abort can happen in the Execution or Validation phase, in which case CormCC calls the abort functions of all protocols respectively.

4.2 Correctness

We first show the criteria for CormCC to generate serializable schedule for a set of concurrent transactions (i.e. its result is equivalent to some serial history of these transactions) to guarantee the consistency of databases.

We then discuss how CormCC avoids deadlock, and show that CormCC is recoverable (i.e. any committed transaction has not read data written by an aborted transaction).

Serializability To guarantee that CormCC is serializable, we require all candidate protocols are commit ordering conflict serializable (COCSR). It means that if two transactions t_i and t_j have conflicts on a record r (i.e. t_i and t_j reads/writes r and at least one of them is a write) and t_j depends on t_i (i.e. t_i accesses r before t_j), then t_i must be committed earlier than t_j.

Given that all candidate protocols are COCSR, we now show that CormCC is also COCSR. Suppose that two transactions t_i and t_j have conflicts on a record set R, we consider two cases. First, if for any conflicted record $r \in R$ the conflicted operation of t_i accesses r before t_j, then we have t_j depends on t_i. Since any candidate protocol is COCSR, for each conflicted record r they ensure that t_i is committed before t_j. Therefore in this case, CormCC can maintain COCSR property. In the second case, there exist two records r_1 and $r_2 \in R$, and t_i accesses r_1 before t_j and t_j accesses r_2 before t_i. We have t_j depends on t_i and t_i depends on t_j. In this case, r_1 and r_2 must be managed by two separate protocols p_1 and p_2 since each single protocol is COCSR and it is not possible to form a conflict-cycle in one protocol. Consider p_1, which manages r_1. Because it is COCSR, it enforces that t_i is committed earlier than t_j since t_j depends on t_i based on their conflicts on r_1. On the other hand, p_2 enforces that t_i is committed earlier than t_j. Therefore, there is no valid commit time for both t_i and t_j to suffice the above two constraints. Thus, in this case committing both transactions is impossible and the COCSR property of CormCC is also maintained. Finally, since COCSR is a sufficient condition for conflict serializable [2], CormCC is conflict serializable.

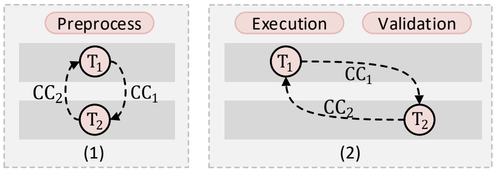

Figure 3: Examples of deadlock across protocols

Deadlock Avoidance While each individual protocol can provide mechanisms to avoid or detect deadlocks, mixing them using CormCC without extra regulation may not make the system deadlock-free. One potential solution can be using a global deadlock detection mechanism. However, this contradicts our spirit of not coordinating candidate protocols.

Alternatively, we examine the causes of deadlock and find that under reasonable assumptions, CormCC can mix single protocols without coordination. Specifically, the deadlock can happen within a single phase or across phases when two transactions wait for each other due to their conflicts on records that are managed by separate protocols. Figure 3 shows two such cases. The first case shows that the single-phase deadlock happens because both protocols CC_1 and CC_2 can make transactions T_1 and T_2 wait within one phase. For the second case, we see that T_1 waits for T_2 in the Execution phase due to CC_1 and additionally introduce conflicts to make T_2 wait for itself based on CC_2 in the Validation phase. Such deadlock is possible because a protocol (e.g. CC_2) can introduce conflicts across phases, that is, the conflicts introduced by T_1 in Execution are detected by T_2 in Validation.

CormCC avoids the two cases by requiring each protocol make transactions wait due to conflicts in no more than one phase, and in each phase only one protocol make transactions wait because of conflicts. If CormCC can meet the two criteria and each protocol can avoid or detect deadlocks, then CormCC is deadlock-free.

Recoverable To guarantee CormCC recoverable, we require that each candidate protocol is strict, which means that a record modified by a transaction is not visible to concurrent transactions until the transaction commits. This ensures transactions never read dirty writes (i.e. uncommited writes) and thus are recoverable [2]. Since each record written by a transaction is managed by a single strict protocol, the execution of CormCC will never read dirty writes and is recoverable.

Supported Protocols A candidate protocol incorporated in CormCC should be COCSR and strict. We find a wide range of protocols can meet these criteria including traditional 2PL and OCC [2], VLL [21], Orthrus [20], PartCC from H-Store [10], and Silo [27].

To enforce that CormCC meets the criteria of deadlock-free, CormCC requires each protocol specifies the phases where it makes transactions wait. Based on these specification, it is easy to detect whether the above criteria hold for a given set of protocols.

4.3 Online Reconfiguration

Online reconfiguration is to switch a protocol for a subset of records without stopping all transaction workers. CormCC uses a coordinator to manage this process. At first, the coordinator collects statistical information from all workers periodically and generates a new concurrency control lookup table. When a worker completes a transaction, it adopts the new lookup table while workers that have not finished their current transactions still use the old one. After all workers use the new table, the old one is deleted. We now introduce the challenge of supporting such online protocol switch.

Challenge The potential problem is that some transaction workers may use the new lookup table while others

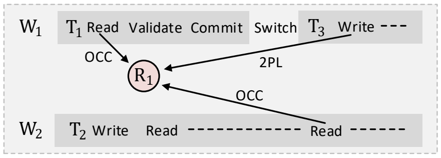

Figure 4: Problems during protocol reconfiguration

are using the old one. Figure 4 shows an example of this problem. Consider two workers W_1 and W_2, which execute transactions T_1 and T_2 respectively. Assume that both T_1 and T_2 access a record (i.e. R_1) that is managed by OCC. During their execution, the coordinator informs that the protocol managing R_1 should be switched to 2PL. Therefore, after T_1 finishes W_1 checks this message, performs the switch (i.e. using 2PL to access R_1), and starts a new transaction (T_3). Since OCC and 2PL maintain a different set of metadata, T_3 and T_2 are not aware of the conflict of T_2 reading R_1 and T_3 writing R_1, which may make database result in an inconsistent state.

Mediated Switching To address this issue, we propose mediated switching; it adopts a *mediated protocol* that is compatible with both old and new protocols. During reconfiguration, the coordinator lets all workers asynchronously change the old protocol to the mediated one; After all workers use the mediated protocol, the coordinator then informs them to adopt the new protocol.

We compose a mediated protocol that can execute concurrency control logic of both old and new protocols. Specifically, a mediated protocol first executes the Preprocess logic of both old and new protocols; then, it enters the Execution phase, where for each record access the mediated protocol executes the Execution logic of both protocols. The mediated protocol's Validation, Commit, and Abort also executes the corresponding logic of both protocols. While it is easy to compose a protocol that executes the logic of both protocols, one problem is how to unify different ways of applying modifications (i.e. insert/delete/write) of different protocols. We find there are two ways to apply modifications: in-place modification during execution and lazy modification during commit phase. In the mediated protocol, we always opt for lazy modification, which means storing the modification in a local buffer during execution and applying them when the transaction is committed. Since all protocols are strict, deferring the actual modification to the commit phase does not violate correctness of protocols. For example, 2PL performs in-place write, while OCC writes the new value into a local buffer and applies it in the commit phase. In our mediated protocol, we choose the OCC approach of applying writes.

We use the example in Figure 5 to illustrate this process, where we need to switch the protocol managing R_1 from OCC to 2PL. The mediated protocol here will execute the logic of both OCC and 2PL (denoted as OPCC). OPCC adopts the following logic:

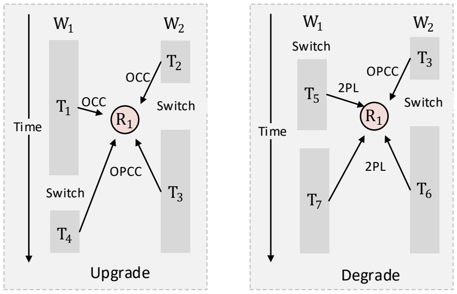

Figure 5: An Example of mediated switching

- If OPCC reads a record, it applies a read lock (2PL) and reads its value and timestamp into the read set (OCC).
- If OPCC writes a record, it applies a write lock (2PL) and stores the record along with new data into the write set (OCC).
- In the validation phase, it locks all records in write set (e.g. for critical section of Silo OCC)[2] and then validate the read set using OCC logic.
- In the commit phase, it applies all writes and release locks acquired by OCC and 2PL respectively.

The switch via mediated protocol is composed of two phases: *upgrade* and *degrade*. The protocol switch is initiated when the coordinator finds that the protocol for a record set *RS* should be changed. It starts the *upgrade phase* by issuing a message to all workers to let them switch the protocol for *RS* to the mediated protocol. Each transaction worker checks for this message between transactions and acknowledges the message to the coordinator. During this asynchronous process, workers that have received the message access *RS* using the mediated protocol, while other workers may access *RS* using the old protocol, which happens when they are running transactions that started before the switch. The left part of Figure 5 shows an example of upgrade phase. We see that worker W_2 finished T_2 first; thus, it begins to access R_1 using OPCC (i.e. in transaction T_3). At the same time, T_1 still accesses R_1 using OCC. According to the above OPCC description, we see that the conflicts on R_1 from W_1 and W_2 can be serialized because OPCC runs the full logic of OCC. After all workers acknowledge the switch for *RS*, the degrade phase begins with the coordinator messaging workers about the degrade to the new protocol. Therefore, workers are using either the mediated protocol or the new protocol, and serializability is guaranteed by the new protocol logic (e.g. 2PL in our example) used in both execution modes. The right part of Figure 5 shows an example of degrade phase, where the conflicts over R_1 can be serialized because OPCC also executes the full logic of 2PL.

[2] Note that OCC and 2PL use different sets of metadata; no deadlock can exist between them

5 Prototype Design

We build a prototype main-memory multi-core database that can dynamically mix PartCC from H-Store [10], OCC from Silo [27], and 2PL from VLL [21] using CormCC. PartCC partitions the database and associates each partition an exclusive lock. Every transaction first acquires all locks for the partitions it needs to read/write in a predefined order before the transaction logic is executed. Then, the transaction is executed by a single thread to the end without additional coordination. In Silo OCC, each record is assigned a timestamp. During transaction execution, Silo OCC tracks read/write operations, and stores the records read by the transactions along with their associated timestamps into a local read set and all writes into a local write set. In the validation phase, Silo OCC locks the write set and validates whether records in read set are changed using their timestamps. If the validation succeeds, it commits; otherwise, it aborts. VLL is an optimized 2PL by co-locating each lock with each record to remove the contention of the centralized lock manager.

Our prototype partitions primary indices and corresponding records using an existing partitioning algorithm [5]. Each partition is assigned with a transaction worker (i.e. thread or process) and each worker is only assigned transactions that will access some data in its partition (the *base partition*), but may also access data in other partitions (the *remote partition*). CormCC selects a protocol for each partition according to its access pattern. A partition routing table maintains the mapping from primary keys to partition numbers and also corresponding protocols. We use stored procedures as the primary interface, which is a set of predefined and parameterized SQL statements. Stored procedures can provide a quick mapping from database operations to the corresponding partitions by annotating the parameters that can be used to identify a base partition to execute the transaction and other involved partitions [10].

The mixed execution of the three protocols start with Preprocess phase, where PartCC acquires all partition locks in a predefined order. Transactions may wait in this phase because of partition lock requests. Next, transactions enter Execution, where CormCC uses PartCC, OCC, and 2PL to process record access operations according to which partition the record belongs to. Note that only 2PL will make transactions wait in this phase, so transactions in the Execution phase will not wait for those blocked in the Preprocess, which indicates deadlocks across PartCC and 2PL is impossible. After the Execution phase, Validation begins and OCC acquires write locks and validates the read set [27]. Only OCC requires transactions to wait; thus, they will not be blocked by previous phases. Finally, there is no wait in commit phase; all protocols apply writes and release all locks. We show that such mixed execution is correct. First, for PartCC and 2PL if a transaction t_i conflicts with another transaction t_j, t_i cannot proceed until t_j commits or vice versa, so PartCC and 2PL are COCSR. Shang et al. [22] have proven that Silo OCC is also COCSR. Therefore, their mixed execution using CormCC maintains COCSR. In addition, each of PartCC, 2PL, and OCC can independently either avoid or detect deadlocks and make transactions conflict-wait in only one mutually exclusive phase among Preprocess, Execution, or Validation. Thus, their mixed execution can also prevent or detect deadlocks. Finally, all protocols are strict, so is their mixed execution.

To enable dynamic protocol reconfiguration, we build two binary classifiers to predict the ideal protocol for each partition. The detailed discussion of classifiers are presented in a technical report [1].

6 Experiments

We now evaluate the effectiveness of mixed execution and online reconfiguration of CormCC. Our experiments answer four questions: 1) How does CormCC perform compared to state-of-the-art mixed concurrency control approaches (Section 6.3)? 2) How does CormCC adaptively mix protocols under varied workloads over time (Section 6.4)? 3) What is the performance benefit and overhead of mixed execution (Section 6.5)? 4) What is the performance benefit and overhead of online reconfiguration (Section 6.6)?

All experiments are run on a single server with four NUMA nodes, each of which has a 8-core Intel Xeon E7-4830 processor (2.13 GHz), 64 GB of DRAM and 24 MB of shared L3 cache, yielding 32 physical cores and 256 GB of DRAM in total. Each core has a private 32 KB of L1 cache and 256 KB of L2 cache. We disable hyperthreading such that each worker occupies a physical core. To eliminate network client latency, each worker combines a client transaction generator.

6.1 Prototype Implementation

We develop a prototype based on Doppel [17], an open-source multi-core main-memory transactional database. Clients issue transaction requests using pre-defined stored procedures, where all parameters are provided when a transaction begins, and transactions are executed to the completion without interacting with clients. Stored procedures issue read/write operations using interfaces provided by the prototype. Each transaction is dispatched to a worker that runs this transaction to the end (commit or abort).

Workers access records via key-value hash tables. Each worker thread occupies a physical core and main-

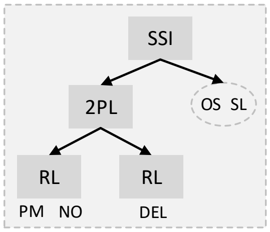

Figure 6: A three-layer configuration of Tebaldi

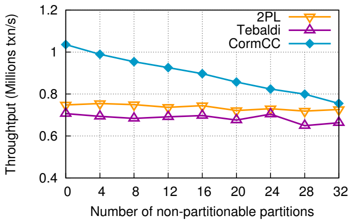

Figure 7: Comparison under different partitionability

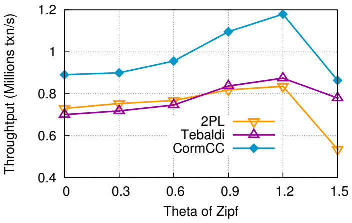

Figure 8: Comparison unber different conflicts

tains its own memory pool to avoid memory allocation contention across many cores [34]. A coordinator thread is used for extracting features for the prediction classifiers from statistics collected by workers and predicting the ideal protocol to be used. Our prototype supports automatically selecting PartCC [10], Silo OCC [27], or No-Wait VLL [21] for each partition. Note that we have compared 2PL variants No-Wait and Wait-Die, and find that 2PL No-Wait performs best in most cases because of lower synchronization overhead of lock management [20]. We do not implement logging in CormCC since prior work shows that logging is not a performance bottleneck [17, 38]. Our comparison additionally includes a general mixed concurrency control framework based on Tebaldi [23] (denoted as Tebaldi) and a hybrid approach of OCC and 2PL [22, 28] (denoted as Hybrid), that adopts locks to protect highly conflicted records but uses validation for the rest. We statically tune the set of highly conflicted records to make Hybrid have the highest throughput. Specifically, for our highly conflicted workload we protect 1000 mostly-conflicted records for each partition and for our lowly conflicted workload no records will be locked and we use OCC for them.

6.2 Benchmarks & Experiment Settings

We use YCSB and TPC-C in our experiments. We generate one table for YCSB that includes 10 million records, each with 25 columns and 20 bytes for each column. Transactions are composed of mixed read and read-modify-write operations. The partitioning of YCSB is based on hashing its primary keys. TPC-C simulates an order processing application. We generate 32 warehouses and partition the store according to warehouse IDs except the Item table, which is shared by all workers. We use the full mix of five procedures.

To generate varied workloads, we tune three parameters. The first is the percentage of cross-partition transactions ranging from 0 to 100. We set the number of partitions a cross-partition transaction will access as 2; The second is the mix of stored procedures for a workload. Note that YCSB only has one stored procedure, and we tune the number of operations per transaction and the ratio of read operations. Finally, we vary data access skewness. We use Zipf to generate record access distribution within a partition. *Theta* of Zipf can be varied from 0 to 1.5. This means for TPC-C within a partition determined by WarehouseID, we skew record access for related tables. We also vary these parameters to train our classifiers for protocol prediction. The detailed configuration of training classifiers is illustrated in [1].

6.3 Comparison with Tebaldi

Tebaldi [23] is a general mixed concurrency control framework that groups stored procedures according to their conflicts and build a hierarchical concurrency control protocols to address in-group and cross-group conflicts. Figure 6 shows a three-layer configuration for TPC-C. We see that NewOrder (NO) and Payment (PM) are in the same group and their conflicts are managed by runtime pipeline (RL). Runtime pipeline is an optimized 2PL that can leverage the semantics of stored procedures to pipeline conflicted transactions. Delivery (DEL) alone is in another group also run by runtime pipeline. Conflicts between the two groups are processed by 2PL. OrderStatus (OS) and StockLevel (SL) are executed in a separate group. Their conflicts with the rest of the groups are processed by Serializable Snapshot Isolation (SSI). For every operation issued by a transaction, it needs to execute all concurrency control logic from the root node to the leaf node to delegate the conflicts to specific protocols. For example, any operation issued by NewOrder needs to go through the logic of SSI, 2PL, and RL. While this approach can process conflicts in a more fine-grained way, the overhead of multiple protocols for all operations can limit the performance. Another restriction of Tebaldi is that it relies on the semantics of stored procedures to assign protocols. For workloads including data dependent behaviour (e.g. hot keys or affinity between keys) and not having stored procedures with rich semantics (i.e. YCSB in our test), Tebaldi can only use one protocol to process the whole workload. In our test, we use this 3-layer configuration for Tebaldi, which has the best performance for TPC-C [23]. Note that we use an optimized Runtime Pipeline reported in [31], which can eliminate the conflicts between Payment and NewOrder.

We first compare CormCC with Tebaldi, implemented in our prototype, using TPC-C over mixing well-partitionable and non-partitionable workloads. We par-

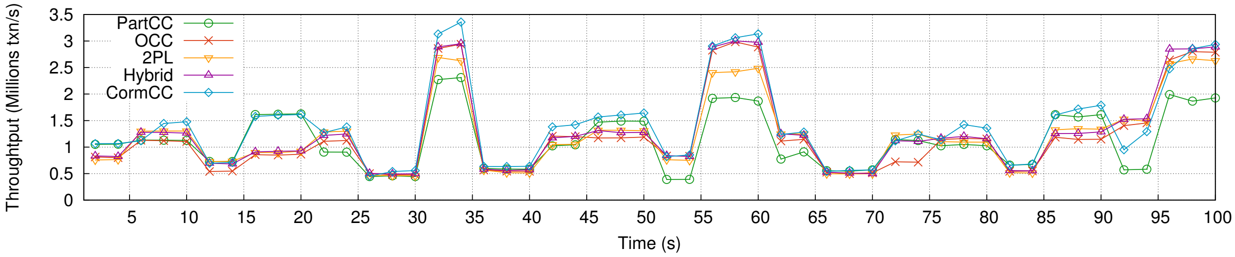

Figure 9: Holistic test for CormCC under YCSB varied workloads over time

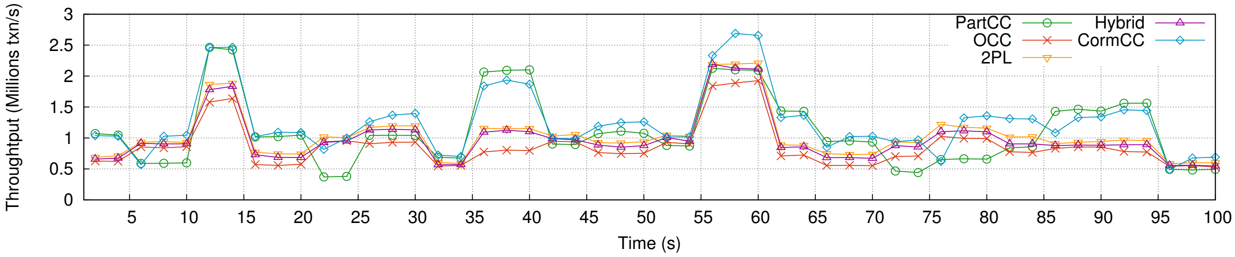

Figure 10: Holistic test for CormCC under TPC-C varied workloads over time

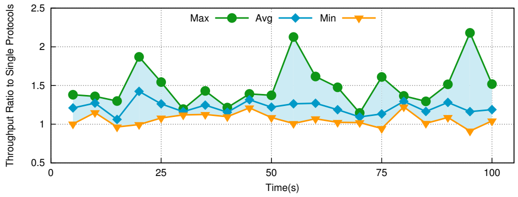

Figure 11: CormCC throughput ratio to single protocols for YCSB

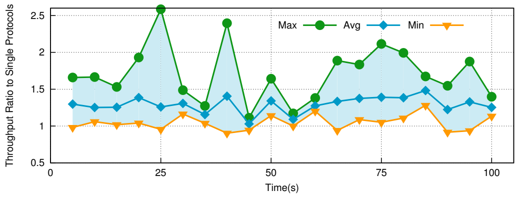

Figure 12: CormCC throughput ratio to single protocols for TPC-C

tition the database into 32 warehouses and start our test with a well-partitionable workload (i.e. each partition receives 100% single-partition transactions), and then increase the number of non-partitionable warehouses (i.e. each receives 100% cross-partition transactions) by an interval of 4. Throughout this test, we use default transaction mix of TPC-C. Since both Tebaldi and CormCC use 2PL as their candidate protocol, our test additionally includes the results of 2PL.

Figure 7 shows the performance results of three protocols. CormCC first adopts PartCC and then proceeds to mix PartCC and 2PL for workloads with mixed partitionability. When the workload becomes non-partitionable, 2PL is used by CormCC. We see that CormCC always performs better than Tabaldi and 2PL because it can leverage the partitionable workloads. Tebaldi always performs slightly worse than 2PL because of its concurrency control overhead from multiple protocols. While such overhead is not substantial in a distributed environment as shown in the original paper [23], it can become a bottleneck in a main-memory multi-core database due to the elimination of network I/O operations.

To highlight Tebaldi's performance benefits of efficiently processing conflicts, we increase the access skewness within each warehouse by varying the *theta* of Zipf distribution from 0 to 1.5 with an interval 0.3. Here, we choose 16 warehouses as partitionable and the rest as non-partitionable. Figure 8 shows that the throughput of all protocols increases at first, because more access skewness introduces better access locality and improves CPU cache efficiency. Then, high conflicts dominate the performance and the throughput decreases for all protocols. We see that with higher conflicts Tebaldi gradually outperforms 2PL, and suffers less throughput loss in the workload with very high conflicts.

These tests show that while Tebaldi can efficiently process conflicts, it comes with a non-trivial concurrency control overhead. In addition, Tebaldi needs to know the conflicts of a workload a priori such that it can utilize the static analysis [23] to make an efficient configuration offline. In contrast, CormCC mixes protocols with minimal overhead, requires no knowledge of conflicts beforehand, and can dynamically choose protocols online.

6.4 Tests on Varied Workloads

We evaluate the holistic benefits of CormCC by running YCSB with randomizing benchmark parameters every 5 seconds. We compare the same randomized run (e.g. same parameters at each interval) with fixed protocols and Hybrid. CormCC collects features every second and concurrently selects the ideal protocol for each partition.

We randomly vary five parameters: i) read rate chosen in 50%, 80%, and 100%; ii) number of operations per transaction, selected between 15 and 25; iii) theta of Zipf for data access distribution; chosen from 0, 0.5, 1, and

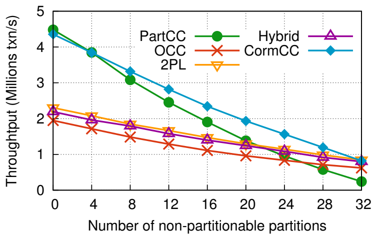

Figure 13: Measuring partitionability

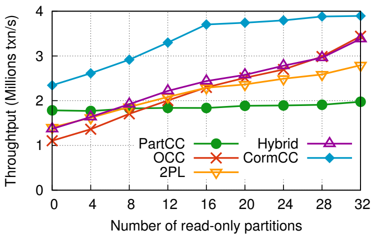

Figure 14: Measuring read/write ratio

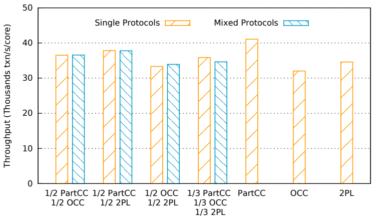

Figure 15: Testing the overhead of mixed execution

1.5; iv) the number of partitions that have cross-partition transactions (with the remaining partitions as well partitionable): we randomly choose the number from 0 to 32 with the interval 4; v) the percentage of cross-partition transactions for partitions in (iv), randomly selected between 50% and 100%.

The test starts with a well-partitionable workload of 80% read rate, 15 operations per transaction, and a uniform access distribution (i.e. $theta = 0$). Figure 9 shows the test results of every 2 seconds for 100 seconds in total. We see that in almost all cases CormCC can either choose the best protocol or find a mixed execution to outperform any candidate protocols and Hybrid approach, while not experiencing long periods of throughput degradation due to switching. CormCC can achieve at most 2.5x, 1.9x, 1.8x, and 1.7x throughput of PartCC, OCC, 2PL, and Hybrid respectively.

We additionally test the performance variations of CormCC under randomized varied workloads of TPC-C. We partition the database into 32 warehouses, and have each worker collect features every second and select the ideal protocol for each warehouse at runtime. We permute four parameters to generate varied workloads. First, we randomly select a transaction mix in 10 candidates, where one is default transaction mix of TPC-C and other nine are randomly generated. Then, we vary the three parameters: record skew for related tables, the number of warehouses that have cross-partition transactions, and the percentage of cross-partition transactions in the same way as YCSB test. We report the results of every 2 seconds in Figure 10. The test starts with well-partitionable default transaction mix of TPC-C and varies workload every 5 seconds. We see that it has similar behaviours of Figure 9, where CormCC can almost always perform the best. In this test, CormCC can achieve at most 2.8x, 2.4x, 1.7x, and 1.8x throughput of PartCC, OCC, 2PL, and Hybrid respectively.

We then report the ratios of the mean throughput of CormCC (after protocol switching) to that of the worst and best single protocols (labeled by `max` and `min` respectively) for each varied workload (i.e. every 5s) of both benchmarks in Figure 11 and Figure 12. We additionally report the ratio of the mean throughput of CormCC to the average throughput of three single fixed protocols (labelled by `avg`) in each varied workload. We see that the highest ratio CormCC can achieve for YCSB and TPC-C is 2.2x and 2.6x respectively. For 55% workloads of YCSB and 85% workloads of TPC-C, the average ratio is at least 1.2x. The lowest ratio in YCSB and TPC-C test is 0.91x and 0.94x respectively, which means that for the two benchmarks CormCC can achieve at least 91% and 94% throughput of the best protocol due to wrong protocol selection for some partitions. These results show that CormCC can achieve significant performance gains when a wrong protocol is selected for a workload, can improve the throughput over single protocols for a wide range of varied workloads, and is robust to dynamic workloads.

6.5 Evaluating Mixed Execution

In this subsection, we first evaluate the performance benefits of CormCC over single protocols and Hybrid approaches, and then test the overhead of CormCC.

We first show how mixed well-partitionable and non-partitionable workloads based on YCSB benchmark influence the relative performance of CormCC to other protocols. We partition the database into 32 partitions, and start our test with a well-partitionable workload and then increase the number of non-partitionable partitions by an interval of 4. In this test, each transaction includes 80% read operations. For these tests, we use transactions consisting 20 operations and skew record access within each partition using Zipf distribution with $theta = 1.5$.

Figure 13 shows that CormCC always performs best because it starts with PartCC and then adaptively mixes PartCC for partitionable workloads and 2PL for highly conflicted non-partitionable counterpart. Compared to CormCC, the performance of PartCC degrades rapidly due to high partition conflicts and other protocols cannot take advantage of partitionable workloads.

We then test workloads with the increasing percentage of read operations. Initially, operations accessing each partition include 80% read operations; we increase the number of partitions receiving 100% read operations by an interval of 4. In this test, our workload includes 16 partitions having 100% cross-partition transactions among them, while the others are only accessed by single-partition transactions.

Figure 14 shows that CormCC has remarkable throughput improvement over other protocols by combining the benefits of PartCC, OCC, and 2PL. Specifically, CormCC first mixes PartCC and 2PL, and then applies OCC for non-partitionable and read-only partitions. While Hybrid can adaptively mix OCC and 2PL, it is sub-optimal due to failing to leverage the benefits of PartCC. In these tests, the speed-ups of CormCC over PartCC, OCC, 2PL, and Hybrid can be up to 3.4x, 2.2x, 1.9x, and 2.0x respectively.

Next, we test the overhead of CormCC. We first execute transactions using CormCC and track the percentage of each transaction's operations executed on records owned by a specific protocol (e.g. 1/2 of the transaction's records use OCC and 1/2 of the transaction's records use 2PL). With the percentages collected, we execute a mix of transactions where a corresponding percentage of the transactions are executed exclusively on a single protocol (e.g. 1/2 of the transactions are only OCC and 1/2 are only 2PL), and compare the throughputs of the two approaches. Note that to test the overhead without involving the performance advantages of CormCC over single protocols, we use a single core to execute all transactions.

Figure 15 shows a micro-benchmark to evaluate mixed execution overhead. We execute 50,000 transactions, each having 20 operations with 50% read operations, with the rest as read-modify-write operations. Key access distribution is uniform. The dataset is partitioned into 32 partitions; 10 of them are managed by OCC, 10 of them are for 2PL, and 12 are PartCC. The "mixed protocols" shows the average throughput of CormCC with different percentage of operations executed by different protocols; the "single protocol" results show the average throughput of a single protocol (e.g. 100% of transactions use OCC), or using single protocols to exclusively execute a corresponding percentage of transactions. We find that our method has roughly the same throughput as a mix of "single protocols", which shows that the overhead of mixed concurrency control is minimal in CormCC. This is largely due to the fact that we do not add extra meta-data operations to synchronize conflicts across protocols.

6.6 Evaluating Mediated Switching

To evaluate the performance benefits and overhead of mediated switching (denoted as Mediated), we compare it with a method of stopping all protocol execution and applying the new protocol (denoted as StopAll). In our test, we perform a protocol switch from OCC to 2PL using five YCSB workloads with uniform key access distribution. The first workload only includes short-lived transactions with each having 10 read and 10 read-modify-write operations. The other workloads include a mix of short and long-running transactions. We generate long-running transactions by introducing client think/wait time to short transactions. The long transactions last 0.5s, 1s, 2s, and 4s for the four workloads respectively and are dedicated to one worker. We collect throughput every second and report the average throughput during protocol switching. We ensure that switch happens at the start, end, and middle of a long running transaction, which represent that switch waits for little, whole, and half of the transaction respectively, and report three test cases for each mixed workload.

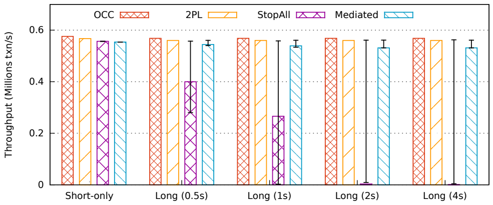

Figure 16: Testing mediated switching

As shown in Figure 16, we see that Mediated and StopAll have a minimal throughput drop compared to 2PL when the workload only includes short transactions. When long-running transactions are introduced, StopAll suffers due to waiting for the completion of long-running transactions, while Mediated can still maintain high throughput during the switch because Mediated does not stop all workers, but let them adopt both 2PL and OCC (i.e. upgrade phase); then, the coordinator notifies all workers to adopt 2PL (i.e. degrade phase) after the long transaction ends. Mediated protocol can achieve at least 93% throughput of OCC or 2PL due to the overhead of executing the logic of two protocols.

In addition, we perform the same test for all other pairwise protocol switching. We find that the overhead is minimal under short-only workload. When long-running transactions are introduced, the maximum throughput drop is about 20% during protocol switching from PartCC to OCC. This is acceptable compared to StopAll, which cannot process new transactions in the switch process. These experiments show that Mediated can maintain reasonable throughput during a protocol switch, even in the presence of long transactions.

7 Conclusion

By exploring the design space of mixed concurrency control, CormCC presents a new approach to generally mixing multiple concurrency control protocols, while not introducing coordination overhead. In addition, CormCC proposes a novel way to reconfigure a protocol for parts of a workload online with multiple protocols running. Our experiments show that CormCC can greatly outperform static protocols, and state-of-the-art mixed concurrency control approaches in various workloads.

Abstract

Measurement plays a key role in network operation and management. An important but unaddressed practical requirement in high speed networks is supporting concurrent applications with diverse and potentially dynamic measurement objectives. We introduce *Flow, a switch accelerated telemetry system for efficient, concurrent, and dynamic measurement. The design insight is to carefully partition processing between switch ASICs and application software. In *Flow, the switch ASIC implements a pipeline that exports telemetry data in a flexible format that allows applications to efficiently compute many different statistics. Applications can operate concurrently and dynamically on identical streams without impacting each other. We implement *Flow as a line rate P4 program for a 3.2 Tb/s commodity switch and evaluate it with four example monitoring applications. The applications can operate concurrently and dynamically, while scaling to measure terabit rate traffic with a single commodity server.

1 Introduction

Measurement plays a critical role in networking. Monitoring systems measure traffic for security [6, 35, 51, 36], load balancing [1, 26] and traffic engineering [55, 23, 27]; while engineers measure traffic and data plane performance to diagnose problems [14, 59, 25, 58, 56] and design new network architectures and systems [47, 5].

In high speed networks, which in 2018 have 100 Gb/s links and multi-Tb/s switches, it is challenging to support measurement without compromising on important practical requirements. Traditional switch hardware is inflexible and supports only coarse grained statistics [21, 45], while servers are prohibitively expensive to scale [50].

Fortunately, advances in switch hardware are presenting new opportunities. As the chip space and power cost of programmability drops [49, 7], switches are quickly moving towards reconfigurable ASICs [42, 44] that are capable of custom packet processing at high line rates. Recent telemetry systems [50, 40] have shown that these programmable forwarding engines (PFEs) can implement custom streaming measurement queries for fine-grained traffic and network performance statistics.

An open question, however, is whether telemetry systems can harness the flexibility and performance of PFEs *while also meeting requirements for practical deployment.* Current PFE accelerated telemetry systems [50, 40] focus on efficiency, compiling queries to minimize workload on servers in the telemetry infrastructure. Efficiency matters, but compiled queries do not address two other practical requirements that are equally important: concurrent measurement and dynamic queries.

First, support for concurrent measurement. In practice, there are likely to be multiple applications measuring the network concurrently, with queries for different statistics. A practical telemetry system needs to multiplex the PFE across all the simultaneously active queries. This is a challenge with compiled queries. Each query requires different computation that, given the line-rate processing model of a PFE [49], must map to dedicated computational resources, which are limited in PFEs.

Equally important for practical deployment is support for *dynamic* querying. As network conditions change, applications and operators will introduce or modify queries. A practical telemetry system needs to support these dynamics at runtime without disrupting the network. This is challenging with compiled PFE queries because recompiling and reloading the PFE is highly disruptive. Adding or removing a query pauses not only measurement, but also *forwarding* for multiple seconds.

Introducing *Flow. We introduce *Flow, a practical PFE accelerated telemetry system that is not only flexible and efficient, but also supports concurrent measurement and dynamic queries. Our core insight is that concurrency and disruption challenges are caused by compiling *too much* of the measurement query to the PFE, and can be resolved without significant impact to performance by carefully lifting parts of it up to software.

At a high level, a query can be decomposed into three logical operations: a *select* operation that determines which packet header and metadata features to capture; a *grouping* operation that describes how to map packets to flows; and a *aggregation function* that defines how to compute statistics over the streams of grouped packet features. The primary benefit of using the PFE lies in its capability to implement the select and grouping operations efficiently because it has direct access to packet headers and low latency SRAM [40]. The challenge is implementing aggregation functions in the PFE, which are computationally complex and query dependent.

`*Flow` is based on the observation that for servers, the situation is exactly reversed. A server cannot efficiently access the headers of every packet in a network, and high memory latency makes it expensive to group packets. However, once the packet features are extracted and grouped, a server can perform coarser grained grouping and mathematical computation very efficiently.

`*Flow`'s design, depicted in Figure 2, plays to the strengths of both PFEs and servers. Instead of compiling entire queries to the PFE, `*Flow` places parts of the *select* and *grouping* logic that are common to all queries into a match+action pipeline in the PFE. The pipeline operates at line rate and exports a stream of records that software can compute a diverse range of custom streaming statistics from *without needing to group per-packet records*. This design maintains the efficiency benefits of using a PFE while eliminating the root causes of concurrency and disruption issues. Further, it *increases* flexibility by enabling more complex aggregation functions than a PFE can support.

Grouped Packet Vectors. To lift the aggregation function off of the PFE, `*Flow` introduces a new record format for telemetry data. In `*Flow`, PFEs export a stream of *grouped packet vectors* (GPVs) to software processors. A GPV contains a flow key, e.g., IP 5-tuple, and a variable-length list of packet feature tuples, e.g., timestamps and sizes, from a sequence of packets in that flow.

Each application can efficiently measure different aggregate statistics from the packet feature tuples in the same GPV stream. Applications can also dynamically change measurement without impacting the network, similar to what a stream of raw packet headers [25] would allow, but without the cost of cloning each packet to a server or grouping in software.

Dynamic in-PFE Cache. Switches generate GPVs at line rate by compiling the `*Flow cache` to their PFEs, alongside other forwarding logic. The cache is an append only data structure that maps packets to GPVs and evicts them to software as needed.

To utilize limited PFE memory, e.g., around 10MB as efficiently as possible, we introduce a key-value cache that supports dynamic memory allocation and can be implemented as a sequence of match+action tables for PFEs. It builds on recent match+action implementations of fixed width key-value caches [40, 29, 50] by introducing a line rate memory pool to support variable sized entries. Ultimately, dynamic memory allocation increases the average number of packet feature tuples that accumulate in a GPV before it needs to be evicted, which lowers the rate of processing that software must support.

Implementation and Evaluation. We implemented the `*Flow` cache [1] for a 100BF-32X switch, a 3.2 Tb/s switch with a Barefoot Tofino [42] PFE that is programmable with P4 [8]. The cache is compiler-guaranteed to run at line rate and uses a fixed amount of hardware resources regardless of the number or form of measurement queries.

To demonstrate the practicality of `*Flow`, we implemented three example monitoring applications that measure traffic in different ways: a host profiler that collects packet level timing details; a traffic classifier that measures complex flow statistics; and a micro-burst attributer that analyzes per-packet queue depths. Although these applications measure different statistics, they all can operate concurrently on the same stream of GPVs and dynamically change measurements without disrupting the network. Benchmarks show that the applications can scale to process GPVs at rates corresponding to Terabit-rate traffic while using under 10 cores.

To further demonstrate the practicality of `*Flow`, we also introduce a simple adapter for executing Marple [40] traffic queries on GPV streams. The adapter, built on top of RaftLib [3], supports high level query primitives (map, filter, groupby, and zip) designed for operator-driven performance monitoring. Using `*Flow` along with the adapter allows operators to run many different queries concurrently, without having to compile them all to the PFE or pause the network to change queries. Analysis shows that the `*Flow` PFE pipeline requires only as many computational resources in the PFE as *one* compiled Marple query. Currently, the adapter scales to measure 15-50 Gb/s of traffic per core, bottlenecked only by overheads in our proof-of-concept implementation.

Contributions. This paper has four main contributions. First, the idea of using *grouped packet vectors* (GPVs) to lift the aggregation functions of traffic queries out of data plane hardware. Second, the design of a novel PFE cache data structure with dynamic memory allocation for efficient GPV generation. Third, the evaluation of a prototype of `*Flow` implemented on a readily available commodity P4 switch. Finally, four monitoring applications that demonstrate the practicality of `*Flow`.

2 Background

In this section, we motivate the design goals of `*Flow` and describe prior telemetry systems.

2.1 Design Goals

*Flow is designed to meet four design goals that are important for a practical PFE accelerated telemetry system.

Efficient. We focus on efficient usage of processing servers in the telemetry and monitoring infrastructure of a network. Efficiency is important because telemetry and monitoring systems need to scale to high throughputs [50] and network coverage [32]. An inefficient telemetry system deployed at scale can significantly increase the total cost of a network, in terms of dollars and power consumption.

Flexible. A flexible telemetry system lets applications define the aggregation functions that compute traffic and data plane performance statistics. There are a wide range of statistics that are useful in different scenario and for different applications. Customizable aggregation functions allow a telemetry system to offer the broadest support.

Flexibility is also important for supporting future applications that may identify new useful metrics and systems that apply machine learning algorithms to analyze the network in many dimensions [43].

Concurrent. Concurrency is the capability to support many measurement queries at the same time. Concurrency is important because different applications require different statistics and, in a real network, there are likely to be many types of applications in use.

Consider a scenario where an operator is debugging an incast [15] and a network-wide security system is auditing for compromised hosts [36]. These applications would ideally run concurrently and need to measure different statistics. Debugging, for example, may benefit from measuring the number of simultaneously active TCP flows in a switch queue over small epochs, while a security application many require per-flow packet counters and timing statistics.

Dynamic. Support for dynamic queries is the capability to introduce or modify new queries at run time. It is important for monitoring applications, which may need to adapt as network conditions change, or themselves be launched at network run-time. Dynamic queries also enable interactive measurement [40] that can help network operators diagnose performance issues, e.g., *which queue is dropping packets between these hosts*?

2.2 Prior Telemetry Systems

Prior telemetry systems meet some, but not all, of the above design goals, as summarized in Table 1.

NetFlow Hardware. Many switches integrate hardware to generate NetFlow records [18] that summarize flows at the granularity of `IP` 5-tuple. NetFlow records are compact because they contain fully- computed aggregate statistics. ASICs [60, 20] in the switch data path do all the work of generating the records, so the overhead for monitoring and measurement applications is low. NetFlow is also dynamic. The ASICs are not embedded into the forwarding path, so a user can select different NetFlow features without pausing forwarding.

However, NetFlow sacrifices flexibility. Flow records have a fixed granularity and users choose statistics from a fixed list. Newer NetFlow ASICs [20] offer more statistics, but cannot support custom user-defined statistics or different granularities.

Software Processing. A more flexible approach is mirroring packets, or packet headers, to commodity servers that compute traffic statistics [19, 24, 22, 37]. Servers can also support concurrent and dynamic telemetry, as they are not in-line with data plane forwarding.

The drawback of software is efficiency. Two of the largest overheads for measurement in software are I/O [46], to get each packet or header to the measurement process, and hash table operations, to group packets by flow [50, 40, 33]. To demonstrate, we implemented a simple C++ application that reads packets from a PCAP, using lpcap, and computes the average packet length for each TCP flow. The application spent an average of 1535 cycles per packet on hash operations alone, using the relatively efficient C++ `std::unordered_map` [4]. In another application, which computed average packet length over pre-grouped vectors of packet lengths, the computation only took an average of 45 cycles per packet.

The benchmarks illustrate that mathematical opera-

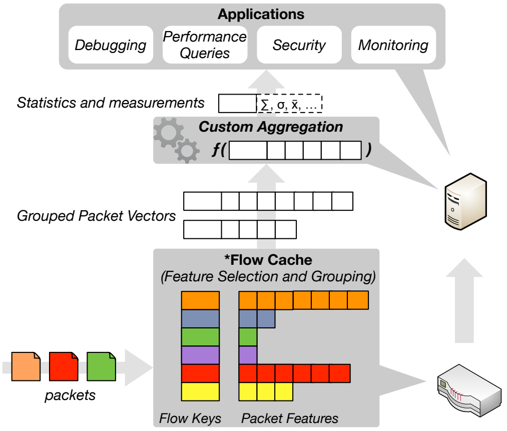

Figure 2: Overview of `*Flow`.

tions for computing aggregate statistics are *not* a significant bottleneck for measurement in software. Modern CPUs with vector instructions can perform upwards of 1 trillion floating point operations per second [39].

PFE Compiled Queries. Programmable forwarding engines (PFEs), the forwarding ASICs in next generation commodity switches [42, 13, 44, 41, 17, 53], are appealing for telemetry because they can perform stateful line-rate computation on packets. Several recent systems have shown that traffic measurement queries can compile to PFE configurations [50, 40]. These systems allow applications (or users) to define custom statistics computation functions and export records that include the aggregate statistics. Compiled queries provide efficiency and flexibility. However, they are not well suited for concurrent or dynamic measurement.

Concurrency is a challenge because of the processing models and computational resources available in a PFE. Each measurement query compiles to its own dedicated computational and memory resources in the PFE, to run in parallel at line rate. Computational resources are extremely limited, particularly those for stateful computation [49], making it challenging to fit more than a few queries concurrently.

Dynamic queries are a challenge because PFEs programs are statically compiled into configurations for the ALUs in the PFE. Adding a compiled query requires reloading the entire PFE program, which pauses all forwarding for multiple seconds, as Figure 1 shows. While it is possible to change forwarding rules at run-time to direct traffic through different pre-compiled functions, the actual computation can only be changed at compile time.

3 PFE Accelerated Telemetry with `*Flow`

`*Flow` is a PFE accelerated telemetry system that supports *efficient*, *flexible*, *concurrent*, and *dynamic* network measurement. It gains efficiency and flexibility by leveraging the PFE to select features from packet headers and group them by flow. However, unlike prior systems, `*Flow` lifts the complex and measurement-specific statistic computation, which are difficult to support in the PFE without limiting concurrent and dynamic measurement, up into software. Although part of the measurement is now in software, the feature selection and grouping done by the PFE reduces the I/O and hash table overheads significantly, allowing it to efficiently compute statistics and scale to terabit rate traffic using a small number of cores.

In this section, we overview the architecture of `*Flow`, depicted in Figure 2.

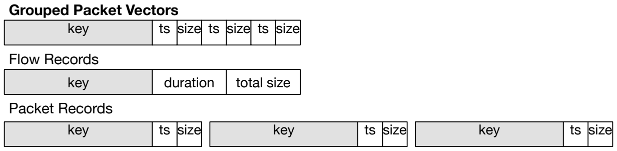

Figure 3: Comparison of grouped packet vectors, flow records, and packet records.

Grouped Packet Vectors. The key to decoupling feature selection and grouping from statistics computation is the *grouped packet vector* (GPV), a flexible and efficient format for telemetry data streamed from switches. A GPV stream is flexible because it contains per-packet features. Each application can measure different statistics from the same GPV stream and dynamically change measurement as needed, without impacting other applications or the PFE. GPVs are also efficient. Since the packet features are already extracted from packets and grouped, applications can compute statistics with minimal I/O or hash table overheads.

`*Flow` Telemetry Switches. Switches with programmable forwarding engines [42, 49] (PFEs) compile the `*Flow` cache to their PFEs to generates GPVs. The cache is implemented as a sequence of match+action tables that applies to packets at line rate and in parallel with other data plane logic. The tables extract features tuples from packets; insert them into per-flow GPVs; and stream the GPVs to monitoring servers, using multicast if there are more than 1.

GPV Processing. A thin `*Flow` agent running on a server receives GPVs from the switch and copies them to per-application queues. Each application defines its own statistics to compute over the packet tuples in GPVs and can dynamically change them as needed. Since the packet tuples are pre-grouped, the computation is extremely efficient because the bottleneck of mapping packets to flows is removed. Further, if fine granularity is needed, the applications can analyze the individual packet feature themselves, e.g., to identify the root cause of short lived congestion events, as Section 6.2 describes.

4 Grouped Packet Vectors (GPVs)

*Flow exports telemetry data from the switch in the grouped packet vector (GPV) format, illustrated in Figure 3, a new record format designed to support the decoupling of packet feature selection and grouping from aggregate statistics computation. A grouped packet vector contains an IP 5-tuple flow key and a variable length vector of feature tuples from sequential packets in the respective flow. As Figure 3 shows, a GPV is a hybrid between a packet record and a flow record. It inherits some of the best attributes of both formats and also has unique benefits that are critical for *Flow.

Similar to packet records, a stream of GPVs contains features from each individual packet. Unlike packet records, however, GPVs get the features to software in a format that is well suited for efficient statistics computation. An application can compute aggregate statistics directly on a GPV, without paying the overhead of receiving each packet, extracting features from it, or mapping it to a flow.

Similar to flow records, each GPV represents multiple packets and deduplicates the IP 5-tuple. They are around an order of magnitude smaller than packet header records and do not require software to perform expensive per-packet key value operations to map packet features to flows. Flow records are also compact and can be processed by software without grouping but, unlike flow records, GPVs do not lock the software into specific statistics. Instead, they allow the software to compute any statistics, efficiently, from the per-packet features. This works well in practice because many useful statistics derive from small, common subsets of packet features. For example, the statistics required by the 3 monitoring applications and 6 Marple queries we describe in Section 6 can all be computed from IP 5-tuples, packet lengths, arrival timestamps, queue depths, and TCP sequence numbers.

5 Generating GPVs

The core of *Flow is a cache that maps packets to GPVs and runs at line rate in a switch's programmable forwarding engine (PFE). A GPV cache would be simple to implement in software. However, the target platforms for *Flow are the hardware data planes of next-generation networks; PFE ASICs that process packets at guaranteed line rates exceeding 1 billion packets per second [49, 9, 16]. To meet chip space and timing requirements, PFEs significantly restrict stateful operations, which makes it challenging to implement cache eviction and dynamic memory allocation.

In this section, we describe the architecture and limitations of PFEs, cache eviction and memory allocation policies that can be implemented in a PFE, and our P4 implementation of the *Flow cache for the Tofino.

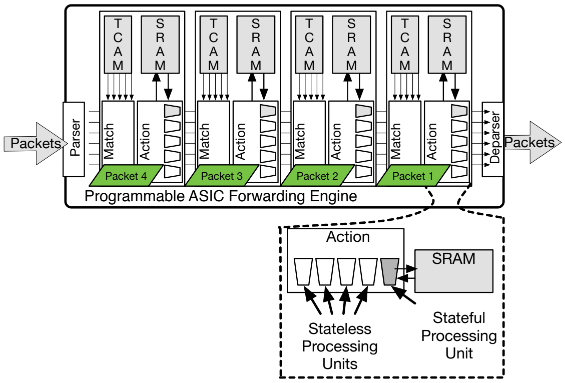

Figure 4: PFE architecture.

5.1 PFE Architecture

Figure 4 illustrates the general architecture of a PFE ASIC. It receives packets from multiple network interfaces, parses their headers, processes them with a pipeline of match tables and action processors, and finally deparses the packets and sends them to an output buffer. PFEs are designed specifically to implement match+action forwarding applications, e.g., P4 [8] programs, at guaranteed line rates that are orders of magnitude higher than other programmable platforms, such as CPUs, network processors [54], or FPGAs, assuming the same chip space and power budgets. They meet this goal with highly specialized architectures that exploit pipelining and instruction level parallelism [49, 9]. PFEs make it straightforward to implement custom terabit rate data planes, so long as they are limited to functionality that maps naturally to the match+action model, e.g., forwarding, access control, encapsulation, or address translation.

It can be challenging to take advantage of PFEs for more complex applications, especially those that require state persisting across packets, e.g., a cache. Persistent arrays, called "register arrays" in P4 programs, are stored in SRAM banks local to each action processor. They are limited in three important ways. First, a program can only access a register array from tables and actions implemented in the same stage. Second, each register array can only be accessed once per packet, using a *stateful ALU* that can implement simple programs for simultaneous reads and writes, conditional updates, and basic mathematical operations. Finally, the sequential dependencies between register arrays in the same stage are limited. In currently available PFEs [42], there can be no sequential dependencies; all of the registers in a stage must be accessed in parallel. Recent work, however, has demonstrated that future PFEs can ease this restriction to support pairwise dependencies, at the cost of slightly increased chip space [49] or lower line rates [16].

5.2 Design

To implement the *Flow cache as a pipeline of match+action tables that can compile to PFEs with the restrictions described above, we simplified the algorithms used for *cache eviction* and *memory allocation*. We do not claim that these are the best possible heuristics for eviction and allocation, only that they are intuitive and empirically effective starting points for a variable width flow cache that operates at multi-terabit line rates on currently available PFEs.

Cache Eviction. The *Flow cache uses a simple *evict on collision* policy. Whenever a packet from an untracked flow arrives and the cache needs to make room for a new entry, it simply evicts the entry of a currently tracked flow with the same hash value. This policy is surprisingly effective in practice, as prior work has shown [34, 50, 40], because it approximates a least recently used policy.

Memory Allocation. The *Flow cache allocates a narrow ring buffer for each flow, which stores GPVs. Whenever the ring buffer fills up, the cache flushes its contents to software. When an active flow fills its narrow buffer for the first time, the cache attempts to allocate a wider buffer for it, drawn from a pool with fewer entries than there are cache slots. If the allocation succeeds, the entry keeps the buffer until the flow is evicted; otherwise, the entry uses the narrow buffer until it is evicted.

This simple memory allocation policy is effective for *Flow because it leverages the long-tailed nature of packet inter-arrival time distributions [5]. In any given time interval, most of the packets arriving will be from a few highly active flows. A flow that fills up its narrow buffer in the short period of time before it is evicted is more likely to be one of the highly active flows. Allocating a wide buffer to such a flow will reduce the overall rate of messages to software, and thus its workload, by allowing the cache to accumulate more packet tuples in the ring buffer before needing to flush its contents to software.

This allocation policy also frees memory quickly once a flow's activity level drops, since frees happen automatically with evictions.

5.3 Implementation

Using the above heuristics for cache eviction and memory allocation, we implemented the *Flow cache as a pipeline of P4 match+action tables for the Tofino [42]. The implementation consists of approximately 2000 lines of P4 code that implements the tables, 900 lines of Python code that implements a minimal control program to install rules into the tables at runtime, and a large library that is autogenerated by the Tofino's compiler toolchain. The source code is available at our repository [2] and has been tested on both the Tofino's cycle-accurate simulator and a Wedge 100BF-32X.

Figure 5 depicts the control flow of the pipeline. It extracts a tuple of features from each packet, maps the tuple to a GPV using a hash of the packet's key, and then either appends the tuple to a dynamically sized ring buffer (if the packet's flow is currently tracked), or evicts the GPV of a prior flow, frees memory, and replaces it with a new entry (if the packet's flow is not currently tracked).

We implemented the evict on collision heuristic using a simultaneous read / write operations when updating the register arrays that store flow keys. The update action writes the current packet's key to the array, using its hash value as an index, and reads the data at that position into metadata in the packet. If there was a collision, which the subsequent stage can determine by comparing the packet's key with the loaded key, the remaining tables will evict and reset the GPV. Otherwise, the remaining tables will append the packet's features to the GPV.

We implemented the memory allocation using a stack. When a cache slot fills its narrow buffer for the first time, the PFE checks a stack of pointers to free extension blocks. If the stack is not empty, the PFE pops the top pointer from the stack. It stores the pointer in a register array that tracks which, if any, extension block each flow owns. For subsequent packets, the PFE loads the pointer from the array before updating its buffers. When the flow is evicted, the PFE removes the pointer from the array and pushes it back onto the free stack.

This design requires the cache to move pointers between the free stack and the allocated pointer array in both directions. We implemented it by placing the stack before the allocated pointer array, and resubmitting the packet to complete the free operation by pushing its pointer back onto the stack. The resubmission is necessary on the Tofino because sequentially dependent register arrays must be placed in different stages and there is no way to move "backwards" in the pipeline.

5.4 Configuration

Compile-time. The current implementation of the *Flow cache has three compile-time parameters: the number of cache slots; the number of entries in the dynamic memory pool; the width of the narrow and wide vectors; and the width of each packet feature tuple.

Feature tuple width depends on application requirements. For the other parameters, we implemented an OpenTuner [2] script that operates on a trace of packet arrival timestamps and a software model of the *Flow cache. The benchmarks in Section 7 show that performance under specific parameters is stable for long periods of time.

[2] https://github.com/jsonch/starflow

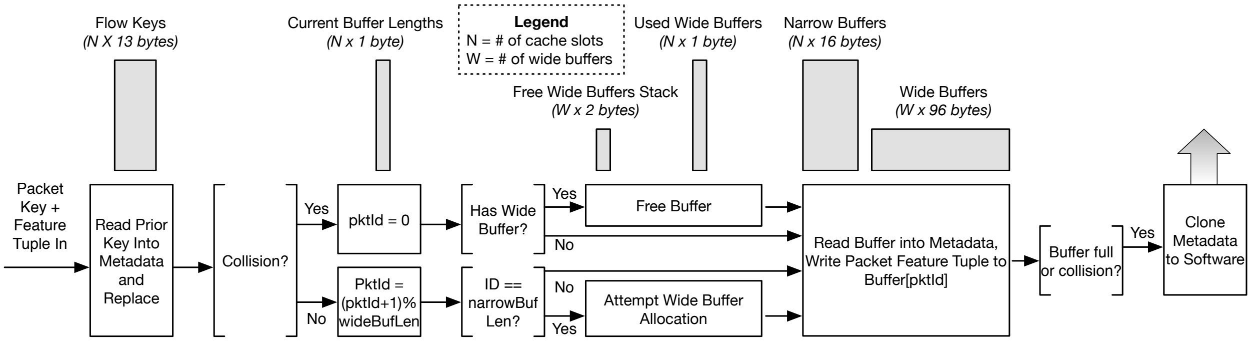

Figure 5: The `*Flow` cache as a match+action pipeline. White boxes represent sequences of actions, brackets represent conditions implemented as match rules, and gray boxed represent register arrays.

Run-time. The `*Flow` cache also allows operators to configure the following parameters at run-time by installing rules into P4 match+action tables. Immediately proceeding the `*Flow` cache, a filtering table lets operators install rules that determine which flows `*Flow` applies to, and which packet header and metadata fields go into packet feature tuples. After the `*Flow` cache, a table sets the destination of each exported GPV. The table can be configured to multicast GPVs to multiple servers and filter the GPV stream that each multicast group receives.

6 Processing GPVs

The `*Flow` cache streams GPVs to processing servers. There, measurement and monitoring applications (potentially running concurrently) can compute a wealth of traffic statistics from the GPVs and dynamically change their analysis without impacting the network.

In this section, we describe the `*Flow` agent that receives GPVs from the `*Flow` cache, three motivating `*Flow` monitoring applications, and the `*Flow` adapter to execute operator-driven network performance measurement queries on GPV streams.

6.1 The `*Flow` Agent

The `*Flow` agent, implemented as a RaftLib [3] application, reads GPV packets from queues filled by NIC drivers and pushes them to application queues. While applications can process GPVs directly, the `*Flow` agent implements three performance and housekeeping functions that are generally useful.

Load Balancing. The `*Flow` agent supports load balancing in two directions. First, a single `*Flow` agent can load balance a GPV stream across multiple queues to support applications that require multiple per-core instances to support the rate of the GPV stream. Second, multiple `*Flow` agents can push GPVs to the same queue, to support applications that operate at higher rates than a single `*Flow` agent can support.

GPV Reassembly. GPVs from a `*Flow` cache typically group packets from short intervals, e.g., under 1 second on average, due to the limited amount of memory available for caching in PFEs. To reduce the workload of applications, the `*Flow` agent can re-assemble the GPVs into a lower-rate stream of records that each represent a longer interval.

Cache Flushing. The `*Flow` agent can also flush the `*Flow` cache if timely updates are a priority. The `*Flow` agent tracks the last eviction time of each slot based on the GPVs it receives. It scans the table periodically and, for any slot that has not been evicted within a threshold period of time, sends a control packet back to the `*Flow` cache that forces an eviction.

6.2 *Flow Monitoring Applications

To demonstrate the practicality of `*Flow`, we implemented three monitoring applications that require concurrent measurement of traffic in multiple dimensions or packet-level visibility into flows. These requirements go beyond what prior PFE accelerated systems could support with compiled queries. With `*Flow`, however, they can operate efficiently, concurrently, and dynamically.

The GPV format for the monitoring applications was a 192 bit fixed width header followed by a variable length vector of 32 bit packet feature tuples. The fixed width header includes IP 5-tuple (104 bits), ingress port ID (8 bits), packet count (16 bits), and start timestamp (64 bits). The packet feature tuples include a 20 bit timestamp delta (e.g., arrival time - GPV start time), an 11 bit packet size, and a 1 bit flag indicating a high queue length during packet forwarding.

Host Timing Profiler. The host timing profiler generates vectors that each contain the arrival times of all packets from a specific host within a time interval. Such timing profiles are used for protocol optimizers [55], simulators [10], and experiments [52].

Prior to `*Flow`, an application would build these vectors by processing per- packet records in software, performing an expensive hash table operation to determine which host transmitted each packet.

With *Flow, however, the application only performs 1 hash operation per GPV, and simply copies timestamps from the feature tuples of the GPV to the end of the respective host timing vector. The reduction in hash table operations lets the application scale more efficiently.

Traffic Classifier. The traffic classifier uses machine learning models to predict which type of application generated a traffic flow. Many systems use flow classification, such as for QoS aware routing [23, 27], security [35, 51], or identifying applications using random port numbers or share ports. To maximize accuracy, these applications typically rely on feature vectors that contain dozens or even hundreds of different flow statistics [35]. The high cardinality is an obstacle to using PFEs for accelerating traffic classifiers, because it requires concurrent measurement in many dimensions.

*Flow is an ideal solution, since it allows an application to efficiently compute many features from the GPV stream generated by the *Flow cache. Our example classifier, based on prior work [43], measures the packet sizes of up to the first 8 packets, the means of packet sizes and inter-arrival times, and the standard deviations of packet size and inter-arrival times.

We implemented both training and classification applications, which use the same shared measurement and feature extraction code. The training application reads labeled "ground truth" GPVs from a binary file and builds a model using Dlib [30]; the classifier reads GPVs and predicts application classes using the model.

Micro-burst Diagnostics. This application detects micro-bursts [28, 48, 15], short lived congestion events in the network, and identifies the network hosts with packets in the congested queue at the point in time when the micro-burst occurred. This knowledge can help an operator or control application diagnose the root cause of periodic micro-bursts, e.g., TCP incasts [15], and also understand which hosts are affected by them.

Micro-bursts are difficult to debug because they occur at extremely small timescales, e.g., on the order of 10 microseconds [57]. At these timescales, visibility into host behavior at the granularity of individual packets is essential. Prior to *Flow, the only way for a monitoring system to have such visibility was to process a record from each packet in software [59, 25, 58, 56] and pay the overhead of frequent hash table operations.

With *Flow, however, a monitoring system can diagnose micro-bursts efficiently by processing a GPV stream, making it possible to monitor much more of the network without requiring additional servers.

The *Flow micro-burst debugger keeps a cache of GPVs from the most recent flows. When each GPV first arrives, it checks if the high queue length flag is set in any packet tuple. If so, the debugger uses the cached GPVs to build a globally ordered list of packet tuples, based on arrival timestamp. It scans the list backwards from the packet tuple with the high queue length flag to identify packet tuples that arrived immediately before it. Finally, the debugger determines the IP source addresses from the GPVs corresponding with the tuples and outputs the set of unique addresses.

6.3 Interactive Measurement Framework

An important motivation for network measurement, besides monitoring applications, is operator-driven performance measurement. Marple [40] is a recent system that lets PFEs accelerate this task. It presents a high level language for queries based around simple primitives (filter, map, group, and zip) and statistics computation functions. These queries, which can express a rich variety of measurement objectives, compile directly to the PFE, where they operate at high rates.

As discussed in Section 2, compiled queries make it challenging to support concurrent or dynamic measurement. Using *Flow, a measurement framework can gain the throughput benefits of PFE acceleration *without* sacrificing concurrency or dynamic queries, by implementing measurement queries in software, over a stream of GPVs, instead of in hardware, over a stream of packets.

To demonstrate, we extended the RaftLib [3] C++ stream processing framework with kernels that implement each of Marple's query primitives on a GPV stream. A user can define any Marple query by connecting the primitive kernels together in a connected graph defined in a short configuration file, similar to a Click [31] configuration file, but written in C++. The configuration compiles to a compact Linux application that operates on a stream of GPVs from the *Flow agent.

We re-wrote 6 example Marple queries from the original publication [40] as RaftLib configurations, listed in Table 4. The queries are functionally equivalent to the originals, but can all run concurrently and dynamically, without impacting each other or the network. These applications operate on GPVs with features used by the *Flow monitoring application, plus a 32 bit TCP sequence number in each packet feature tuple.

7 Evaluation

In this section, we evaluate our implementations of the *Flow cache, *Flow agent, and GPV processing applications. First, we analyze the PFE resource requirements and eviction rates of the *Flow cache to show that it is practical on real hardware. Next, we benchmark the *Flow agent and monitoring applications to quantify the scalability and flexibility benefits of GPVs. Finally, we

compare the `*Flow` measurement query framework with Marple, to showcase `*Flow`'s support for concurrent and dynamic measurement.

All benchmarks were done with 8 unsampled traces from 10 Gbit/s core Internet routers taken in 2015 [11]. Each trace contained around 1.5 billion packets.

7.1 The `*Flow` Cache

We analyzed the resource requirements of the `*Flow` cache to understand whether it is practical to deploy and how much it can reduce the workload of software.

PFE Resource Usage. We analyzed the resource requirements of the `*Flow` cache configured with a tuple size of 32-bits, to support the `*Flow` monitoring applications, and a maximum GPV buffer length of 28, the maximum length possible while still fitting entirely into an ingress or egress pipeline of the Tofino. We used the tuning script, described in Section 5.4, to choose the remaining parameters using a 60 second trace from the 12/2015 dataset [12] and a limit of 1 MB of PFE memory.

Table 7.1 shows the computational and memory resource requirements for the `*Flow` cache on the Tofino, broken down by function. Utilization was low for most resources, besides stateful ALUs and stages. The cache used stateful ALUs heavily because it striped flow keys and packet feature vectors across the tofino's 32 bit register arrays, and each register array requires a separate sALU. It required 12 stages because many of the stateful operations were sequential: it had to access the key and packet count before attempting a memory allocation or free; and it had to perform the memory operation before updating the feature tuple buffer.

Despite the high sALU and stage utilization, it is still practical to deploy the `*Flow` cache alongside other common data plane functions. Forwarding, access control, multicast, rate limiting, encapsulation, and many other common functions do not require stateful operations, and so do not need sALUs. Instead, they need tables and SRAM, for exact match+action tables; TCAM, for longest prefix matching tables; and VLIWs, for modifying packet headers. These are precisely the resources that `*Flow` leaves free.

Further, the stage requirements of `*Flow` do not impact other applications. Tables for functions that are independent of `*Flow` can be placed in the same stages as the `*Flow` cache tables. The Tofino has high instruction parallelism and applies multiple tables in parallel, as long as there are enough computational and memory resources available to implement them.

PFE Resources Vs. Eviction Rate. Figure 6 shows the average packet and GPV rates for the Internet router traces, using the `*Flow` cache with the Tofino pipeline configuration described above. Shaded areas represent the range of values observed. An application operating on GPVs from the `*Flow` cache instead of packet headers needed to process under 18% as many records, on average, while still having access to the features of individual packets. The cache tracked GPVs for an average of 640MS and a maximum of 131 seconds. 14% of GPVs were cached for longer than 1 second and 1.3% were cached for longer than 5 seconds.

To analyze workload reduction with other configurations, we measured *eviction ratio*: the ratio of evicted GPVs to packets. Eviction ratio depends on the configuration of the cache: the amount of memory it has available; the maximum possible buffer length; whether it uses the dynamic memory allocator; and its eviction policy. We measured eviction ratio as these parameters varied using a software model of the `*Flow` cache. The software model allowed us to evaluate how `*Flow` performs on not only today's PFEs, but also on future architectures. We analyzed configurations that use up to 32 MB of memory, pipelines long enough to store buffers for 32 packet feature tuples, and hardware support for an 8 way LRU eviction policy. Larger memories, longer pipelines, and more advanced eviction policies are all proposed features that are practical to include in next generation PFEs [9, 16, 40].

Figure 7 plots eviction ratio as cache memory size varies, for 4 configurations of caches: with or without dynamic memory allocation; and with either a hash on collision eviction policy or an 8 way LRU. Division of memory between and buffer slots between the narrow and wide buffers was selected by the AutoTuner script. With dynamic memory allocation, the eviction ratio was between 0.25 and 0.071. This corresponds to an event rate reduction of between 4*X* and 14*X* for software, compared to processing packet headers directly.

On average, dynamic memory allocation reduced the amount of SRAM required to achieve a target eviction ratio by a factor of 2. It provided as much benefit as an 8

way LRU, but without requiring new hardware.

Figure 8 shows eviction rates as the maximum buffer length varied. Longer buffers required more pipeline stages, but significantly reduced eviction ratio when dynamic memory allocation was enabled.

7.2 *Flow Agent and Applications

We benchmarked the *Flow agent and monitoring applications, described in Section 6.2, to measure their throughput and quantify the flexibility of GPVs.

Experimental Setup. Our test server contained a Intel Xeon E5-2683 v4 CPU (16 cores) and 128 GB of RAM. We benchmarked maximum throughput by prepopulating buffers with GPVs generated by the *Flow cache. We configured the *Flow agent to read from these buffers and measured its throughput for reassembling the GPVs and writing them to a placeholder application queue. We then measured the throughput of each application individually, driven by a process that filled its input queue from a pre-populated buffer of reassembled GPVs. To benchmark multiple cores, we divided the GPVs across multiple buffers, one per core, that was each serviced by separate instances of the applications.

Throughput. Table 7.2 shows the average throughput of the *Flow agent and monitoring applications, in units of reassembled GPVs processed per second. For perspective, the average reassembled GPV rates for the 2015 10 Gbit/s Internet router traces, which are equal to their flow rates, are under 20 *thousand* per second [11].

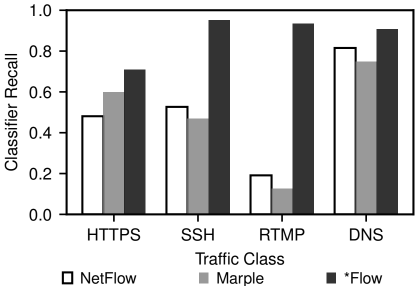

Figure 9: Recall of *Flow and baseline classifiers.

The high throughput makes it practical for a single server to scale to terabit rate monitoring. A server using 10 cores, for example, can scale to cover over 100 such 10 Gb/s links by dedicating 8 cores to the *Flow agent and 2 cores to the profiler or classifier.

Throughput was highest for the profiler and classifier. Both applications scaled to over 10 M reassembled GPVs per second, each of which contained an average of 33 packet feature tuples. This corresponds to a processing rate of over 300 M packet tuples per second, around 750X the average packet rate of an individual 10 Gb/s Internet router link.

Throughput for the *Flow agent and debugging application was lower, bottlenecked by associative operations. The bottleneck in the *Flow agent was the C++ `std::unordered_map` that it used to map each GPV to a reassembled GPV. The reassembly was expensive, but allowed the profiler and classifier to operate without similar bottlenecks, contributing to their high throughput.

In the debugger, the bottleneck was the C++ `std::map` it used to globally order packet tuples. In our benchmarks, we intentionally stressed the debugger by setting the high queue length flag in every packet feature tuple, forcing it to apply the global ordering function frequently. In practice, throughput would be much higher because high queue lengths only occur when there are problems in the network.

Configuration	# Stages	# Atoms	Max Width
`*Flow` cache	**11**	**33**	**5**
Marple Queries			
Concurrent Connections	4	10	3
EWMA Latencies	6	11	4
Flowlet Size Histogram	11	31	6
Packet Counts per Source	5	7	2
TCP Non-Monotonic	5	6	2
TCP Out of Sequence	7	14	4

Table 4: Banzai pipeline usage for the `*Flow` cache and compiled Marple queries.

Classifier Accuracy. To quantify the flexibility benefits of GPVs, we compared the `*Flow` traffic classifier to traffic classifiers that only use features that prior, less flexible, telemetry systems can measure. The *NetFlow* classifier uses metrics available from a traditional NetFlow switch: duration, byte count, and packet count. The *Marple classifier* also includes the average and maximum packet sizes as features, representing a query that compiles to use approximately the same amount of PFE resources as the `*Flow` cache.

Figure 9 shows the recall of the traffic classifiers on the 12/2015 Internet router trace. The `*Flow` classifier performed best because it had access to additional features from the GPVs. This demonstrates the inherent benefit of `*Flow`, and flexible GPV records, for monitoring applications that rely on machine learning and data mining. Also, as Table 7.2 shows, the classifier was performant enough to classify >1 million GPVs per second per core, making it well suited to live processing.

7.3 Comparison with Marple

Finally, to showcase `*Flow`'s support for concurrent and dynamic measurement, we compare the resource requirements for operator driven measurements using compiled Marple queries against the requirements using `*Flow` and the framework described in Section 6.3.

PFE Resources. For comparison, we implemented the `*Flow` cache for the same platform that Marple queries compile to: Banzai [49], a configurable machine model of PFE ASICs. In Banzai, the computational resources of a PFE are abstracted as *atoms*, similar to sALUs, that are spread across a configurable number of stages. The pipeline has a fixed width, which defines the number of atoms in each stage.

Table 4 summarizes the resource usage for the Banzai implementation. The requirements for `*Flow` were similar to those of a *single* statically compiled Marple query. Implementing all 6 queries, which represent only a small fraction of the possible queries, would require 79 atoms, over 2X more than the `*Flow` cache. A GPV stream contains the information necessary to support *all* the queries concurrently, and software can dynamically change them as needed without interrupting the network.

Server Resources. The throughput of the `*Flow` analytics framework was between 40 to 45K GPVs/s per core. This corresponded to a per-core monitoring capacity of 15 - 50 Gb/s, depending on trace. Analysis suggested that the bottleneck in our current prototype is message passing overheads in the underlying stream processing library that can be significantly optimized [38].

Even without optimization, the server resource requirements of the `*Flow` analytics framework are similar to Marple, which required around one 8 core server per 640 Gb/s switch [40] to support measurement of flows that were evicted from the PFE early.

8 Conclusion

Measurement is important for both network monitoring applications and operators alike, especially in large and high speed networks. Programmable forwarding engines (PFEs) can enable flexible telemetry systems that scale to the demands of such environments. Prior systems have focused on leveraging PFEs to scale efficiently with respect to throughput, but have not addressed the equally important requirement of scaling to support many concurrent applications with dynamic measurement needs. As a solution, we introduced `*Flow`, a PFE-accelerated telemetry system that supports dynamic measurement from many concurrent applications without sacrificing efficiency or flexibility. The core idea is to intelligently partition the query processing between a PFE and software. In support of this, we introduced GPVs, or grouped packet vectors, a flexible format for network telemetry data that is efficient for processing in software. We designed and implemented a `*Flow` cache that generates GPVs and operates at line rate on the Barefoot Tofino, a commodity 3.2 Tb/s P4 forwarding engine. To make the most of limited PFE memory, the `*Flow` cache features the first implementation of a dynamic memory allocator in a line rate P4 program. Evaluation showed that `*Flow` was practical in the switch hardware and enabled powerful GPV based applications that scaled efficiently to terabit rates with the capability for flexible, dynamic, and concurrent measurement.

Applying Hardware Transactional Memory for Concurrency-Bug Failure Recovery in Production Runs

Yuxi Chen   Shu Wang   Shan Lu

University of Wisconsin – Madison

Abstract

Concurrency bugs widely exist and severely threaten system availability. Techniques that help recover from concurrency-bug failures during production runs are highly desired. This paper proposes BugTM, an approach that leverages Hardware Transactional Memory (HTM) on commodity machines for production-run concurrency-bug recovery. Requiring **no** knowledge about where are concurrency bugs, BugTM uses static analysis and code transformation to insert HTM instructions into multi-threaded programs. These BugTM-transformed programs will then be able to recover from a concurrency-bug failure by rolling back and re-executing the recent history of a failure thread. BugTM greatly improves the recovery capability of state-of-the-art techniques with low run-time overhead and no changes to OS or hardware, while guarantees not to introduce new bugs.

1 Introduction

1.1 Motivation

Concurrency bugs are caused by untimely accesses to shared variables. They are difficult to expose during in-house testing. They widely exist in production-run software [26] and have caused disastrous failures [23, 32, 40]. Production run failures severely hurt system availability: the restart after a failure could take long time and even lead to new problems if the failure leaves inconsistent system states. Furthermore, comparing with many other types of bugs, failures caused by concurrency bugs are particularly difficult to diagnose and fix correctly [50]. Techniques that handle production-run failures caused by concurrency bugs are highly desired.

Rollback-and-reexecution is a promising approach to recover failures caused by concurrency bugs. When a failure happens during a production run, the program rolls back and re-executes from an earlier checkpoint. Due to the unique non-determinism nature of concurrency bugs, the re-execution could get around the failure.

This approach is appealing for several reasons. It is generic, requiring no prior knowledge about bugs; it improves availability, masking the manifestation of concurrency bugs from end users; it avoids causing system inconsistency or wasting computation resources, which often come together with naive failure restarts; even if not successful, the recovery attempts only delays the failure by a negligible amount of time.

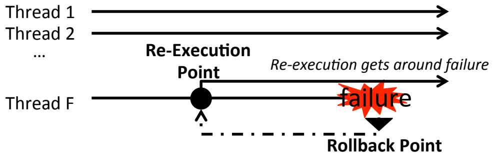

Figure 1: Single-threaded recovery for concurrency bugs

This approach also faces challenges in performance, recovery capability, and correctness (i.e., not introducing new bugs), as we elaborate below.

Traditional rollback recovery conducts full-blown multi-threaded re-execution and whole-memory checkpointing. It can help recover almost all concurrency-bug failures, but incurs too large overhead to be deployed in production runs [35, 39]. Even with support from operating systems changes, periodic full-blown checkpointing still often incurs more than 10% overhead [35].

A recently proposed recovery technique, ConAir, conducts single-threaded re-execution and register-only checkpointing [55]. As shown in Figure 1, when a failure happens at a thread, ConAir rolls back the register content of this thread through an automatically inserted `longjmp` and re-executes from the return of an automatically inserted `setjmp`, which took register checkpoints. This design offers great performance (<1% overhead), but also imposes severe limitations to failure-recovery capability. Particularly, with no memory checkpoints and re-executing only one thread, ConAir does not allow its re-execution regions to contain writes to shared variables (referred to as W_s) for correctness concerns, severely hurting its chance to recover many failures.

This limitation can be demonstrated by the real-world example in Figure 2. In this example, the `NULL` assignment from Thread-2 could execute between the write (A_1) and the read (A_2) on `s`→`table` from Thread-1, and cause failures. At the first glance, the failure could be recovered if we could rollback Thread-1 and re-execute both A_1 and A_2. However, such rollback and re-execution cannot be allowed by ConAir, as correctness can no longer be guaranteed if a write to a shared variable is re-executed (W_s in Figure 2): another thread t could have read the old value of s→table, saved it to a local pointer, the re-execution then gave s→table a new value, causing inconsistency between t and Thread-1 and deviation from the original program semantics.

```
//Thread-1                                //Thread-2
s->table = newTable(...); //A1, Ws
                                          s->table = NULL;
if(!s->table)              //A2
    //fatal-error message; software fails
```

Figure 2: A real-world concurrency bug from Mozilla

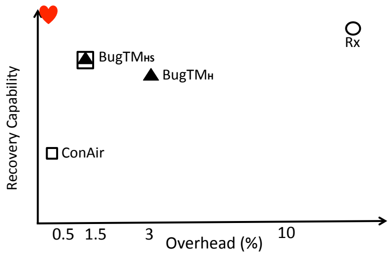

Figure 3: Design space of concurrency-bug failure recovery (Heart: non-existing optimal design; Rx [35] changes OS)

1.2 Contributions

Existing recovery techniques only touch two corners of the design space — good performance but limited recovery capability or good recovery capability but limited performance — as shown in Figure 3. It is desirable to have new recovery techniques that combine the performance and recovery capability strengths of the existing two corners of design, while maintaining correctness guarantees. BugTM provides such a new technique leveraging hardware transactional memory (HTM) support that already exists in commodity machines.

At the first glance, the opportunity seems obvious, as HTM provides a powerful mechanism for concurrency control and rollback-reexecution. Previous work [46] also showed that TM can be used to **manually** fix concurrency bugs **after** they are detected.

However, **automatically** inserting HTMs to help tackle **unknown** concurrency bugs during **production runs** faces many challenges not encountered by *manually* fixing *already detected* concurrency bugs *off-line*:

Performance challenges: High frequency of transaction uses would cause large overhead unacceptable for production runs. Unsuitable content of transactions, like trapping instructions[1], high levels of transaction nesting, and long loops, would also cause performance degradation due to repeated and unnecessary transaction aborts.

Correctness challenges: Unpaired transaction-start and transaction-commit could cause software to crash. Deterministic aborts, such as those caused by trapping instructions, could cause software to hang if not well handled. We need to guarantee these cases do not happen and ensure software semantics remains unmodified.

	ReExecution Point	RollBack Point	Checkpoint Memory ?	ReExecution contains W_s?
ConAir	setjmp	longjmp	✗	✗
BugTM$_H$	StartTx	AbortTx	✓	✓
BugTM$_{\text{HS}}$	setjmp or StartTx	longjmp or AbortTx	✓✗	✓

Table 1: Design comparisons (W_s: shared-variable writes)

Failure recovery challenges: In order for HTM to help recovery, we need to improve the chances that software executes in a transaction when a failure happens and we need to carefully design HTM-abort handlers to correctly process the corresponding transaction aborts.

BugTM addresses these challenges by its carefully designed and carefully inserted, based on static program analysis, HTM start, commit, and abort routines. Specifically, we have explored two BugTM designs: BugTM$_H$ and BugTM$_{\text{HS}}$, as highlighted in Table 1. They are both implemented as LLVM compiler passes that automatically instrument software in the following ways.

Hardware BugTM, short for BugTM$_H$, uses HTM techniques[2] *exclusively* to help failure recovery. When a failure is going to happen, a hardware transaction abort causes the failing thread to roll back. The re-execution naturally starts from the beginning of the enclosing transaction, carefully inserted by BugTM$_H$.

BugTM$_H$ provides better recovery capability than ConAir — benefiting from HTM, its re-execution region can contain shared variable writes. However, HTM costs more than setjmp/longjmp. Therefore, the performance of BugTM$_H$ is worse than ConAir, but much better than full-blown checkpointing, as shown in Figure 3.

Hybrid BugTM, short for BugTM$_{\text{HS}}$, uses HTM techniques and setjmp/longjmp *together* to help failure recovery. BugTM$_{\text{HS}}$ inserts both setjmp/longjmp and HTM APIs into software, with the latter inserted only when beneficial (i.e., when able to extend re-execution regions). When a failure is going to happen, the rollback is carried out through transaction abort if under an active transaction or longjmp otherwise.

BugTM$_{\text{HS}}$ provides performance almost as good as ConAir and recovery capability even better than BugTM$_H$ by carefully combining BugTM$_H$ and ConAir.

We thoroughly evaluated BugTM$_H$ and BugTM$_{\text{HS}}$ using 29 real-world concurrency bugs, including *all* the bugs used by a set of recent papers on concurrency bug detection and avoidance [17, 19, 41, 55, 56, 57]. Our evaluation shows that BugTM schemes can recover from

[1] Certain instructions such as system calls will deterministically cause HTM abort and are referred to as trapping instructions.

[2] This paper's implementation is based on Intel TSX. However, the principles apply to other vendors' HTM implementations.

many more concurrency-bug failures than state of the art, ConAir, while still provide good run-time performance — 3.08% and 1.39% overhead on average for BugTM$_H$ and BugTM$_{HS}$, respectively.

Overall, BugTM offers an easily deployable technique that can effectively tackle concurrency bugs in production runs, and presents a novel way of using HTM. Instead of using transactions to replace existing locks, BugTM automatically inserts transactions to harden the most failure-vulnerable part of a multi-threaded program, which already contains largely correct lock-based synchronization, with small run-time overhead.

2 Background

2.1 Transactional Memory (TM)

TM is a widely studied parallel programming construct [13, 15]. Developers can wrap a code region in a transaction (Tx), and the underlying TM system guarantees its atomicity, consistency, and isolation. Hardware transactional memory (HTM) provides much better performance than its software counterpart (STM), and has been implemented in IBM [12], Sun [8], and Intel commercial processors [1].

In this paper, we focus on Intel Transactional Synchronization Extensions (TSX). TSX provides a set of new instructions: `XBEGIN`, `XEND`, `XABORT`, and `XTEST`. We will denote them as `StartTx`, `CommitTx`, `AbortTx`, and `TestTx`, respectively for generality. Here, `CommitTx` may succeed or fail with the latter causing Tx abort. `AbortTx` explicitly aborts the current Tx, which leads to Tx re-execution unless special fallback code is provided. `TestTx` checks whether the current execution is under an active Tx.

There are multiple causes for Tx aborts in TSX. *Unknown abort* is mainly caused by trapping instructions, like exceptions and interrupts (abort code `0x00`). *Data conflict abort* is caused by conflicting accesses from another thread that accesses (writes) the write (read) set of the current Tx (abort code `0x06`). *Capacity abort* is due to out of cache capacity (abort code `0x08`). *Nested transaction abort* happens when there are more than 7 levels Tx nesting (abort code `0x20`). *Manual abort* is caused by `AbortTx` operation, with programmers specifying abort code.

2.2 ConAir

ConAir is a static code transformation tool built upon LLVM compiler infrastructure [22]. It is a state-of-the-art concurrency bug failure recovery technique as discussed in Section 1. We describe some techniques and terminologies that will be used in later sections below.

```
1 //Thread-1                            1 //Thread-2
2 if(thd->proc){    //A1                2
3     *buf++ = ' '; //Ws                3
4     strcat(buf,thd->proc);//A2        4 thd->proc = NULL;
5                       //failure site
6 }
```

Figure 4: A real-world concurrency bug from MySQL

Recovery capability limitations ConAir does not allow its re-execution regions to contain any writes to shared variables. Many of its re-execution points (i.e., `setjmps`) are put right after shared-variable writes, which prevent re-execution regions from growing longer and severely limit the recovery capability of ConAir.

ConAir fundamentally cannot recover **any** RAW[3] violations (e.g., the bug in Figure 2) and WAR violations, as Table 2 shows. The reason is that the (RA)W and W(AR) have to be re-executed for successful recoveries, but ConAir cannot re-execute shared-variable writes.

ConAir also cannot recover other types of concurrency bugs if a shared-variable write happens to exist between the failure location and the ideal re-execution point. For example, the RAR atomicity violation in Figure 4 cannot be recovered by ConAir due to the write to `*buf` on Line 3. If Line 3 did not exist, ConAir could have rolled back Thread-1 to re-execute Line 2 and gotten around the failure. With Line 3, ConAir can only repeatedly re-execute the `strcat` on Line 4, with no chance of recovery.

Failure instruction *f* ConAir automatically identifies where failures may happen so that rollback APIs can be inserted right there. This identification is based on previous observations that >90% of concurrency bugs lead to four types of failures [56]: assertion violations, segmentation faults, deadlocks, and wrong outputs. BugTM will reuse this technique to identify potential failure locations, denoted as *failure instructions f* in the remainder of the paper. Specifically, ConAir identifies the invocations of `__assert_fail` or other sanity-check macros as failure instructions for assertion failures. ConAir then automatically transforms software to turn segmentation faults and deadlocks into assertion failures: ConAir automatically inserts assertions to check whether a shared pointer variable *v* is `null` right before *v*'s dereference and check whether a pointer parameter of a string-library function is `null` right before the library call; ConAir automatically turns lock functions into time-out lock functions, with a long timeout indicating a likely deadlock failure, and inserts assertions accordingly. ConAir can help recover from wrong output failures as long as developers provide output specifications using assertions.

3 BugTM$_H$

3.1 High-Level Design

We discuss our high-level idea about where to put Txs, and compare with some strawman ideas based on perfor-

[3] (R/W)A(R/W) is short for (Read/Write)-after-(Read/Write).

	Atomicity Violations				Order Violations	Deadlocks

Types						BugTM$_H$	✓✓	✓✓	✓✓	✓✓	✓✓	✓✓
ConAir	✓	–	–	✓	✓	✓

Table 2: Common types of concurrency bugs and how BugTM$_H$ and ConAir attempt to recover from them. (R/W: read/write to a shared variable; thick vertical line: the execution of one thread; dashed arrowed line: the re-execution region of BugTM$_H$; thin arrowed line: the re-execution region of ConAir; explosion symbol: a failure; -: cannot recover; ✓: sometimes can recover if the recovery does not require re-executing shared-variable writes; ✓✓: mostly can recover. The recovery procedure under BugTM$_{\text{HS}}$ is a mix of BugTM$_H$ and ConAir and hence is not shown in table.)

mance and failure-recovery capability.

Strawman approaches One approach is to chunk software to many segments and put every segment inside a hardware Tx [28]. This approach could avoid some atomicity violations, the most common type of concurrency bugs. However, it does not help recover from order violations, another major type of concurrency bugs. Furthermore, its excessive use of Txs will lead to unacceptable overhead for production-run deployment. Another approach is to replace all lock critical regions with Tx. However, this approach will not help eliminate many failures that are caused by missing lock.

Our approach In BugTM$_H$, we selectively put hardware Txs around places where failures may happen, like the invocation of an `__assert_fail`, the dereference of a shared pointer, etc. This design has the potential to achieve good performance because it inserts Txs only at selected locations. It also has the potential to achieve good recovery capability because in theory it can recover from all common types of concurrency bugs, as shown in Table 2 and explained below.

An atomicity violation (AV) happens when the atomicity of a code region $\mathbb{C}$ is unexpectedly violated, such as the bug shown in Figure 2. It contributes to more than 70% of non-deadlock concurrency bugs based on empirical studies [26], and can be further categorized into 4 sub-types depending on the nature of $\mathbb{C}$, as demonstrated in Table 2. Conflicting accesses would usually trigger a rollback recovery before the failure occurs, shown by the dashed arrow lines in Table 2(a)(b)(c), benefiting from the strong atomicity guarantee of Intel TSX — a Tx will abort even if the conflicting access comes from non-Tx code. For the bug shown in Figure 2 (an RAW atomicity violation), if we put the code region in Thread-1 inside a Tx, the interleaving NULL assignment from Thread-2 would trigger a data conflict abort in Thread-1 before the `if` statement has a chance to read the NULL. The re-execution of Thread-1 Tx will then re-assign the valid value to `s` → `table` for the `if` statement to read from, successfully avoiding the failure.

An order violation (OV) happens when an instruction *A* unexpectedly executes after, instead of before, instruction *B*, such as the bug in Figure 5. Different from AVs, conflicting memory accesses related to OVs may not all happen inside a small window. In fact, *A* may not have executed when a failure occurs in the thread of *B*. Consequently, the Tx abort probably will be triggered by a software failure, instead of a conflicting access, depicted by the dashed arrow in Table 2(e). Fortunately, the rollback reexecution will still give the software a chance to correct the unexpected ordering and recover from the failure. Take the bug shown in Figure 5 as an example. If we put a hardware Tx in Thread-1, when order violation leads to the assertion failure, the Tx will abort, rollback, and re-execute. Eventually, the pointer `ptr` will be initialized and the Tx will commit.

```
//Thread-1                      //Thread-2
                                //ptr is NULL until
assert (ptr); //B               //initialized at A
//should execute after A        ptr = malloc (K); //A
```

Figure 5: A real-world OV bug (simplified from `Transmission`)

Deadlock bugs occur when different threads each holds resources and circularly waits for each other. As shown in Table 2(f), it can be recovered by Tx rollback and re-execution too, as long as deadlocks are detected.

Of course, BugTM$_H$ cannot recover from *all* failures, because some error-propagation chains cannot fit into a HTM Tx, which we will discuss more in Section 7.

Next, we will discuss in details how BugTM$_H$ surrounds failure sites with hardware Txs— how to automatically insert `StartTx`, `CommitTx`, `AbortTx`, and fallback-/retry code into software, while targeting three goals: (1) good recovery capability; (2) good run-time performance; (3) not changing original program semantics.

3.2 Design about `AbortTx`

BugTM$_H$ uses the same technique as ConAir to identify where failures would happen as discussed in Sec-

```
        if(_xtest()){
                //manually abort with abort code 0xFF
                _xabort(0xFF);
        }
```

Figure 6: BugTM$_H$`AbortTx` wrapper function (`my_xabort`)

tion 2.2. BugTM$_H$ puts an `AbortTx` wrapper function `my_xabort` right before every failure instruction f, so that a Tx abort and re-execution is triggered right before a failure manifests. `my_xabort` uses a unique abort code `0xFF` for its `AbortTx` operation (as shown in Figure 6), so that BugTM$_H$ can differentiate different causes of Tx aborts and handle them differently.

3.3 Design about `StartTx` and `CommitTx`

Challenges We elaborate on two key challenges in placing `StartTx` and `CommitTx`, and explain why we can**not** simply insert well-structured atomic blocks (e.g., `__transaction_atomic` supported by GCC) into programs.

First, poor placements could cause frequent Tx aborts. Trapping instructions (e.g., system calls) and heavy TM nesting (>7 level) deterministically cause aborts, while long Txs abort more likely than short ones due to timer-interrupts and memory-footprint threshold. These aborts hurt not only performance, but also recovery — deterministic aborts of a Tx will eventually force us to execute the Tx region[4] in non-transaction mode, leaving no hope for failure recovery.

Second, poor placements could cause unpaired execution of `StartTx` and `CommitTx`, hurting both correctness and performance. When `CommitTx` executes without `StartTx`, the program will crash; when `StartTx` executes without a pairing `CommitTx`, its Tx will repeatedly abort.

Taking Figure 7 as an example, we want to put A_1 and A_2, both accessing global variable `G`, into a Tx together with `__assert_fail` on Line 6 for failure recovery. However, if we naively put `StartTx` on Line 2 and `CommitTx` on Line 12, forming a well structured atomic block, correct runs will incur repeated Tx aborts and huge slowdowns due to I/Os on Line 10. Simply moving `CommitTx` to right after Line 4 and keeping `StartTx` on Line 2 still will not work — when `else` is taken, the earlier `StartTx` has no pairing `CommitTx` and the Tx still aborts due to I/Os.

We address the first challenge by carefully placing `StartTx` and `CommitTx`. We address the second challenge mainly through our `StartTx`, `CommitTx` wrapper-functions.

```
 1 void func(...){                              1 void func(...){
 2                                              2 + my_xbegin();
 3   G = g;  //A1                               3   G = g;
 4   if(!G){         //A2                       4   if(!G){
 5                                              5 +   my_xabort();
 6     __assert_fail;//f: failure instr.        6     __assert_fail;
 7   }                                          7   }
 8   else{                                      8   else{
 9                                              9 +   my_xend();
10     IO(...);   //computation & I/O          10     IO(...);
11   }                                         11   }
12                                             12 + my_xend();
13 }                                           13 }
```

Figure 7: A toy example adapted from Figure 2 (left-side) and its BugTM$_H$ transformation (right-side)

```
    if(_xtest() == 0){//no active Tx
        Retrytimes = 0;
        prev_status = -1;
retry:  if((status = _xbegin()) == _XBEGIN_STARTED){
          //Tx starts
        }else{
          //abort fallback handler, no active Tx at this point
          Retrytimes++;
          if(status==0x00||status==0x08){
          //unknown or capacity abort
            if(!(prev_status==0x00 && status==0x00) &&
                !(prev_status==0x08 && status==0x08))
             { prev_status=status; goto retry;}
           }else if(status==0x06 || status==0xFF){
             if(Retrytimes < RetryThreshold)
               {prev_status=status; goto retry;}
           }
           //continue execution in non-Tx mode
        }
    }
```

Figure 8: BugTM$_H$`StartTx` wrapper function (`my_xbegin`)

Where to `StartTx` and `CommitTx` The design principle is to minimize the chance of aborts that are unrelated to concurrency bugs, tackling the first challenge above. BugTM$_H$ achieves this by making sure that its Txs do not contain function calls, which avoids system calls and many trapping instructions, or loops, which avoids large memory footprints. The constraint of not containing function calls will be relaxed in Section 3.5.

Specifically, for every failure instruction f inside a function F, BugTM$_H$ puts a `StartTx` wrapper function right after the first function call instruction or loop-exit instruction or the entrance of F, whichever encountered first along every path tracing backward from f to the entrance of F. BugTM$_H$ puts `CommitTx` wrapper functions right before the exit of F, every function call in F, and every loop header instruction in F, unless the corresponding loop contains a failure instruction, in which case we want to extend re-execution regions for possible failures inside the loop.

Analysis for different failure instructions may decide to put multiple `StartTx` (`CommitTx`) at the same program location. In these cases, we will only keep one copy.

For the toy example in Figure 7, the intra-procedural BugTM$_H$ identifies Line 2 to put a `StartTx`, and identifies Line 9 and 12 to put `CommitTx`, as shown in the figure.

[4] We will refer to the code region between our `my_xbegin` and `my_xend` as a Tx region, which may be executed in transactional mode.

```
if(_xtest())
    _xend(); //terminate an active transaction
```

Figure 9: BugTM$_H$CommitTx wrapper function (my_xend)

How to StartTx and CommitTx The above algorithm does not guarantee one-to-one pairing of the execution of StartTx and CommitTx, the second challenge discussed above. BugTM$_H$ addresses this through TestTx checkings conducted in my_xbegin and my_xend, BugTM$_H$ wrapper functions for StartTx and CommitTx. That is, StartTx will execute only when there is no active Txs, as shown in Figure 8; CommitTx will execute only when there exists an active Tx, as shown in Figure 9.

Overall, our design so far satisfies performance, correctness, and failure-recovery goals by guaranteeing a few properties. For performance, BugTM$_H$ guarantees that its Txs do not contain system/library calls or loops or nested Txs, and always terminate by the end of the function where the Tx starts. For correctness, BugTM$_H$ guarantees not to introduce crashes caused by unpairing CommitTx. For recovery capability, BugTM$_H$ makes the best effort in letting failures occur under active Txs.

3.4 Design for fallback and retry

Challenges It is not trivial to automatically and correctly generate fallback/retry code for all Txs inserted by BugTM$_H$. Since many Tx aborts may be unrelated to concurrency bugs, inappropriate abort handling could lead to performance degradation, hangs, and lost failure-recovery opportunities.

Solutions BugTM$_H$ will check the abort code and react to different types of aborts differently. Specifically, BugTM$_H$ implements the following fallback/retry strategy through its my_xbegin wrapper (Figure 8).

Aborts caused by AbortTx inserted by BugTM$_H$ indicates software failures. We should re-execute the Tx under HTM, hoping that the failure will disappear in retry (Line 14–17). To avoid endless retry, BugTM$_H$ keeps a retry-counter Retrytimes (Figure 8). This counter is configurable in BugTM$_H$, with the default being 1000000.

Data conflict aborts (Line 14–17) are caused by conflicting accesses from another thread. They are handled in the same way as above, because they could be part of the manifestation of concurrency bugs.

Unknown aborts and capacity aborts (Line 9–13) have nothing to do with concurrency bugs or software failures. In fact, the same abort code may appear repeatedly during retries, causing performance degradation without increasing the chance of failure recovery. Therefore, the fallback code will re-execute the Tx region in non-transaction mode once these two types of aborts are observed in two consecutive aborts. Nested Tx aborts would not be encountered by BugTM$_H$, because BugTM$_H$ Txs are non-nested.

The above wrapper function not only implements fallback/retry strategy, but also allows easy integration into the target software, as demonstrated in Figure 7.

3.5 Inter-procedural Designs and Others

The above algorithm allows no function calls or returns in Txs, keeping the whole recovery attempt within one function F. This is too conservative as many functions contain no trapping instructions and could help recovery.

To extend the re-execution region into callees of F, we put my_xend before every system/library call instead of every function call. To extend the re-execution region into the callers of F, we slightly change the policy of putting my_xbegin. When the basic algorithm puts my_xbegin at the entrance of F, the inter-procedural extension will find all possible callers of F, treat the callsite of F in its caller as a failure instruction, and apply my_xbegin insertion and my_xend insertion in the caller.

We then adjust our strategy about when to finish a BugTM$_H$ Tx. The basic BugTM$_H$ may end a Tx too early: by placing my_xend before every function exit, the re-execution will end in a callee function of F before returning to F and reaching the potential failure site in F. Our adjustment changes the my_xend wrapper inserted at function exits, making it take effect only when the function is the one which starts the active Tx.

Finally, as an optimization, we eliminate Txs that contain no shared-variable reads the failure instruction f has control or data dependency on. In these cases, the execution and outcome of f is deterministic during re-execution, and hence the failure cannot be recovered.

4 BugTM$_{HS}$

Rollback and re-execution techniques based on HTM (Section 3) and setjmp/longjmp [55] each has its own strengths and weaknesses. The former allows re-execution regions to contain shared variable writes, which is a crucial improvement over the latter in terms of failure recovery capability. However, it also has higher overhead than the latter. Furthermore, some operations not allowed inside an HTM Tx (e.g. malloc, memcpy, pthread_cond_wait), could potentially be correctly re-executed through software techniques [37, 45].

To combine the strengths of the above two approaches, we design BugTM$_{HS}$. The high level idea is that we apply ConAir to insert setjmp and longjmp recovery code into a program first[5]; and then, only at places where the growth of re-execution regions are stopped by shared-variable writes, we apply BugTM$_H$ to extend re-execution regions through HTM-based recovery.

[5] Intel TSX allows setjmp/longjmp to execute inside Txs.

Next, we will discuss in details how we carry out this high level idea to achieve the **union** of BugTM$_H$ and ConAir's recovery capability, while greatly enhancing the performance of BugTM$_H$.

Where to setjmp and StartTx ConAir and BugTM$_H$ insert setjmp and StartTx using similar algorithms, easing the design of BugTM$_{\text{HS}}$. That is, for every failure instruction f inside a function F, ConAir (BugTM$_H$) traverses backward through every path p that connects f with the entrance of F on CFG, and puts a setjmp wrapper function (StartTx wrapper function) right after the first appearance of a *killing instruction*. We will refer to this location as loc$_{\text{setjmp}}$ and loc$_{\text{StartTx}}$, respectively. For ConAir, the killing instructions include the entrance of F, writes to any global or heap variables, and a selected set of system/library calls; for BugTM$_H$, the killing instructions include the entrance of F, the loop-exit instruction, and all system/library calls [6].

BugTM$_{\text{HS}}$ slightly modifies the above algorithm. Along every path p, BugTM$_{\text{HS}}$ inserts the setjmp wrapper function at every loc$_{\text{setjmp}}$, where ConAir would insert it. In addition, BugTM$_{\text{HS}}$ inserts the StartTx wrapper function at loc$_{\text{StartTx}}$, when loc$_{\text{StartTx}}$ is farther away from f than loc$_{\text{setjmp}}$ (i.e., offering longer re-execution). Note that BugTM$_{\text{HS}}$ inserts setjmp at every location loc$_{\text{setjmp}}$ where ConAir would have inserted setjmp because every loc$_{\text{setjmp}}$ might be executed without an active hardware transaction due to unexpected HTM aborts and others. When loc$_{\text{setjmp}}$ is same as loc$_{\text{StartTx}}$, BugTM$_{\text{HS}}$ would only insert setjmp without inserting StartTx wrapper function.

Where to CommitTx BugTM$_{\text{HS}}$ inserts CommitTx wrapper functions exactly where BugTM$_H$ inserts them. Note that, BugTM$_{\text{HS}}$ inserts fewer StartTx than BugTM$_H$, and hence starts fewer Txs at run time. Fortunately, this does not affect the correctness of how BugTM$_{\text{HS}}$ inserts CommitTx, because the wrapper function makes sure that CommitTx executes only under an active Tx.

How to retry ConAir and BugTM$_H$ insert longjmp and AbortTx wrapper functions, which are responsible for triggering rollback-based failure recovery, using the same algorithm — right before a failure is going to happen as described in Section 2.2 and Section 3.2.

BugTM$_{\text{HS}}$ inserts its rollback function (Figure 10) at the same locations. We design BugTM$_{\text{HS}}$ rollback wrapper to first invoke HTM-rollback (i.e., AbortTx) if it is under an active transaction, which will allow a longer re-execution region and hence a higher recovery probability. The BugTM$_{\text{HS}}$ rollback wrapper invokes longjmp rollback if it is not under an active transaction. To make sure that the program would not keep attempting hopeless recoveries, BugTM$_{\text{HS}}$ continues to use the HTM-abort statistics in the StartTx wrapper function shown in Figure 8 and continues to keep the longjmp retry count threshold shown in Figure 10.

```
if(_xtest())
  _xabort(0xFF); //terminate an active transaction
else //use longjmp for recovery
    if(longjmp_retry ++ < 1000000) // avoid endless retry
        longjmp(buf1,-1);
```

Figure 10: BugTM$_{\text{HS}}$ rollback wrapper function

For examples shown in Figure 2, 4, and 7, BugTM$_{\text{HS}}$ would insert both setjmp and StartTx into the buggy code regions, because StartTx would provide longer re-execution regions in all three cases. However, if the *buf++ = ' '; statement does not exist in Figure 4, BugTM$_{\text{HS}}$ would not insert StartTx there. Consequently, if failures happen, longjmp will be used for recovery.

Overall, we expect BugTM$_{\text{HS}}$ to improve the performance of BugTM$_H$ and improve the recovery capability of both BugTM$_H$ and ConAir. This will be confirmed through experiments in Section 7.

5 Failure Diagnosis

Previous recovery techniques like ConAir and naive system restart leave failure diagnosis completely to developers, which is often very time consuming. To address this limitation, we design BugTM$_{\text{HS}}$ to support failure diagnosis through the root-cause inference routine shown in Figure 11 and extra logging during recovery.

The root-cause inference shown in Figure 11 is mostly straightforward. The rationale of diagnosis based on the number of re-executions (Line 5 and 7) is the following. If the recovery success relies on a code region $\mathbb{C}$ in the failure thread to re-execute atomically, probably one re-execution attempt is sufficient, because another unserializable interleaving during re-execution is very rare. This case applies to RAR violation, as shown in Table 2. If the recovery success relies on something to happen in another thread, multiple re-executions are probably needed. This applies to WAW violations and order violations, as shown in Table 2.

Note that, BugTM$_{\text{HS}}$ and BugTM$_H$ could detect and recover the software from concurrency bugs before explicit failures getting triggered. As shown in Table 2, for several types of atomicity violation bugs, the retry would be triggered by HTM data-conflict aborts, instead of explicit failures. In these cases (Line 9), BugTM$_{\text{HS}}$ cannot affirmatively conclude that concurrency bugs have happened. It can only provide hints that certain types of atomicity violations may be the reason for HTM aborts. Along this line, future work could extend BugTM to contain more concurrency-bug detection capability, in addi-

[6] BugTM$_{\text{HS}}$ also combines the inter-procedural recovery of ConAir and BugTM$_H$ in a similar way. We skip details for space constraints.

```
Input: information from a successful recovery
if (timeout failures)
    output: deadlock
else if (other explicit failures)
    if (first re-execution succeeds)
      output: RAR atomicity violation
    else
      output: Order Violation or WAW atomicity violation
else if (implicit failures) //HTM data conflict aborts
    output: possible RAR, WAR, or RAW atomicity violations
```

Figure 11: Recovery-guided root-cause diagnosis

tion to its failure recovery capability.

BugTM$_{HS}$ also logs memory access type (read/write), addresses, values, and synchronization operations during re-execution, which helps diagnosis with no run-time overhead and only slight recovery delay.

Of course, some real-world concurrency bugs are complicated. However, complicated bugs can often be decomposed into simpler ones. Furthermore, some principles still hold. For example, if the re-execution succeeds with just one attempt, it is highly likely that an atomicity violation happened to the re-execution region.

6 Methodology

Implementation BugTM is implemented using LLVM infrastructure (v3.6.1). We obtained the source code of ConAir, also built upon LLVM. All the experiments are conducted on 4-core Intel Core i7-5775C (Broadwell) machines with 6MB cache, 8GB memory running Linux version 2.6.32, and O3 optimization level.

Benchmark suite We have evaluated BugTM on 29 bugs, including *all* the real-world bug benchmarks in a set of previous papers on concurrency-bug detection, fixing, and avoidance [17, 19, 41, 55, 56, 57]. They cover all common types of concurrency-bug root causes and failure symptoms. They are from server applications (e.g., MySQL database server, Apache HTTPD web server), client applications (e.g., Transmission BitTorrent client), network applications (e.g., HawkNL network library, HTTrack web crawler, Click router), and many desktop applications (e.g., PBZIP2 file compressor, Mozilla JavaScript Engine and XPCOM). The sizes of these applications range 50K — 1 million lines of code. Finally, our benchmark suite contains 3 extracted benchmarks: Moz52111, Moz209188, and Bank.

The goal of BugTM is to *recover* from production-run failures, **not** to *detect* bugs. Therefore, our evaluation uses previously known concurrency bugs that we know how to trigger failures. In all our experiments, the evaluated recovery tools do **not** rely on any knowledge about specific bugs in their failure recovery attempts.

Setups and metrics We will measure the recovery capability and overhead of BugTM$_H$ and BugTM$_{HS}$. We will also evaluate and compare with ConAir [55], the state of the art concurrency-bug recovery technique.

	RootCause	ConAir	BugTM$_H$	BugTM$_{HS}$
MySQL2011	AV$_{RAR}$	–	✓	✓
MySQL38883	AV$_{RAR}$	–	✓	✓
Apache21287	AV$_{RAW}$	–	✓	✓
Moz-JS18025	AV$_{RAW}$	–	✓	✓
Moz-JS142651	AV$_{RAW}$	–	✓	✓
Bank	AV$_{WAR}$	–	✓	✓
Transmission	OV	✓	–	✓
Total		1	6	7

Table 3: Recovery capability comparison (Moz-JS: Mozilla JavaScript Engine.)

To measure recovery capability, we follow the methodology of previous work [18, 55], and insert `sleeps` into software, so that the corresponding bugs will manifest frequently. We then run each bug-triggering workload with each tool applied for 1000 times.

To measure the run-time overhead. We run the original software **without** any `sleeps` with each tool applied. We report the average overhead measured during 100 failure-**free** runs, reflecting the performance during **regular** execution. We also evaluate alternative designs of BugTM, such as not conducting inter-procedural recovery, not excluding system calls from Txs, not excluding loops, etc. Due to space constraints, we only show this set of evaluation results on Mozilla and MySQL benchmarks, two widely used client and server applications.

7 Experimental Results

Overall, BugTM$_H$ and BugTM$_{HS}$ both have better recovery capability than ConAir, and both provide good performance. BugTM$_{HS}$ provides the best combination of recovery capability and performance among the three.

7.1 Failure recovery capability

Among all the 29 benchmarks, 9 cannot be recovered by any of the evaluated techniques, no matter ConAir or BugTM, and the remaining 20 can be recovered by at least one of the techniques (BugTM$_{HS}$ can recover all of these 20). Table 3 shows the result of 7 benchmarks where different tools show different recovery capability.

ConAir fails to recover from 6 out of 7 failures in Table 3, mainly because it does not allow shared-variable writes in re-execution regions. As a result, it cannot recover from any RAW or WAR atomicity bugs, and some RAR bugs, including the one in Figure 4.

BugTM$_H$ can successfully recover from all the 6 failures that ConAir cannot in Table 3. BugTM$_H$ cannot recover from the Transmission bug, because recovering this bug requires re-executing `malloc`, a trapping operation for Intel TSX but handled by ConAir. In fact, `malloc` is allowed in some more sophisticated TM designs [37, 45].

BugTM$_{HS}$ combines the strengths of BugTM$_H$ and ConAir, and hence can successfully recover from all 7

	Run-time Overhead			`#setjmp`	`#StartTx`		`#StartTx` per 10μs		Abort%

Table 4: Overhead during regular execution and detailed performance comparison (red font denotes >3% overhead; #: count of dynamic instances; Abort%: percentage of aborted dynamic Txs.)

benchmarks in Table 3. It recovers the first 6 failures through HTM retries. It recovers from the Transmission failure through `longjmp` (it rolls back the `malloc` that cannot be handled by HTM-retry through `free`).

Unrecoverable benchmarks There are 9 benchmarks that no tools can help recover for mainly three reasons. Some of these issues go beyond the scope of failure recovery, yet others are promising to address in the future. First, two order violation benchmarks cause failures when the failure thread is unexpectedly slow. Therefore, re-executing the failure thread would not help correct the timing. Fortunately, both failures can be prevented by delaying resource deallocation, a prevention approach proposed before for memory-bug failures [29, 35]. Second, three benchmarks, Cherokee326, Apache25520, and MySQL169, cause failures that are difficult to detect (i.e., silent data corruption). Tackling them goes beyond the scope of failure recovery. Third, the remaining four failures cannot be recovered due to un-reexecutable instructions, which are promising to address. For example, Intel TSX does not support putting `memcpy`, `cond_wait`, or `I/O` into its Txs. More sophisticated TMs with OS support [37, 45] could help recover these failures.

7.2 Performance

Table 4 shows the regular-run overheads of applying BugTM schemes to 20 benchmarks, all the benchmarks that are recoverable by BugTM$_{HS}$.

BugTM$_H$ incurs more overhead, about 3% on average, than ConAir does, about 0.3% on average, mainly because a Tx is much more expensive than a `setjmp`.

Fortunately, BugTM$_{HS}$ wins most of the lost performance back, incurring 1.4% overhead on average and less than 3% for **all but 3** benchmarks. In the worst cases, it incurs 4.2% and 5.3% overhead for two benchmarks in Mozilla JavaScript Engine (JSE), a browser component with little I/O. If we apply BugTM$_{HS}$ to the whole browser, the overhead would be much smaller, as JSE never takes >20% of the whole page-loading time based on our profiling and previous work [31].

Comparing BugTM$_{HS}$ with BugTM$_H$, BugTM$_{HS}$ is faster mainly because it has greatly reduced the number of transactions at run time. For example, for the four benchmarks that incur the largest overhead under BugTM$_H$ (Moz-JS18025, Moz-JS142651, Click, and Moz-JS79054), BugTM$_{HS}$ reduces the #`StartTx` per 10μs from 9.4 — 30.4 to 2.6 — 12.6, and hence dropping the overhead from 8.11–11.9% to 2.6–5.3%.

Tx abort rate is less than 1% for all benchmarks, with more than 95% of all aborts being unknown aborts (timer interrupts, etc.). As Section 7.4 will show, abort rates and overhead are much worse in alternative designs.

Recovery time & Comparison with whole-program restart A successful BugTM failure recovery takes little time. In our experiments, the recovery of atomicity violations and deadlocks mostly takes less than 100 μ-seconds (median is 76 μ-seconds). The recovery of order violations takes slightly longer time, as it highly depends on how much `sleep` is inserted to trigger the failure. BugTM recovery is much faster than a system restart, which could take a few minutes or even more for complicated systems. It also avoids wasting already conducted computation and crash inconsistencies. For example, without BugTM, MySQL791 would crash the database after a table is changed but before this change is logged, leaving inconsistent persistent states.

Understanding BugTM$_H$ overhead The overhead of BugTM$_H$ differs among benchmarks, ranging from

	BugTM$_H$	Intra-proc	Trapping-Ins	Loop
Moz-xpcom	0.45% ✓	0.44% ✗	0.54% ✓	0.20% ✓
Moz-JS18025	9.03% ✓	7.01% ✓	16.8% ✓	11.3% ✓
Moz-JS79054	11.7% ✓	11.4% ✗	14.0% ✓	11.1% ✓
Moz-JS142651	11.9%✓	7.6% ✗	19.6% ✓	12.2%✓
MySQL791	1.98% ✓	1.50% ✓	11.4% ✓	11.5% ✓
MySQL2011	0.13% ✓	0.13% ✗	1.50% ✓	0.06% ✓
MySQL3596	3.10% ✓	3.05% ✓	108% ✗	2.63% ✓
MySQL16582	3.03% ✓	0.16% ✓	93.1% ✓	1.89% ✓
MySQL38883	3.08% ✓	3.04% ✓	106% ✗	2.52% ✓

Table 5: BugTM$_H$ vs. alternative designs (%: the overhead over baseline execution w/o recovery scheme applied; ✓: failure recovered; ✗: failure not recovered.)

0.00% to 11.9%. As TM researchers found before, performance in TM systems is often complicated [4, 34]. An indicating metrics for our benchmarks is the frequency of dynamic `StartTx`. As shown in the #`StartTx` per 10μs column of Table 4, BugTM$_H$ executes more than 1 `StartTx` per 10 micro second on average for 10 benchmarks, and incurs more than 1% overhead for 9 of them.

7.3 Diagnosis

BugTM$_{\text{HS}}$ can provide diagnosis information for all the 20 benchmarks that it can help recover from. For 13 benchmarks, recoveries through `longjmp` or HTM rollback are initiated right before explicit failures, for which BugTM$_{\text{HS}}$ provides accurate root-cause diagnosis following Figure 11. For the other 7, the recoveries are triggered by HTM data-conflict aborts, for which BugTM$_{\text{HS}}$ correctly suggests that there might be RAR, RAW, or WAR atomicity violations behind these aborts but cannot provide more detailed root-cause information.

BugTM$_{\text{HS}}$ provides the option to log memory accesses during failure recovery attempts initiated by `longjmp`. Evaluation shows that this extra logging incurs 1.01X – 2.5X slowdowns to failure recovery with no overhead to regular execution. The 2.5X slowdown happens during a fast half-microsecond recovery.

7.4 Alternative designs of BugTM

Table 5 shows the performance and recovery capability of three alternative designs of BugTM$_H$. Due to space constraints, we only show results on benchmarks in MySQL database server and Mozilla browser suite (non-extracted). Since BugTM$_H$ is the foundation of BugTM$_{\text{HS}}$, an alternative design that degrades the performance or recovery capability of BugTM$_H$ will also degrade BugTM$_{\text{HS}}$ accordingly as discussed below.

Inter-procedural vs. Intra-procedural BugTM$_H$ uses the inter-procedural algorithm discussed in Section 3.5. This design adds 0.00 – 4.3 % overhead to its intra-procedural alternative, as shown in Table 5. In exchange, there are 4 benchmarks in Table 5 that require inter-procedural re-execution of BugTM$_H$ to recover from. Among them, two can be recovered by ConAir and hence can still be recovered by intra-procedural BugTM$_{\text{HS}}$; the other two require inter-procedural BugTM$_{\text{HS}}$ to recover. Recovering MySQL2011, Moz-xpcom, Moz-JS79054 has to re-execute not only function F where failures occur, but also F's caller. As for Moz-JS142651, we need to re-execute a callee of F where a memory access involved in the atomicity violation resides.

Including trapping instructions in Txs Clearly, if BugTM$_H$ did not intentionally exclude system calls from its Txs, more Txs will abort. This alternative design hurts performance a lot, incurring around 100% overhead for three MySQL benchmarks shown in Table 5. Such design also causes BugTM$_{\text{HS}}$ to incur more than 20% overhead on these benchmarks. Furthermore, these aborts may hurt recovery capability, as they will cause corresponding Tx regions to execute in non-transaction mode to avoid endless aborts and hence lose the opportunity of failure recovery. This indeed happens for two benchmarks in Table 5. One of them will also fail to be recovered by BugTM$_{\text{HS}}$ under this alternative design.

Including loops in Txs could lead to more capacity aborts, which are indeed observed for all benchmarks in Table 5. The overhead actually does not change much for most benchmarks. Having said that, it raises the overhead of MySQL791 from 1.98% to 11.5%.

More Txs We also tried randomly inserting more `StartTx`. The overhead increases significantly. For Moz-JS142651, when we double, treble, and quadruple the number of dynamic Txs through randomly inserted Txs, the overhead goes beyond 30%, 100%, and 800%. The impact to BugTM$_{\text{HS}}$ would also be huge accordingly.

7.5 Discussion

As the evaluation and our earlier discussion show, BugTM does not guarantee to recover from all concurrency bug failures, particularly if the bug has a long error propagation before causing a failure. However, we believe BugTM, particularly BugTM$_{\text{HS}}$, would provide a beneficial safety net to most multi-threaded software with little deployment cost or performance loss.

Several practices can help further improve the benefit of BugTM. First, as discussed in Section 7.1, some improvements of HTM design would greatly help BugTM to recover from more concurrency-bug failures. Second, developers' practices of inserting sanity checks into software would greatly help BugTM. With more sanity checks, fewer concurrency bugs would have long error propagation and hence more concurrency-bug failures would be recovered by BugTM. Third, different from locks, which protect the atomicity of a code region only when the region and *all* its conflicting code are all protected by the same lock, BugTM can help protect a code region regardless how other code regions are written. Consequently, developers could choose to selectively apply BugTM to parts of software where he/she is least certain about synchronization correctness.

Finally, BugTM can be applied to software that is already using HTMs. BugTM will choose not to make its HTM regions nesting with existing HTM regions.

8 Related Work

Concurrency-bug failure prevention The prevention approach works by perturbing the execution timing, hoping that failure-triggering interleavings would not happen. It either relies on prior knowledge about a bug/failure [19, 27] to prevent the same bug from manifesting again, or relies on extensive off-line training [53, 51] to guide the production run towards likely failure-free timing. It is not suitable for avoiding production-run failures caused by previously unknown concurrency bugs. Particularly, the LiteTx work [51] proposes hardware extensions that are like lightweight HTM (i.e., without versioning or rollback) to constrain production-run thread interleavings, proactively prohibiting interleavings that have not been exercised during off-line testing. BugTM and LiteTx are fundamentally different on how they prevent/recover-from concurrency-bug failures and how they use hardware support.

Automated concurrency-bug fixing Static analysis and code transformation techniques have been proposed to automatically generate patches for concurrency bugs [17, 18, 25, 47]. They work at off-line and rely on accurate bug-detection results. A recent work [16] proposes a data-privatization technique to automatically avoid some read-after-write and read-after-read atomicity violations. When a thread may access the same shared variable with no blocking operations in between, this technique would create a temporary variable to buffer the result of the earlier access and feed it to the later read access. Although inspiring, this previous work is clearly different from BugTM. It does not handle many other types of concurrency bugs, including write-after-read and write-after-write atomicity violations and order violations. Furthermore, it relies on analyzing traces of previous execution of the program to carry out data privatization. The different usage contexts lead to different designs.

Failure recovery Rollback and re-execution have long been a valuable recovery [35, 44] and debugging [7, 20, 33, 43] technique. Many rollback-reexecution techniques target full system/application replay and hence are much more complicated and expensive than BugTM.

Feather-weight re-execution based on idempotency has been used before for recovering hardware faults [6, 9]. Using it to help recover from concurrency-bug failures was recently pioneered by ConAir [55]. BugTM greatly improved ConAir. BugTM$_H$ and ConAir use not only different rollback/reexecution mechanisms, but also completely different static analysis and code transformation. The `setjmp` and `longjmp` used by ConAir have different performance and correctness implications from `StartTx`, `CommitTx`, and `AbortTx`, which naturally led to completely different designs in BugTM$_H$ and ConAir.

Recent work leverages TM to help recover from transient hardware faults [21, 24, 49]. Due to the different types of faults/bugs these tools and BugTM are facing, their designs are different from BugTM. They wrap the whole program into transactions, which inevitably leads to large overhead (around 100% overhead [21, 49]) or lots of hardware changes to existing HTM [24], and different design about how/where to insert Tx APIs. They use different ways to detect and recover from the occurrence of faults, and hence have different Tx abort handling from BugTM. They either rely on **non**-existence of concurrency bugs to guarantee determinism [21] or only apply for single-threaded software [24, 49], which is completely different from BugTM.

Others Lots of research was done on HTM and STM [2, 3, 5, 11, 13, 14, 30, 36, 42]. Recent work explored using HTM to speed up distributed transaction systems [48], race detection [10, 54], etc. Previous empirical studies have examined the experience of using Txs, instead of locks, in developing parallel programs [38, 52]. They all look at different ways of using TM systems from BugTM.

9 Conclusions

Concurrency bugs severely affect system availability. This paper presents BugTM that leverages HTM available on commodity machines to help automatically recover concurrency-bug failures during production runs. BugTM can recover failures caused by all major types of concurrency bugs and incurs very low overhead (1.39%). BugTM does not require any prior knowledge about concurrency bugs in a program and guarantees not to introduce any new bugs. We believe BugTM improves the state of the art of failure recovery, presents novel ways of using HTM techniques, and provides a practical and easily deployable solution to improve the availability of multi-threaded systems with little cost.

Tailwind: Fast and Atomic RDMA-based Replication

Yacine Taleb*, Ryan Stutsman†, Gabriel Antoniu*, Toni Cortes‡

**Univ Rennes, Inria, CNRS, IRISA †University of Utah, ‡BSC and UPC*

Abstract

Replication is essential for fault-tolerance. However, in in-memory systems, it is a source of high overhead. Remote direct memory access (RDMA) is attractive to create redundant copies of data, since it is low-latency and has no CPU overhead at the target. However, existing approaches still result in redundant data copying and active receivers. To ensure atomic data transfers, receivers check and apply only fully received messages. Tailwind is a zero-copy recovery-log replication protocol for scale-out in-memory databases. Tailwind is the first replication protocol that eliminates *all* CPU-driven data copying and fully bypasses target server CPUs, thus leaving backups idle. Tailwind ensures all writes are atomic by leveraging a protocol that detects incomplete RDMA transfers. Tailwind substantially improves replication throughput and response latency compared with conventional RPC-based replication. In symmetric systems where servers both serve requests and act as replicas, Tailwind also improves normal-case throughput by freeing server CPU resources for request processing. We implemented and evaluated Tailwind on RAMCloud, a low-latency in-memory storage system. Experiments show Tailwind improves RAMCloud's normal-case request processing throughput by 1.7×. It also cuts down writes median and 99th percentile latencies by 2x and 3x respectively.

1 Introduction

In-memory key-value stores are an essential building block for large-scale data-intensive applications [3, 19]. Recent research has led to in-memory key-value stores that can perform millions of operations per second per machine with a few microseconds remote access times. Harvesting CPU power and eliminating conventional network overheads has been key to these gains. However, like many other systems, they must replicate data in order to survive failures.

As the core frequency scaling and multi-core architecture scaling are both slowing down, it becomes critical to reduce replication overheads to keep-up with shifting application workloads in key-value stores [13]. We show that replication can consume up to 80% of the CPU cycles for write-intensive workloads (§4.4), in strongly-consistent in-memory key-value stores. Techniques like remote-direct memory access (RDMA) are promising to improve overall CPU efficiency of replication and keep predictable tail latencies.

Existing RDMA-based approaches use message-passing interfaces: a sender remotely places a message into a receiver's DRAM; a receiver must actively poll and handle new RDMA messages. This approach guarantees the atomicity of RDMA transfers, since only fully received messages are applied by the receiver [4, 10, 30]. However, this approach defeats RDMA efficiency goals since it forces receivers to use their CPU to handle incoming RDMA messages and it incurs additional memory copies.

The main challenge of efficiently using RDMA for replication is that failures could result in partially applied writes. The reason is that receivers are not aware of data being written to their DRAM. Leaving receivers idle is challenging because there is no protocol to guarantee data consistency in the event of failures.

A second key limitation with RDMA is its low scalability. This limitation comes from the connection-oriented nature of RDMA transfers. Senders and receivers have to setup queue pairs (QP) to perform RDMA. Lots of recent work has observed the high cost of NIC connection cache misses [4, 11, 32]. Scalability is limited as it typically depends on the cluster size.

To address the above challenges, we developed Tailwind, a zero-copy primary-backup log replication protocol that completely bypasses CPUs on all target backup servers. In Tailwind, log records are transferred directly from the source server's DRAM to I/O buffers at target servers via RDMA writes. Backup servers are *completely passive* during replication, saving their CPUs for other purposes; they flush these buffers to solid-state drives (SSD) periodically when the source triggers it via remote procedure call (RPC) or when power is interrupted. Even though backups are idle during replication, Tailwind is strongly consistent: it has a protocol that allows backups to detect incomplete RDMA transfers.

Tailwind uses RDMA write operations for all data movement, but all control operations such as buffer allocation and setup, server failure notifications, buffer flushing and freeing are all handled through conventional RPCs. This simplifies such complex operations without slowing down data movement. In our implementation, RPCs only account for 10^{-5} of the replication requests. This also makes Tailwind easier to use in systems that use log replication over distributed blocks even if they were not designed to exploit RDMA.

Since Tailwind needs only to maintain connections between a primary server and its backups, the number of connections scales with the size of a replica group, not with the cluster size, making Tailwind a scalable approach.

We implemented and evaluated Tailwind on RAMCloud, a scale-out in-memory key-value store that exploits fast kernel-bypass networking. Tailwind is suited to RAMCloud's focus on strong consistency and low latency. Tailwind significantly improves RAMCloud's throughput since each PUT operation in the cluster results in three remote replication operation that would otherwise consume server CPU resources.

Tailwind improves RAMCloud's throughput by 1.7× on the YCSB benchmark, and it reduces durable PUT median latency from 32 µs to 16 µs and 99th percentile latency from 78 µs to 28 µs. Theses results stem from the fact that Tailwind significantly reduces the CPU cycles used by the replication operations: Tailwind only needs 1/3 of the cores RAMCloud uses to achieve the same throughput.

This paper makes four key contributions;

- it analyzes and quantifies CPU related limitations in modern in-memory key-value stores;
- it presents Tailwind's design, it describes its implementation in the RAMCloud distributed in-memory key-value store, and it evaluates its impact on RAMCloud's normal-case and recovery performance;
- to our knowledge, Tailwind is the first log replication protocol that eliminates all superfluous data copying between the primary replica and its backups, and it is the first log replication protocol that leaves servers CPU idle while serving as replication targets; this allows servers to focus more resources on normal-case request processing;
- Tailwind separates the replication data path and control path and optimizes them individually; it uses RDMA for heavy transfer, but it retains the simplicity of RPC for rare operations that must deal with complex semantics like failure handling and resource exhaustion.

2 Motivation and Background

Replication and redundancy are fundamental to fault tolerance, but at the same time they are costly. Primary-backup replication (PBR) is popular in fault-tolerant storage systems like file systems and key-value stores, since it tolerates f stop-failures with $f+1$ replicas. Note that, we refer to a primary replica server as *primary*, and secondary replica server as *secondary* or *backup*. In some systems, backup servers don't process user-facing requests, but in many systems each node acts as both a primary for some data items and as a backup for other data items. In some systems this is implicit: for example, a key-value store may store its state on HDFS [28], and a single physical machine might run both a key-value store frontend and an HDFS chunkserver.

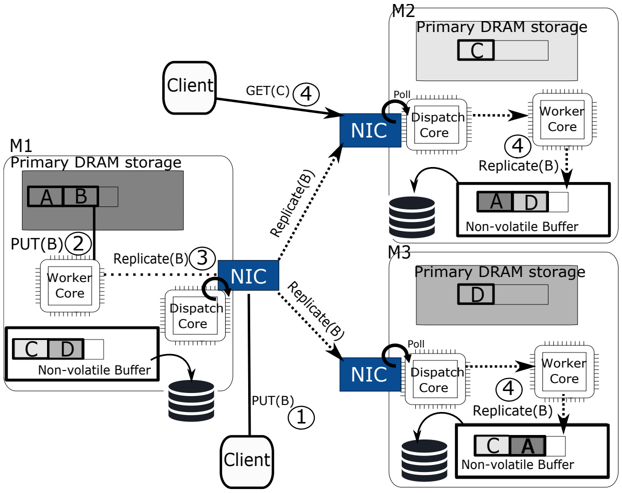

Figure 1: Flow of primary-backup replication

Replication is expensive for three reasons. First, it is inherently redundant and, hence, brings overhead: the act of replication itself requires moving data over the network. Second, replication in strongly consistent systems is usually synchronous, so a primary must stall while holding resources while waiting for acknowledgements from backups (often spinning a CPU core in low-latency stores). Third, in systems, where servers (either explicitly or implicitly) serve both client-facing requests and replication operations, those operations contend.

Figure 1 shows this in more detail. Low-latency, high-throughput stores use kernel-bypass to directly poll NIC control (with a dispatch core) rings to avoid kernel code paths and interrupt latency and throughput costs. Even so, a CPU on a primary node processing an update operation must receive the request, hand the request off to a core (worker core) to be processed, send remote messages, and then wait for multiple nodes acting as backup to process these requests. Batching can improve the number of backup request messages each server must receive, but at the cost of increased latency. Inherently, though, replication can double, triple, or quadruple the number of messages and the amount of data generated by client-issued write requests. It also causes expensive stalls at the primary while it waits for responses. In these systems, responses take a few microseconds which is too short a time for the primary to context switch to another thread, yet its long enough that the worker core spends a large fraction of its time waiting.

2.1 The Promise of RDMA

Recently, remote-direct memory access (RDMA) has been used in several systems to avoid kernel overhead and to reduce CPU load. Though the above kernel-bypass-based request processing is sometimes called (*two-sided*) RDMA, it still incurs request dispatching

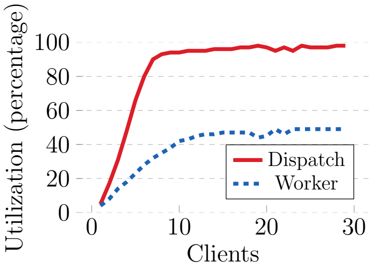

Figure 2: Dispatch and worker cores utilization percentage of a single RAMCloud server. Requests consist of 95/5 GET/PUT ratio.

and processing overhead because a CPU, on the destination node, must poll for the message and process it. RDMA-capable NICs also support so called *one-sided* RDMA operations that directly access the remote host's memory, bypassing its CPU altogether. Remote NICs directly service RDMA operations without interrupting the CPU (neither via explicit interrupt nor by enqueuing an operation that the remote CPU must process). One-sided operations are only possible through reliable-connected queue pairs (QP) that ensure in-order and reliable message delivery, similar to the guarantees TCP provides.

2.1.1 Opportunities

One-sided RDMA operations are attractive for replication; replication inherently requires expensive, redundant data movement. Backups are (mostly) passive; they often act as dumb storage, so they may not need CPU involvement. Figure 2 shows that RAMCloud, an in-memory low-latency kernel-bypass-based key-value store, is often bottlenecked on CPU (see §4 for experimental settings). For read-heavy workloads, the cost of polling network and dispatching requests to idle worker cores dominates. Only 8 clients are enough to saturate a single server dispatch core. Because of that, worker cores cannot be fully utilized. One-sided operations for replicating PUT operations would reduce the number of requests each server handles in RAMCloud, which would indirectly but significantly improve read throughput. For workloads with a significant fraction of writes or where a large amount of data is transferred, write throughput can be improved, since remote CPUs needn't copy data between NIC receive buffers and I/O or non-volatile storage buffers.

2.1.2 Challenges

The key challenge in using one-sided RDMA operations is that they have simple semantics which offer little control on the remote side. This is by design; the remote NIC executes RDMA operations directly, so they lack the generality that a conventional CPU-based RPC handlers would have. A host can issue a remote *read* of a single, sequential region of the remote processes virtual address space (the region to read must be *registered* first, but a process could register its whole virtual address space). Or, a host can issue a remote *write* of a single, sequential region of the remote processes virtual address space (again, the region must be registered with the NIC). NICs support a few more complex operations (compare-and-swap, atomic add), but these operations are currently much slower than issuing an equivalent two-sided operation that is serviced by the remote CPU [11, 30]. These simple, restricted semantics make RDMA operations efficient, but they also make them hard to use safely and correctly. Some existing systems use one-sided RDMA operations for replication (and some also even use them for normal case operations [4, 5]).

However, no existing primary-backup replication scheme reaps the full benefits of one-sided operations. In existing approaches, source nodes send replication operations using RDMA writes to push data into ring buffers. CPUs at backups poll for these operations and apply them to replicas. In practice, this is is effectively emulating two-sided operations [4]. RDMA reads don't work well for replication, because they would require backup CPUs to schedule operations and "pull" data, and primaries wouldn't immediately know when data was safely replicated.

Two key, interrelated issues make it hard to use RDMA writes for replication that fully avoids the remote CPUs at backups. First, a primary can crash when replicating data to a backup. Because RDMA writes (inherently) don't buffer all of the data to be written to remote memory, its possible that an RDMA write could be partially applied when the primary crashes. If a primary crashes while updating state on the backup, the backup's replica wouldn't be in the "before" or "after" state, which could result in a corrupted replica. Worse, since the primary was likely mutating all replicas concurrently, it is possible for all replicas to be corrupted. Interestingly, backup crashes during RDMA writes don't create new challenges for replication, since protocols must deal with that case with conventional two-sided operations too. Well-known techniques like log-structured backups [18, 23, 25] or shadow paging [35] can be used to prevent update-in-place and loss of atomicity. Traditional log implementations enforce a total ordering of log entries [9]. In database systems, for instance, the order is used to recreate a consistent state during recovery.

Unfortunately, a second key issue with RDMA operations makes this hard: each operation can only affect a single, contiguous region of remote memory. To be efficient, one-sided writes must replicate data in its final, stable form, otherwise backup CPU must be involved, which defeats the purpose. For stable storage, this generally requires some metadata. For example, when a backup uses data found in memory or storage it must know which portions of memory contain valid objects, and it must be able to verify that the objects and the markers that delineate them haven't been corrupted. As a result, backups need some metadata about the objects that they host in addition to the data items themselves. However, RDMA writes make this hard. Metadata must inherently be intermixed with data objects, since RDMA writes are contiguous. Otherwise, multiple round trips would be needed, again defeating the efficiency gains.

Tailwind solves these challenges through a form of low-overhead redundancy in log metadata. Primaries incrementally log data items and metadata updates to remote memory on backups via RDMA writes. Backups remain unaware of the contents of the buffers and blindly flush them to storage. In the rare event when a primary fails, all backups work in parallel scanning log data to reconstruct metadata so data integrity can be checked. The next section describes its design in detail.

3 Design

Tailwind is a strongly-consistent RDMA-based replication protocol. It was designed to meet four requirements:

Zero-copy, Zero-CPU on Backups for Data Path. In order to relieve backups CPUs from processing replication requests, Tailwind relies on one-sided RDMA writes for all data movement. In addition, it is zero-copy at primary and secondary replicas; the sender uses kernel-bypass and scatter/gather DMA for data transfer; on the backup side, data is directly placed to its final storage location via DMA transfer without CPU involvement.

Strong Consistency. For every object write Tailwind synchronously waits for its replication on all backups before notifying the client. Although RDMA writes are one-sided, reliable-connected QPs generate work completion to notify the sender once a message has been correctly sent and acknowledged by the receiver NIC (i.e. written to remote memory) [8]. One-sided operation raise many issues, Tailwind is designed to cover *all* corner cases that may challenge correctness (§3.4).

Overhead-free Fault-Tolerance. Backups are unaware of replication as it happens, which can be unsafe in case of failures. To address this, Tailwind appends a piece of metadata in the log after every object update. Backups use this metadata to check integrity and locate valid objects during recovery. Although a few backups have to do little extra work during crash recovery, that work has no impact on recovery performance (§4.6).

Preserves Client-facing RPC Interface. Tailwind has no requirement on the client side; all logic is implemented between primaries and backups. Clients observe the same consistency guarantees. However, for write operations, Tailwind highly improves end-to-end latency and throughput from the client perspective (§4.2).

3.1 The Metadata Challenge

Metadata is crucial for backups to be able to use replicated data. For instance, a backup needs to know which portions of the log contain valid data. In RPC-based systems, metadata is usually piggybacked within a replication request [11, 21]. However, it is challenging to update both data and metadata with a single RDMA write since it can only affect a contiguous memory region. In this case, updating both data and metadata would require sending two messages which would nullify one-sided RDMA benefits. Moreover, this is risky: in case of failures a primary may start updating the metadata and fail before finishing, thereby invalidating all replicated objects.

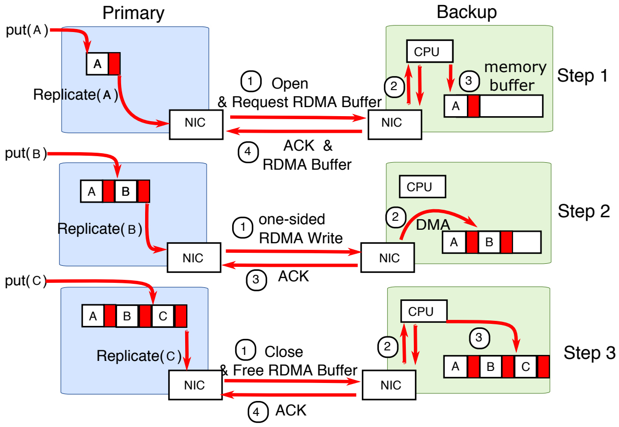

Figure 3: The three replication steps in Tailwind. During the first (open) and third (close) steps, the communication is done through RPCs. While the second step involves one-sided writes only.

For log-structured data, backups need two pieces of information: (1) the *offset* through which data in the buffer is valid. This is needed to guarantee the atomicity of each update. An outdated offset may lead the backup to use old and inconsistent data during crash recovery. (2) A *checksum* used to check the integrity of the length fields of each log record during recovery. Checksums are critical for ensuring log entry headers are not corrupted while in buffers or on storage. These checksums ensure iterating over the buffer is safe; that is, a corrupted length field does not “point” into the middle of another object, out of buffer, or indicate an early end to the buffer.

The protocol assumes that each object has a *header* next to it [4, 12, 26]. Implementation-agnostic information in headers should include: (1) the size of the object next to it to allow log traversal; (2) an integrity check that ensures the integrity of the contents of the log entry.

Tailwind checksums are 32-bit CRCs computed over log entry headers. The last checksum in the buffer covers all previous headers in the buffer. For maximum protection, checksums are end-to-end: they should cover the data while it is in transit over the network and while it occupies storage.

To be able to perform atomic updates with one-sided RDMAs in backups, the last checksum and the current offset in the buffer must be present and consistent in the backup after *every* update. A simple solution is to append the checksum and the offset before or after every object update. A single RDMA write would suffice then for both data and metadata. The checksum *must* necessarily be sent to the backup. Interestingly, this is not the case for the offset. The nature of log-structured data and the properties of one-sided RDMA make it possible, with careful design, for the backup to compute this value at recovery time without hurting consistency. This is possible because RDMA writes are performed (at the receiver side) in an increasing address order [8]. In addition, reliable-connected QPs ensure that updates are applied in the order they were sent.

Based on these observations, Tailwind appends a checksum in the log after every object update; at any point of time a checksum guarantees, with high probability, the integrity of all previous headers preceding it in the buffer. During failure-free time, a backup is ensured to always have the latest checksum, at the end of the log. On the other hand, backups have to compute the offset themselves during crash recovery.

3.2 Non-volatile Buffers

In Tailwind, at start up, each backup machine allocates a pool of in-memory I/O buffers (8 MB each, by default) and registers them with the NIC. To guarantee safety, each backup limits the number of buffers outstanding unflushed buffers it allows. This limit is a function of its local, durable storage speed. A backup denies opening a new replication buffer for a primary if it would exceed the amount of data it could flush safely to storage on backup power. Buffers are pre-zeroed. Servers require power supplies that allow buffers to be flushed to stable storage in the case of a power failure [4, 5, 20]. This avoids the cost of a synchronous disk write on the fast path of PUT operations.

Initiatives such as the OpenCompute Project propose standards where racks are backed by batteries backup, that could provide a minimum of 45 seconds of power supply [1] at full load, including network switches. Battery-backed DIMMs could have been another option, but they require more careful attention. Because we use RDMA, batteries need to back the CPU, the PCIe controller, and the memory itself. Moreover, there exists no clear way to flush data that could still be residing in NIC cache or in PCIe controller, which would lead to firmware modifications and to a non-portable solution.

3.3 Replication Protocol

3.3.1 Write Path

To be able to perform replication through RDMA, a primary has to has to reserve an RDMA-registered memory buffer from a secondary replica. The first step in Figure 3 depicts this operation: a primary sends an `open` RPC to a backup ①. Tailwind does not enforce any replica placement policy, instead it leaves backup selection up to the storage system. Once the `open` processed ② + ③, the backup sends an acknowledgement to the primary and piggybacks necessary information to perform RDMA writes ④ (i.e. `remote_key` and `remote_address` [8]). The open call fails if there are no available buffers. The primary has then to retry.

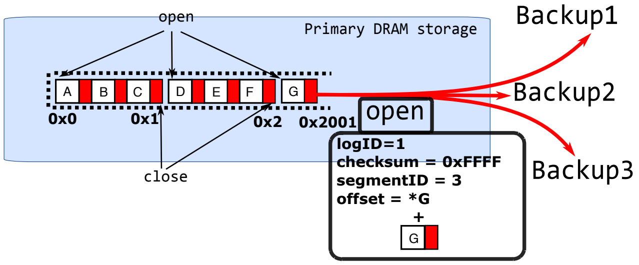

Figure 4: Primary DRAM storage consists of a monotonically growing log. It is logically split into fixed-size segments.

At the second step in Figure 3, the primary is able to perform all subsequent replication requests with RDMA writes ①. Backup NIC directly put objects to memory buffers via DMA transfer ② without involving the CPU. The primary gets work completion notification from its corresponding QP ③.

The primary keeps track of the last written offset in the backup buffer. When the next object would exceed the buffer capacity, the primary proceeds to the third step in Figure 3. The last replication request is called `close` and is performed through an RPC ①. The `close` notifies the backup ② + ③ that the buffer is full and thus can be flushed to durable storage. This eventually allows Tailwind to reclaim buffers and make them available to other primaries. Buffers are zeroed again when flushed.

We use RPCs for `open` and `close` operations because it simplifies the design of the protocol without hurting latency. As an example of complication, a primary may choose a secondary that has no buffers left. This can be challenging to handle with RDMA. Moreover, these operations are not frequent. If we consider 8 MB buffers and objects of 100 B, which corresponds to real workloads object size [19], `open` and `close` RPCs would account for 2.38×10^{-5} of the replication requests. Larger buffers imply less RPCs but longer times to flush backup data to secondary storage.

Thanks to all these steps, Tailwind can effectively replicate data using one-sided RDMA. However, without taking care of failure scenarios the protocol would not be correct. Next, we define essential notions Tailwind relies on for its correctness.

3.3.2 Primary Memory Storage

The primary DRAM log-based storage is logically sliced into equal *segments* (Figure 4). For every `open` and `close` RPC the primary sends a metadata information about current state: *logID*, latest checksum, *segmentID*, and current offset in the last segment. In case of failures, this information helps the backup in finding backup-data it stores for the crashed server.

At any given time, a primary can only replicate a single segment to its corresponding backups. This means a backup has to do very little work during recovery; if a primary replicates to *r* replicas then only *r* segments would be open, in case the primary fails.

```
input  : Pointer to a memory buffer rdmaBuf
output: Size of durably replicated data offset
currPosition = rdmaBuf ;
offset = currPosition ;
while currPosition < MAX_BUFFER_SIZE do
    /* Create a header in the current position */
    header = (Header)currPosition;
    currPosition += sizeof(header);
    /* Not Corrupted or incomplete header */
    if header→type != INVALID then
        if header→type == checksumType then
            checksum = (Checksum)currPosition;
            if checksum != currChecksum then
                /* Primaries never append a zero
                   checksum, check if it is 1. */
                if currChecksum == 0 and checksum == 1 then
                    offset = currPosition + sizeOf(checksum);
                else
                    return offset;
            else
                /* Move the offset at the end of
                   current checksum */
                offset = currPosition + sizeOf(checksum);
        else
            currChecksum = crc32(currChecksum, header);
    else
        return offset;
    /* Move forward to next entry */
    currPosition += header→objectSize;
/* We should only reach this line if a primary
   crashed before sending close */
return offset;
```

Algorithm 1: Updating RDMA buffer metadata

3.4 Failure Scenarios

When a primary or secondary replica fail the protocol must recover from the failure and rebuild lost data. Primary and secondary replicas failure scenarios require different actions to recover.

3.4.1 Primary-replica Failure

Primary replica crashes are one of the major concerns in the design. In case of such failures, Tailwind has to: (1) locate backup-data (of crashed primary) on secondary replicas; (2) rebuild up-to-date metadata information on secondary replicas; (3) ensure backup-data integrity and consistency; (4) start recovery.

Locating Secondary Replicas. After detecting a primary replica crash, Tailwind sends a query to all secondary replicas to identify the ones storing data belonging to the crashed primary. Since every primary has a unique logID it is easy for backups to identify which buffers belong to that logID.

Building Up-to-date Metadata. Backup buffers can either be in `open` or `close` states. Buffers that are `closed` do not pose any issue, they already have up-to-date metadata. If they are in disk or SSD they will be loaded to memory to get ready for recovery. However, for `open` buffers, the backup has to compute the offset and find the last checksum. Secondary replicas have to **scan** their `open` buffers to update their respective checksum and offset. To do so, they iterate over all entries as depicted in Algorithm 1.

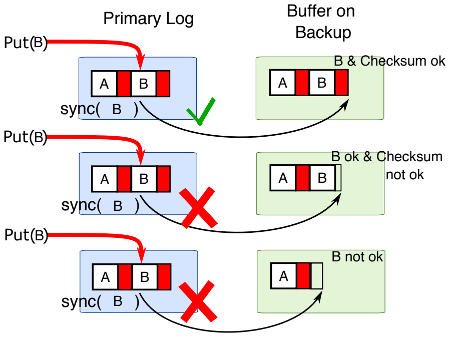

Figure 5: From top to bottom are three scenarios that can happen when a primary replica crashes while writing an object (B in this case) then synchronizing with backups. In the first scenario the primary replica fully writes the message to the backup leaving the backup in a correct state. B can be recovered in this case. In the second scenario, the object B is written but the checksum is partially written. Therefore, B is discarded. Similarly for the third scenario where B is partially written.

Basically, the algorithm takes an `open` buffer and tries to iterate over its entries. It moves forward thanks to the size of the entry which should be in the header. For every entry the backup computes a checksum over the header. When reaching a checksum in the buffer it is compared with the most recently computed checksum: the algorithm stops in case of checksum mismatch. There are three stop conditions: (1) integrity check failure; (2) invalid object found; (3) end of buffer reached.

A combination of three factors guarantee the correctness of the algorithm: (1) **the last entry is always a checksum**; Tailwind implicitly uses this condition as an end-of-transmission marker. (2) **Checksums are not allowed to be zero**; the primary replica always verifies the checksum before appending it. If it is zero it sets it to 1 and then appends it to the log. Otherwise, an incomplete object could be interpreted as valid zero checksum. (3) **Buffers are pre-zeroed**; combined with condition (2), a backup has a means to correctly detect the last valid offset in a buffer by using Algorithm 1.

3.4.2 Corrupted and Incomplete Objects

Figure 5 shows the three states of a backup RDMA buffer in case a primary replica failure. The first scenario shows a successful transmission of an object B and the checksum ahead of it. If the primary crashes, the backup is able to safely recover all data (i.e. A and B).

In the second scenario. the backup received B, but the checksum was not completely received. In this case the integrity check will fail. Object A will be recovered and B will be ignored. This is safe, since the client's PUT of B could not have been acknowledged.

The third scenario is similar: B was not completely transmitted to the backup. However, there creates two possibilities. If B's header was fully transmitted, then the algorithm will look past the entry and find a 0-byte at the end of the log entry. This way it can tell that the RDMA operation didn't complete in full, so it will discard the entry and treat the prefix of the buffer up through A as valid. If the checksum is partially written, it will still be discarded, since it will necessarily end in a 0-byte: something that is disallowed for all valid checksums that the primary creates. If B's header was only partially written, some of the bytes of the length field may be left zero. Imagine that o is the offset of the start of B. If the primary intended B to have length l and l' is the length actually written into the backup buffer. It is necessarily the case that $l' < l$, since lengths are unsigned and l' is a subset of the bits in l. As a result, $o + l'$ falls within the range where the original object data should have been replicated in the buffer. Furthermore, the data there consists entirely of zeroes, since an unsuccessful RDMA write halts replication to the buffer, and replication already halted before $o +$ `sizeof(Header)`. As a result, this case is handled identically to the incomplete checksum case, leaving the (unacknowledged) B off of the valid prefix of the buffer.

A key property maintained by Tailwind is that torn writes never depend on checksum checks for correctness. They can also be detected by careful construction of the log entries headers and checksums and the ordering guarantees that RDMA NICs provide.

Bit-flips The checksums, both covering the log entry headers and the individual objects themselves ensure that recovery is robust against bit-flips. The checksums ensure with high probability that bit-flip anywhere in any replica will be detected. In `closed` segments, whenever data corruption is detected, Tailwind declares the replica corrupted. The higher-level system will still successfully recover a failed primary, but it must rely on replicas from other backups to do so. In `open` segments data corruption is treated as partially transmitted buffers; as soon as Tailwind immediately stops iterating over the buffer and returns the last valid offset.

3.4.3 Secondary-replica Failure

When a server crashes the replicas it contained become unavailable. Tailwind must re-create new replicas on other backups in order to keep the same level of durability. Luckily, secondary-replica crashes are dealt with naturally in storage systems and do not suffer from one-sided RDMA complications. Tailwind takes several steps to allocate a new replica: (1) It suspends all operations on the corresponding primary replica; (2) It **atomically** creates a new secondary replica; (3) It resumes normal operations on the primary replica. Step (1) ensures that data will always have the same level of durability. Step (2) is crucial to avoid inconsistencies if a primary crashes while re-creating a secondary replica. In this case the newly created secondary replica would not have all data and cannot be used.

However, it can happen that a secondary replica stops and restarts after some time, which could lead to inconsistent states between secondary replicas. To cope with this, Tailwind keeps, at any point of time, a version number for replicas. If a secondary replica crashes, Tailwind updates the version number on the primary and secondaries. Since secondaries need to be notified, Tailwind uses an RPC instead of an RDMA for this operation. Tailwind updates the version number right after the step (2) when re-creating a secondary replica. This ensures that the primary and backups are synchronized. Replication can start again from a consistent state. Note that this RPC is rare and only occurs after the crash of a backup.

3.4.4 Network Partitioning

It can happen that a primary is considered crashed by a subset of servers. Tailwind would start locating its backups, then rebuilding metadata on those backups. While metadata is rebuilt, the primary could still perform one-sided RDMA to its backups, since they are always unaware of these type of operations. To remedy this, as soon as a primary or secondary failure is detected, all machines close their respective QPs with the crashed server. This allows Tailwind to ensure that servers that are alive but considered crashed by the environment do not interfere with work done during recovery.

4 Evaluation

We implemented Tailwind on RAMCloud a low-latency in-memory key-value store. Tailwind's design perfectly suits RAMCloud in many aspects:

Low latency. RAMCloud's main objective is to provide low-latency access to data. It relies on fast networking and kernel-bypass to provide a fast RPC layer. Tailwind can further improve RAMCloud (PUT) latency (§4.2) by employing one-sided RDMA without any additional complexity or resource usage.

Replication and Threading in RAMCloud. To achieve low latency, RAMCloud dedicates one core solely to poll network requests and dispatch them to worker cores (Figure 1). Worker cores execute all client and system tasks. They are never preempted to avoid context switches that may hurt latency. To provide strong consistency, RAMCloud always requests acknowledgements from all backups for every update. With the above threading-model, replication considerably slows down the overall performance of RAMCloud [31]. Hence Tailwind can greatly improve RAMCloud's CPU-efficiency and remove replication overheads.

Log-structured Memory. RAMCloud organizes its memory as an append-only log. Memory is sliced into smaller chunks called *segments* that also act as the unit of replication, i.e., for every segment a primary has to choose a backup. Such an abstraction makes it easy to replace RAMCloud's replication system with Tailwind. Tailwind checksums can be appended in the log-storage, with data, and replicated with minimal changes to the code. In addition, RAMCloud provides a log-cleaning mechanism which can efficiently clean old checksums and reclaim their storage space.

CPU	Xeon E5-2450 2.1 GHz 8 cores, 16 hw threads
RAM	16 GB 1600 MHz DDR3
NIC	Mellanox MX354A CX3 @ 56 Gbps
Switch	36 port Mellanox SX6036G
OS	Ubuntu 15.04, Linux 3.19.0-16, MLX4 3.4.0, libibverbs 1.2.1

Table 1: Experimental cluster configuration.

We compared Tailwind with RAMCloud replication protocol, focusing our analysis on three key questions:

Does Tailwind improve performance? Measurements show Tailwind reduces RAMCloud's median write latency by 2× and 99th percentile latency by 3× (Figure 7). Tailwind improves throughput by 70% for write-heavy workloads and by 27% for workloads that include just a small fraction of writes.

Why does Tailwind improve performance? Tailwind improves per-server throughput by eliminating backup request processing (Figure 9), which allows servers to focus effort on processing user-facing requests.

What is the Overhead of Tailwind? We show that Tailwind's performance improvement comes at no cost. Specifically, we measure and find no overhead during crash recovery compared to RAMCloud.

4.1 Experimental Setup

Experiments were done on a 35 server Dell r320 cluster (Table 1) on the CloudLab [24] testbed.

We used three YCSB [2] workloads to evaluate Tailwind: update-heavy (50% PUTs, 50% GETs), read-heavy (5% PUTs, 95% GETs), and update-only (100% PUTs). We intitially inserted 20 million objects of 100 B plus 30 B for the key. Afterwards, we ran up to 30 client machines. Clients generated requests according to a Zipfian distribution ($\theta = 0.99$). Objects were uniformly inserted in active servers. The replication factor was set to 3 and RDMA buffers size was set to 8 MB. Every data point in the experiments is averaged over 3 runs.

RAMCloud's RPC-based replication protocol served as a baseline for comparison. Note that, in the comparison with Tailwind, we refer to RAMCloud's replication protocol as RAMCloud for simplicity.

4.2 Performance Improvement

The primary goal of Tailwind is to accelerate basic operations throughput and latency. To demonstrate how Tailwind improves performance we show Figure 6, i.e. throughput per server as we increase the number of clients. When client operations consist of 5% PUTs and 95% GETs, RAMCloud achieves 500 KOp/s per server while Tailwind reaches up to 635 KOp/s. Increasing the update load enables Tailwind to further improve the throughput. For instance with 50% PUTs Tailwind sustains 340 KOp/s against 200 KOp/s for RAMCloud, which is a 70% improvement. With update-only workload, improvement is not further increased: In this case Tailwind improves the throughput by 65%.

Tailwind can improve the number of read operations serviced by accelerating updates. CPU cycles saved allow servers (that are backups as well) to service more requests in general.

Figure 7 shows that update latency is also considerably improved by Tailwind. Under light load Tailwind reduces median and 99th percentile latency of an update from 16 µs to 11.8 µs and from 27 µs to 14 µs respectively. Under heavy load, i.e. 500 KOp/s Tailwind reduces median latency from 32 µs to 16 µs compared to RAMCloud. Under the same load tail latency is even further reduced from 78 µs to 28 µs.

Tailwind can effectively reduce end-to-end client latency. With reduced acknowledgements waiting time, and more CPU power to process requests faster, servers can sustain a very low latency even under heavy concurrent accesses.

4.3 Gains as Backup Load Varies

Since all servers in RAMCloud act as both backups and primaries, Tailwind accelerates normal-case request processing indirectly by eliminating the need for servers to actively process replication operations. Figure 8 shows the impact of this effect. In each trial load is directed at a subset of four RAMCloud storage nodes; "Active Primary Servers" indicates the number of storage nodes that process client requests. Nodes do not replicate data to themselves, so when only one primary is active it is receiving no backup operations. All of the active primary's backup operations are directed to the other three otherwise idle nodes. Note that, in this figure, throughput is per-active-primaries. So, as more primaries are added, the aggregate cluster throughput increases.

As client GET/PUT operations are directed to more nodes (more active primaries), each node slows down because it must serve a mix of client operations intermixed with an increasing number of incoming backup operations. Enough client load is offered (30 clients) so that storage nodes are the bottleneck at all points in the graphs. With four active primaries, every server node is saturated processing client requests and backup operations for all client-issued writes.

Even when only 5% of client-issued operations are writes (Figure 8a), Tailwind increasingly improves performance as backup load on nodes increases. When a primary doesn't perform backup operations Tailwind improves throughput 3%, but that increases to 27% when the primary services its fair share of backup operations. The situation is similar when client operations are a 50/50 mix of reads and writes (Figure 8b) and when clients only issue writes (Figure 8c).

As expected, Tailwind enables increasing gains over RAMCloud with increasing load, since RDMA elimi-

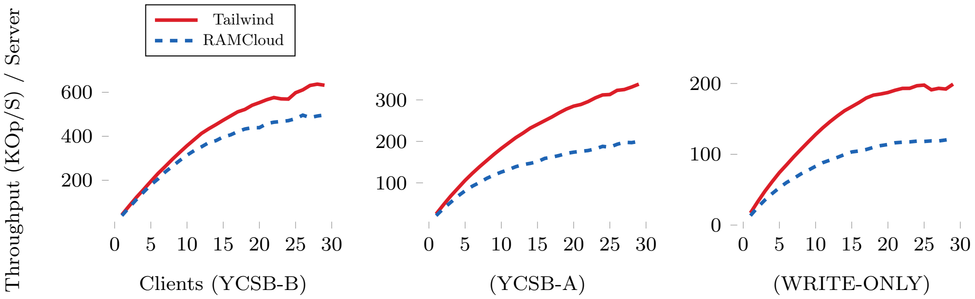

Figure 6: Throughput per server in a 4 server cluster.

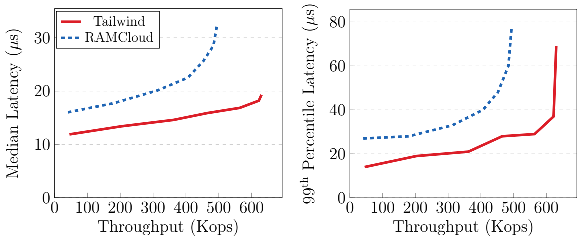

(a) (b)

Figure 7: (a) Median latency and (b) 99th percentile latency of PUT operations when varying the load.

nates three RPCs that each server must handle for each client-issued write, which, in turn, eliminates worker core stalls on the node handling the write.

In short, the ability of Tailwind to eliminate replication work on backups translates into more availability for normal request processing, and, hence, better GET/PUT performance.

4.4 Resource Utilization

The improvements above have shown how Tailwind can improve RAMCloud's baseline replication normal-case. The main reason is that operations contend with backup operations for worker cores to process them. Figure 9a illustrates this: we vary the offered load (updates-only) to a 4-server cluster and report aggregated active worker cores. For example, to service 450 KOp/s, Tailwind uses 5.7 worker cores while RAMCloud requires 17.6 active cores, that is 3× more resources. For the same scenario, we also show Figure 9b that shows the aggregate active dispatch cores. Interestingly, gains are higher for dispatch, e.g., to achieve 450 KOp/s, Tailwind needs only 1/4 of dispatch cores used by RAMCloud.

Both observations confirm that, for updates, most of the resources are spent in processing replication requests. To get a better view on the impact when GET/PUT operations are mixed, we show Figure 10. It represents active worker and dispatch cores, respectively, when varying clients. When requests consist of updates only, Tailwind reduces worker cores utilization by 15% and dispatch core utilization by 50%. This is stems from the fact that a large fraction of dispatch load is due to replication requests in this case. With 50/50 reads and writes, worker utilization is slightly improved to 20% while it reaches 50% when the workload consists of 5% writes only.

Interestingly, dispatch utilization is not reduced when reducing the proportion of writes. With 5% writes Tailwind utilizes even more dispatch than RAMCloud. This is actually a good sign, since read workloads are dispatch-bound. Therefore, Tailwind allows RAMCloud to process even more reads by accelerating write operations. This is implicitly shown in Figure 10 with "Replication" graphs that represent worker utilization due to waiting for replication requests. For update-only workloads, RAMCloud spends 80% of the worker cycles in replication. With 5% writes RAMCloud spends 62% of worker cycles waiting for replication requests to complete against 49% with Tailwind. The worker load difference is spent on servicing read requests.

4.5 Scaling with Available Resources

We also investigated how Tailwind improves internal server parallelism (i.e. more cores). Figure 11 shows throughput and worker utilization with respect to available worker cores. Clients (fixed to 30) issue 50/50 reads and writes to 4 servers. Note that we do not count the dispatch core with available cores, as it is always available. With only a single worker core per machine, RAMCloud can serve 430 KOp/s compared to 660 KOp/s for Tailwind with respectively 4.5 and 3.5 worker cores utilization. RAMCloud can over-allocate resources to avoid deadlocks, which explains why it can go above the limit of available cores. Interestingly, when increasing the available worker cores, Tailwind enables better scaling. RAMCloud does not achieve more throughput with more than 5 available cores. Tailwind continues to improve throughput up to all 7 available cores per machine.

Even though both RAMCloud and Tailwind exhibit a plateau, this is actually due to the dispatch thread limit that cannot take more requests in. This suggests that Tailwind allows RAMCloud to better take advantage of per-machine parallelism. In fact, by eliminating the replication requests from dispatch, Tailwind allows more client-

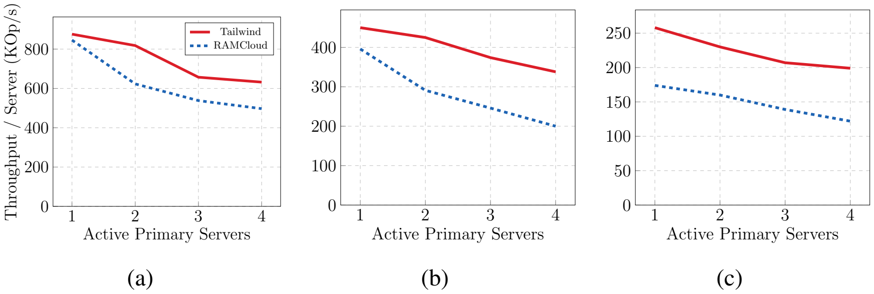

Figure 8: Throughput per active primary servers when running (a) YCSB-B (b) YCSB-A (c) WRITE-ONLY with 30 clients.

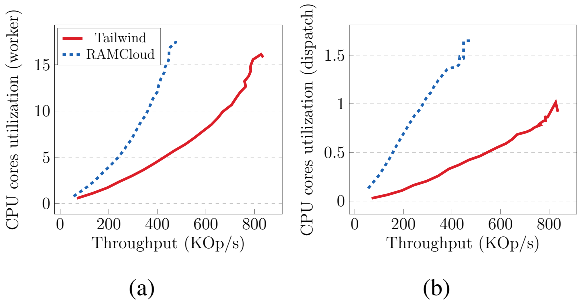

Figure 9: Total (a) worker and (b) dispatch CPU core utilization on a 4-server cluster. Clients use the WRITE-ONLY workload.

issued requests in the system.

4.6 Impact on Crash Recovery

Tailwind aims to accelerate replication while keeping strong consistency guarantees and without impacting recovery performance. Figure 12 shows Tailwind's recovery performance against RAMCloud. In this setup data is inserted into a primary replica with possibility to replicate to 10 other backups. RAMCloud's random backup selection makes it so that all backups will end up with approximately equal share of backup data. After inserting all data, the primary kills itself, triggering crash recovery.

As expected, Tailwind almost introduces no overhead. For instance, to recover 1 million 100 B objects, it takes half a second for Tailwind and 0.48 s for RAMCloud. To recover 10 million 100 B objects, Both Tailwind and RAMCloud take roughly 2.5 s.

Tailwind must reconstruct metadata during recovery (§3.4.1), but this only accounts for a small fraction of the total work of recovery. Moreover, reconstructing metadata is only necessary for open buffers, i.e. still in memory. This can be orders of magnitude faster than loading a buffer previously flushed on SSD, for example.

5 Discussion

5.1 Metadata Space Overhead

In its current implementation, Tailwind appends metadata after every write to guarantee RDMA writes atomicity (§3.1). Although this approach appears to introduce space overhead, RAMCloud's log-cleaning mechanism efficiently removes old checksums without performance impact [26]. In general, Tailwind adds only 4 bytes per object which is much smaller than, for example, RAMCloud headers (30 bytes).

5.2 Applicability

Tailwind can be used in many systems that leverage distributed logging [4, 12, 18, 20, 22, 33] provided they have access to RDMA-based networks. Recently, RDMA is supported in Ethernet in the form of RoCE or iWARP [8] and is becoming prevalent in datacenters [17, 39]. To be properly integrated in any system, Tailwind needs: (1) appending a checksum after each write; (2) implementing algorithm 1 during recovery. Aspects such as memory/buffer management do not impact Tailwind's core design nor performance gains because Tailwind reclaims replication-processing CPU cycles at backups.

6 Related Work

One-sided RDMA-based Systems. There is a wide range of systems recently introduced that leverage RDMA [4, 5, 10, 15, 16, 27, 30, 33, 34, 36, 38]. For instance, many of them use RDMA for normal-case operations. Pilaf [15] implements client-lookup operations with one-sided RDMA reads. In contrast, with HERD [10] clients use one-sided RDMA writes to send GET and PUT requests to servers, that poll their receive RDMA buffers to process requests. In RFP [10] clients use RDMA writes to send requests, and RDMA reads to poll (remotely) replies. Crail [29] uses one-sided RDMA to transfer I/O blocks, but it is not designed for availability or fault-tolerance. LITE [32] is a kernel module providing efficient one-sided operations and could be used to implement Tailwind.

Many systems also use one-sided RDMA for replication. For instance, FaRM [4, 5], HydraDB [33], and DARE [22] use one-sided RDMA writes to build a message-passing interface. Replication uses this interface to place messages in remote ring buffers. Servers have to poll these ring buffers in order to fetch messages, process them, and apply changes. In [6] authors use one-sided RDMA for VM migration. The sender asynchronously replicate data and notifies the receiver at

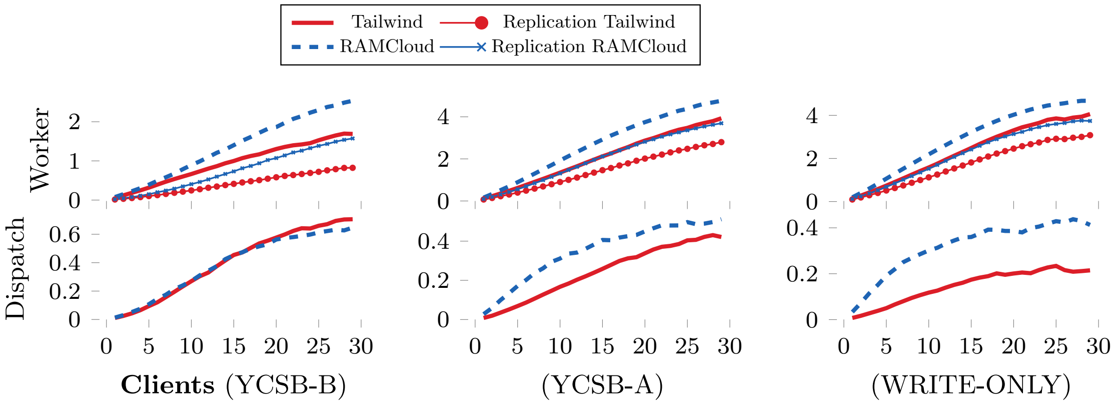

Figure 10: Total dispatch and worker cores utilization per server in a 4-server cluster. "Replication" in worker graphs represent the fraction of worker load spent on processing replication requests on primary servers.

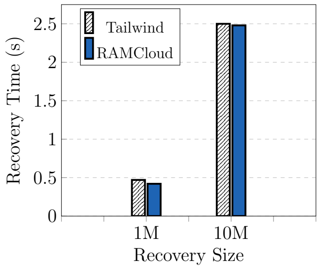

Figure 12: Time to recover 1 and 10 million objects with 10 backups.

the end of transfer then the backup applies changes in a transactional way.

No system that uses RDMA writes for replication leaves the receiver CPU completely idle. Instead, the receiver must poll receive buffers and process requests, which defeats one-sided RDMA efficiency purposes. Tailwind frees the receiver from processing requests by directly placing data to its final storage location.

Reducing Replication Overheads. Many systems try to reduce replication overheads either by relaxing/tuning consistency guarantees [3, 7, 14] or using different approaches for fault-tolerance [37]. Mojim [38] is a replication framework intended for NVMM systems. For each server it considers a mirror (backup) machine to which it will replicate all data through (two-sided) RDMA. It supports multiple levels of consistency and durability. RedBlue [14] and Correctables [7] provide different consistency levels to the applications and allows them to trade consistency for performance. Tailwind does not sacrifice consistency to improve normal-case system performance.

7 Conclusion

Tailwind is the first replication protocol that fully exploits one-sided RDMA; it improves performance without sacrificing durability, availability, or consistency. Tailwind leaves backups unaware of RDMA writes as they happen, but it provides them with a protocol to rebuild metadata in case of failures. When implemented in RAMCloud, Tailwind substantially improves throughput and latency with only a small fraction of resources originally needed by RAMCloud.

Abstract

Erasure codes are used in large-scale storage systems to allow recovery of data from a failed node. A recently developed class of erasure codes, termed *locally repairable codes (LRCs)*, offers tradeoffs between storage overhead and repair cost. LRCs facilitate more efficient recovery scenarios by storing additional parity blocks in the system, but these additional blocks may eventually increase the number of blocks that must be reconstructed. Existing codes differ in their use of the additional parity blocks, but also in their locality semantics and in the parameters for which they are defined. As a result, existing theoretical models cannot be used to directly compare different LRCs to determine which code will offer the best recovery performance, and at what cost.

In this study, we perform the first systematic comparison of existing LRC approaches. We analyze Xorbas, Azure's LRCs, and the recently proposed Optimal-LRCs in light of two new metrics: the *average degraded read cost*, and the *normalized repair cost*. We show the tradeoff between these costs and the code's fault tolerance, and that different approaches offer different choices in this tradeoff. Our experimental evaluation on a Ceph cluster deployed on Amazon EC2 further demonstrates the different effects of realistic network and storage bottlenecks on the benefit from each examined LRC approach. Despite these differences, the normalized repair cost metric can reliably identify the LRC approach that would achieve the lowest repair cost in each setup.

1 Introduction

In large-scale storage systems consisting of hundreds of thousands of servers, node failures are the norm rather than the exception. For this reason, redundancy is added to ensure availability of the data despite the failures. Typically, the redundancy of hot data is achieved by *replication* of each data object, ensuring the availability of the data as long as one replica is available. This also allows efficient reconstruction of data that was stored on a failed node from the surviving replicas.

Due to the high overhead of replication, most of the data is stored redundantly by erasure coding. With an (n,k) *erasure code*, the data is split into k *data blocks* that are used to generate $n-k$ *parity blocks*. The blocks are distributed across n different nodes, so that the original data can be reconstructed as long as at least k blocks are available. The *storage overhead* of erasure coding is $\frac{n}{k}$ —considerably lower than that of replication. However, reconstruction of one data block requires reading k surviving blocks—an overhead considerably higher than that of replication.

Storage systems distinguish between two types of node failures. *Transient failures* may be caused by system restarts or updates, after which the node is available again. During this time, read operations of data stored on the failed node are served as *degraded reads*—only the required data blocks are reconstructed from the surviving blocks. *Permanent failures* occur when the node malfunctions and is no longer accessible. Typically, a failure is considered permanent after 15 minutes of unavailability, which triggers full recovery of its data. Recent studies indicate that transient failures comprise 90% of failure events [28], and only the remaining 10% trigger full node recovery. Nevertheless, recovery traffic incurs significant load on the data center's servers and network—up to 180TB of data transfer between racks each day, according to a recent study on Facebook's data centers [24].

The vast majority of failures (up to 98% [24]) constitute exactly one unavailable node. Thus, several approaches have been used to design erasure codes that can withstand several concurrent failures, but optimize the recovery cost of a single node. These include preprocessing the surviving data to minimize repair network bandwidth [6,22,25], and reducing the amount of data read from each surviving node [7, 9, 12, 14, 23, 38]. These codes can reduce the amount of data read by up to 50%, but in many realistic settings, this reduction is no more than 25%, or not applicable due to the required I/O granularity [18].

A different approach increases the storage overhead and utilizes the added redundancy to optimize the recovery of a single data node. An (n,k,r) *locally repairable code (LRC)* supports the *local* recovery of an unavailable block by reading at most r surviving blocks. These codes were originally designed to reduce the cost of degraded reads, and thus most of them optimize only the recovery of data blocks [10,11]. Others further optimize the recov-

Figure 1: (10,6) Reed-Solomon

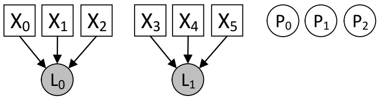

Figure 2: (11,6,3) Azure-LRC

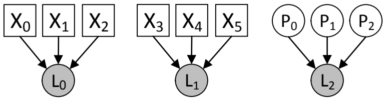

Figure 3: (12,6,3) Optimal-LRC

ery of all of the parity blocks, but do so for a limited set of system parameters [28]. In a recent work [30], new codes were constructed that support local recovery of both data and parity blocks, with the same storage overhead as previously known constructions.

LRCs present an inherent tradeoff. On the one hand, they considerably reduce the amount of data that must be read for degraded reads and recovery. On the other hand, in order to store the additional parity, the system must store more blocks on each of its nodes, or allocate more nodes for the same amount of data. In the first case, more data must be reconstructed whenever a node fails, while the latter increases the probability of failure in the system. As a result, LRCs not only increase the system's storage overhead, but might also increase its overall recovery costs. Different codes offer different tradeoffs between storage overhead and recovery cost, and between recovery cost and the cost of degraded reads. Furthermore, they are defined for different (n,k,r) combinations and differ in their locality semantics. Thus, directly comparing their costs and benefits is a nontrivial task, which makes it hard to choose the optimal code and configuration for a given system.

In this study, we perform the first comprehensive analysis of the different LRC approaches. We take into account the overall cost of recovery, including data and parity blocks, as well as the maximum number of failed blocks the code can recover. Our analysis includes *Xorbas* [28], *Azure-LRC*—the LRC codes used by Microsoft Azure [11], and *Optimal-LRC*—a recently proposed theoretically optimal code [30]. We also define a new code, *Azure-LRC+1*, which is based on Azure-LRC and supports efficient recovery of all parity blocks.

We conduct a theoretical comparison between the different LRC approaches. Our analysis demonstrates the limitations of existing measures, such as locality and average repair cost. Thus, we define new metrics that model each code's overhead, full-node repair cost, degraded read cost, and fault tolerance. Our results demonstrate the tradeoff between the objectives measured by these costs, and how different codes optimize different objectives.

We follow the theoretical analysis with an evaluation of these codes in a Ceph cluster deployed in AWS EC2. Our experimental evaluation shows that we can accurately predict the amount of data required by each code for reconstructing an entire storage node. This prediction also provides a good estimate of the time required for reconstruction, for most combinations of storage type, network configurations, and foreground traffic.

The rest of this paper is organized as follows. Section 2 presents LRCs and motivates our analysis. We describe our new LRC and metrics in Section 3, and our theoretical analysis in Section 4. Our system-level setup is described in Section 5, with the evaluation in Section 6. We survery related work in Section 7, and conclude in Section 8.

2 Preliminaries

The storage overhead of an erasure code is defined as $\frac{n}{k}$. Its *minimal distance*, d, is defined as the smallest number of concurrent node failures that may cause data loss. In other words, there is at least one combination of d node failures from which the code will not be able to recover the data. An important class of codes, termed *maximum distance separable (MDS)* codes, is characterized by the relation $d = n-k+1$, and provides the largest possible d for given n and k. In MDS codes, k surviving blocks are required to recover a failed block. Reed-Solomon codes [26] are the most commonly used MDS codes owing to their parameter flexibility and efficient implementation.

An (n,k,r) locally repairable code (LRC) consists of k data blocks and $n-k$ parity blocks. The data blocks are grouped into *local groups* no larger than r. A *local parity* is computed from each local group of blocks and can be used for the recovery of any block in this group. In total, each local group of LRC contains at most $r+1$ blocks. In case of an arbitrary failure of one block in a local group, r surviving blocks are required for its recovery. A *global parity* is a function of all data blocks, and can thus be used to recover any lost block. Pyramid codes [10], which are based on (n,k) Reed-Solomon codes were the first suggested family of LRCs. Another family, Azure-LRC, is a variation of Pyramid codes and is used in Windows Azure [11].

Figure 1 depicts a (10,6) Reed-Solomon code, and Figure 2 shows the (11,6,3) Azure-LRC which results from replacing one of its global parities with two local parities. In this example, P_3 was replaced with L_0 and L_1, which can be used in the recovery of groups (X_0,X_1,X_2) and (X_3,X_4,X_5), respectively. In the new code, any of the data blocks can be repaired by reading the remaining three blocks in its local group. Thus, the recovery cost of a data block is reduced by 50%. However, the overhead increases by 10%, from $\frac{10}{6}$ to $\frac{11}{6}$. Note also that the new code is non-MDS: it can repair any four missing blocks but not any five, therefor $d = 5$, but $n-k+1 = 6$.

Azure-LRC successfully reduces the repair cost of data blocks and local parities, and, as a result, the degraded

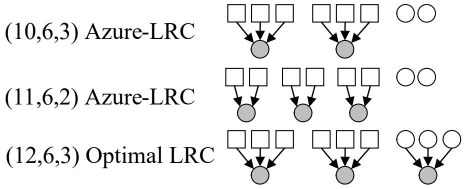

Figure 4: Three LRCs with the same k, demonstrating different tradeoffs between locality and overhead.

read cost. However, due to the allocation of blocks to nodes, when an entire node must be reconstructed, this node will include a significant number of global parities, which will require k surviving blocks for recovery. For example, in (11,6,3) Azure-LRC, which contains $m = 3$ global parities, an average of $\frac{3}{11} = 27.2\%$ of the blocks stored on each node will be global parities.

Coding theory distinguishes between two types of (n,k,r) LRCs. In codes with *information-symbol locality*, only the data blocks can be repaired in a local fashion by r surviving blocks, while the global parities require k blocks for recovery. We refer to these codes as *data-LRCs*. Pyramid and Azure-LRC are data-LRCs. In contrast, in codes with *all-symbol locality*, all the blocks, including the global parities, can be repaired locally from r surviving blocks. We refer to such codes as *full-LRCs*.

Optimal-LRC is a recently proposed full-LRC [30]. In this code, k data blocks and m global parities are divided into groups of size r, and a local parity is added to each group, allowing repair of *any* lost block by the r surviving blocks in its group. r does not necessarily divide $m+k$, but Optimal-LRC requires that $n \bmod (r+1) \neq 1$. Figure 3 shows a (12,6,3) Optimal-LRC. Each of the global parities, P_0, P_1, and P_2, can be reconstructed from the other global parities and the local parity L_2. The overhead of this code is higher than that of the (11,6,3) Azure-LRC in Figure 2, but its minimum distance is also higher ($d = 6$).

Full-LRCs introduce a new point in the tradeoff between fault tolerance and performance, which previously consisted only of MDS codes and data-LRCs. Gopalan et al. [8] proved that an upper bound on the minimal distance for an (n,k,r) LRC is $d \leq n - k - \lceil \frac{k}{r} \rceil + 2$. Codes that achieve this bound are regarded as optimal; in particular, Optimal-LRC has been shown to achieve this bound. Specifically, the minimum distance of Optimal-LRC was shown to be [30]:

$$d = n - k - \left\lceil \frac{k}{r} \right\rceil + 2, \quad \text{if } (r+1)|n$$

$$d \geq n - k - \left\lceil \frac{k}{r} \right\rceil + 1, \quad \text{if } (r+1) \not| n, \quad r|(k+1).$$

Challenges. Azure-LRC provides an appealing tradeoff when compared to Reed-Solomon codes: a 10% increase in storage overhead can halve the cost of all degraded reads and most block repairs. Unfortunately, the comparison between data-LRCs and full-LRCs is not similarly straightforward. Consider, for example, the three codes in Figure 4. The (11,6,2) Azure-LRC has three local parities, one more than the (10,6,3) Azure-LRC, which reduces its r from 3 to 2, but increases its overhead by 10%. The (12,6,3) Optimal-LRC also has three local parities. However, rather than reducing r, the additional local parity enables local repair of the global parities. Thus, r represents different locality semantics in each of these models. In addition, each model represents a different tradeoff between the cost of degraded read and the cost of full node repair, and between these costs and the overhead.

It is not entirely clear which of these codes will have the lowest repair cost. Clearly, r alone cannot serve as a metric for comparing data-LRCs to full-LRCs. The *average repair cost (ARC)* used in previous analyses [11] fails to capture the effect the code's overhead has on its repair cost. In the next section, we introduce three composite metrics that facilitate a systematic comparison of LRCs.

The task of comparing different codes is further complicated by the fact that existing codes are not all defined for the same range of parameters. Our new metrics alleviate this problem to some extent. To eliminate the problem completely, we adopt a somewhat 'flexible' interpretation of Azure-LRC. We also use a new construction of Optimal-LRC, which is optimal for parameters for which an explicit construction has not been given before.

Finally, theoretically proven benefits are not always achievable in real systems. The repair-cost benefit of different codes may be determined by factors such as storage and network bandwidth, the nature and priority of the foreground load, and the system-level implementation. Thus, we complement our theoretical analysis with an evaluation on a distributed cluster in Amazon EC2, where we verify our metrics and identify additional factors that should be taken into account when designing an erasure coded storage system.

3 Methodology

Metrics. The starting point of our theoretical analysis consists of the existing measures described above: r is the maximal number of blocks required for the recovery of any block or a data block, in full-LRCs and data-LRCs, respectively. The *overhead* of the code is $\frac{n}{k}$, and its minimal distance is d. We use d to represent the code's fault tolerance, despite its inherent limitation—two codes with the same d may be considered equally fault tolerant, although one may prevent data loss in more combinations of correlated failures than the other [11]. The *mean time to data loss (MTTDL)* is considered a more accurate measure for fault tolerance. However, to calculate the MTTDL of a code, one must construct a Markov chain for every specific set of n,k,r parameters. In addition, this model does not always yield an analytic closed-form equation. Thus, d is more appropriate for our large-scale analysis. For a limited comparison of a small set of constructions, d can be replaced with MTTDL.

The average repair cost (ARC) has been used in previous studies [11], and is based on the assumption that the probability of repair due to failure is the same for all blocks. It is defined as

$$ARC = \frac{\sum_{i=1}^{n} cost(b_i)}{n},$$

where b_i is the ith block in the code, and $cost(b_i)$ is the number of blocks required for the repair of b_i. For example, the ARC of the (10,6,3) Azure-LRC in Figure 4 is $\frac{(8\times3)+(2\times6)}{10} = 3.6$. Similarly, in the same figure, the ARC of the (11,6,2) Azure-LRC is 2.73 and that of the (12,6,3) Optimal-LRC is 3.

ARC does not take into account the higher overhead of some of these codes, which implies that more blocks will have to be repaired in the event of a node failure. We address this by defining a new composite metric for the cost of full-node repair. The *normalized repair cost (NRC)* of a code is the product of its ARC and overhead:

$$NRC = ARC \times \frac{n}{k} = \frac{\sum_{i=1}^{n} cost(b_i)}{k}.$$

NRC can also be viewed as the average cost of repairing a failed data block, where the cost of repairing the parity blocks is amortized over the k data blocks. For example, the NRC of the (10,6,3) Azure-LRC in Figure 4 is $\frac{(8\times3)+(2\times6)}{6} = 6$. Similarly, the NRC of the (11,6,2) Azure-LRC is 5 and that of the (12,6,3) Optimal-LRC is 6.

ARC is also inappropriate for modeling the cost of degraded reads. By definition, degraded reads refer to data blocks only, while ARC averages the repair cost of all blocks—data and parity alike. We define the *average degraded read cost* (*'degraded cost'*, in short) as the average cost of repairing data blocks only:

$$Degraded\ cost = \frac{\sum_{i=1}^{k} cost(b_i)}{k},$$

where blocks $b_1,...,b_k$ are the object's data blocks. For example, the degraded cost of the (10,6,3) Azure-LRC and the (12,6,3) Optimal-LRC in Figure 4 is $\frac{6\times3}{6} = 3$. Similarly, the degraded cost of the (11,6,2) Azure-LRC is 2. Note that in the general case, the degraded cost is not always equal to r.

We base our analysis on three existing LRCs: Xorbas, Azure-LRC, and Optimal-LRC. We use Reed-Solomon codes as a baseline for some of our comparisons. Below, we describe how we extended the definitions of these codes for our analysis and evaluation.

Xorbas. Xorbas [28] is a full-LRC, in which the global parities can be recovered from the local parities. Figure 5 shows a (16,10,5) Xorbas code. Each local parity belongs to a group containing five data blocks. The special construction of Xorbas ensures that any of the global parities can be reconstructed by the remaining global parities and the two local parities. Thus, $r = 5$ for *all* the blocks in the code. This special property can be maintained if we remove the same number of blocks from each group. For example, a (13,8,4) Xorbas code can be obtained by removing two data blocks and one global parity from the original construction. The number of global parities can be further reduced to achieve a lower overhead, without reducing r. For example, a (12,8,4) Xorbas code has the same r as the (13,8,4) code, but a smaller d.

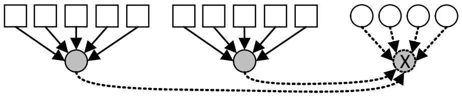

Figure 5: (16,10,5) Xorbas. ⊗ marks a function computed by the local parities, not a real block.

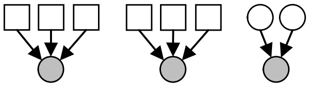

Figure 6: (11,6,3) Azure-LRC+1

Azure-LRC. We use Azure-LRC as the data-LRC in our evaluation. It is explicitly defined in its original paper only for (n,k,r) where r divides k, and the number of local parities is $l = \frac{k}{r}$ [11]. For the sake of analysis, we extend this code to the general case as follows. In an (n,k,r) Azure-LRC where r does not divide k, the number of local parities is $l = \lceil \frac{k}{r} \rceil$. $l-1$ groups contain r data blocks and one local parity. The remaining group contains $k \mod r$ data blocks and one local parity. For the code to have at least one global parity, we must only ensure that $k+l < n$. Although this extension results in asymmetric allocation of data blocks to groups, it allows us to consider Azure-LRC in most (n,k,r) combinations.

Azure-LRC+1. For the sake of analysis, we define a new full-LRC which is based on Azure-LRC. An (n,k,r) *Azure-LRC+1* code is constructed by adding one local parity to the group of global parities of an $(n-1,k,r)$ Azure-LRC. This local parity is computed as the XOR of all the global parities. Figure 6 shows an (11,6,3) Azure-LRC+1 constructed from the (10,6,3) Azure-LRC in Figure 4. When one global parity block is missing, it can be repaired from the remaining global parities and the additional local parity. Thus, Azure-LRC+1 will have $l+1$ local parities, $l = \lceil \frac{k}{r} \rceil$, and can be constructed as long as $k+l+1 < n$. This naïve definition implies that an Azure-LRC+1 construction may result in a local parity added to a 'group' of one global parity. Nevertheless, it has the added value of being directly and easily applicable to any system that uses Azure-LRC or Pyramid codes, and is thus an important aspect of our analysis.

Optimal-LRC. The original Optimal-LRC construction [30] was shown to be optimal for the cases described in Section 2. However, extending this construction to all admissible (n,k,r) combinations results in a code with lower d, which is suboptimal. To address this issue, we devised a new construction of codes in the spirit of the original construction. The advantage of the new construction is that it applies to all parameters n,k,r such that $n \bmod (r+1) \neq 1$. Furthermore, it can be shown that our new construction attains the largest possible minimum distance even when the upper bound $n-k-\lceil\frac{k}{r}\rceil+2$ is not attainable. In summary, the new construction is the first optimal construction for *all* admissible parameters. The construction and the proof of its optimality can be found in [13].

Evaluation parameters. We computed the ARC, NRC, degraded cost, overhead, and d for each of the codes described above, for all (n,k,r) combinations for which they are defined, where $9 \leq n \leq 19$ and $\frac{n}{k} \leq 2$. These combinations include specific sets of parameters that appear in the literature and in documented deployments: (18,12,3) Azure-LRC [11], (16,10,5) Xorbas, (14,10) Reed-Solomon [24], and (9,6) Reed-Solomon [37]. Due to space constraints, and for clarity of presentation, we show only results for $12 \leq n \leq 18$ and $\frac{n}{k} \leq 1.6$, which include the more common combinations. This range of parameters suffices for demonstrating our observations, which we verified on the complete range.

4 Theoretical Analysis

Figure 7 shows NRC and the degraded read cost of the different codes. For the same n, k, and r, the degraded cost is usually the same for all codes. It is different when r does not divide k, where the codes differ in their allocation of blocks to groups. As we expected, for the same n and k, increasing r increases each code's degraded read cost and NRC. However, when comparing different codes, neither r nor the degraded read cost can indicate which code will have the lowest full-node repair cost. For example, the NRC of (14,10,6) Azure-LRC+1 is lower than that of (14,10,5) Azure-LRC, although its degraded cost is higher.

Figure 8 shows the minimum distance, d, of the different codes. Figures 7 and 8 together demonstrate a clear tradeoff between repair costs and fault tolerance. In general, for given n, k, and r, to increase d one must either increase n or increase r, thus increasing both the degraded cost and NRC. Nevertheless, different codes offer different points in this tradeoff.

Data-LRC vs. full-LRC. For the same (n,k,r), there is always one full-LRC with a lower NRC than that of Azure-LRC. However, in most settings, the reduction in NRC is coupled with a reduction in d. In the settings in which it is defined, Xorbas achieves the same d but a higher NRC than Azure-LRC+1 and Optimal-LRC. Optimal-LRC and Azure-LRC+1 achieve the same d and NRC in many settings. In the settings where the NRC of Azure-LRC+1 is lower than that of Optimal-LRC, its d is also lower (except for a few corner cases discussed below).

In Figure 9, we compare the NRC of (n,k,r) Azure-LRC to that of the $(n+1,k,r)$ full-LRCs with the same d. The full-LRCs use an additional local parity to allow fast repair of the global parities. This addition always reduces the repair cost, despite the increase in storage overhead.

Optimality of Optimal-LRC. Despite its optimal properties, our analysis reveals that for a given (n,k,r), Optimal-LRC does not always achieve the lowest NRC. Optimal-LRC is designed to accommodate the global parities with the data blocks in the same group. However, when the number of global parities is much smaller than r, this results in increasing the size of one of the groups, thus increasing the NRC. For example, Figure 10 shows a (12,8,5) Azure-LRC whose NRC is lower than that of (12,8,5) Optimal-LRC, and a (16,10,6) Azure-LRC+1 whose NRC is lower than that of (16,10,6) Optimal-LRC. In both cases, Optimal-LRC can achieve a lower NRC with a smaller r, possibly at the cost of reducing d.

NRC vs. d. Our results demonstrate a subtle tradeoff between repair cost (NRC) and d. Codes with the same (n,k,r) may or may not have the same d, and are thus not directly comparable: one may satisfy fault tolerance requirements that the other does not. To facilitate a more systematic comparison, we defined another composite metric, *repair-distance ratio (rd-ratio)*, $\frac{NRC}{d}$. This can be viewed as a measure of the efficiency with which a code allocates its local parities, with the conflicting objectives of maximizing d and minimizing *NRC*.

Figure 11 shows the *rd*-ratio of all LRCs. It shows that the code with the lowest *rd*-ratio is different for different (n,k,r) combinations, and is not necessarily a full-LRC. For example, when (n,k,r) is (14,10,5), Azure-LRC has the lowest *rd*-ratio. Another interesting observation is that when fixing n and k, different codes achieve their minimal *rd*-ratio with different values of r. For example, the *rd*-ratio of (17,12,5) Optimal-LRC is lower than that of (17,12,4) Optimal LRC. When we fix (n,k) and consider the "best" r for each code, we observe that Optimal-LRC achieves the lowest *rd*-ratio. This demonstrates that this code is optimal in its allocation of local parity blocks—it efficiently reduces the repair cost with minimal reduction in d. The *rd*-ratio can be generalized to reflect different weights of NRC and d, e.g., by defining it as $\frac{NRC}{d^x}$.

Target fault tolerance. The required fault tolerance in a distributed storage system is determined by many factors, including the number of nodes, their organization into racks and clusters, and the anticipated causes of failure. Nevertheless, once the required level of fault tolerance is determined, the goal is to select a code which will provide this level at the lowest cost. In this context,

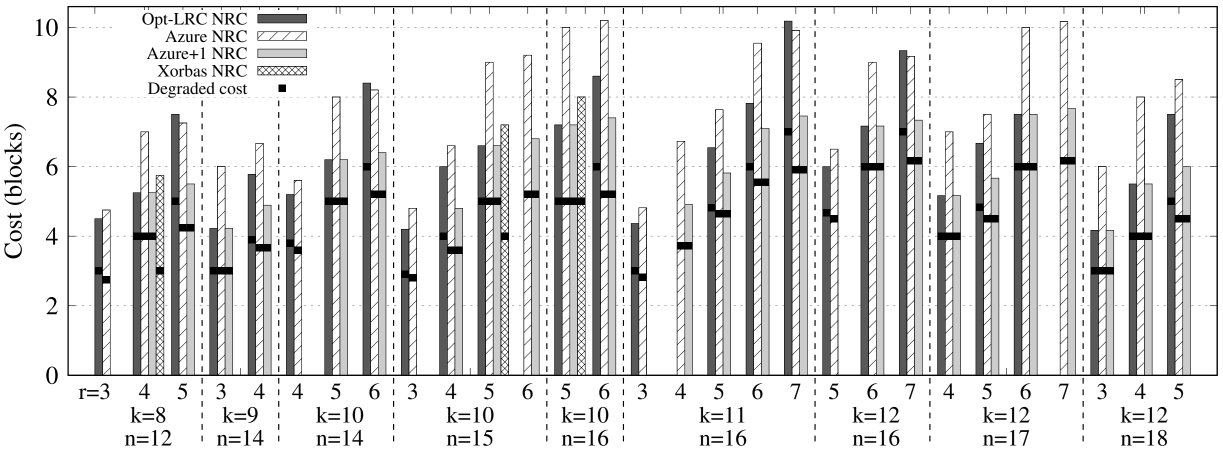

Figure 7: NRC and the degraded cost for all the codes in our evaluation. The repair cost of the full-LRCs is always lower than that of Azure-LRC.

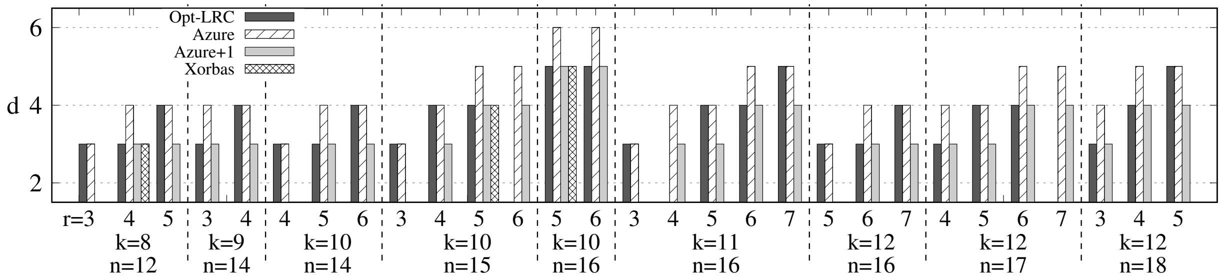

Figure 8: *d* for all the codes in our evaluation.

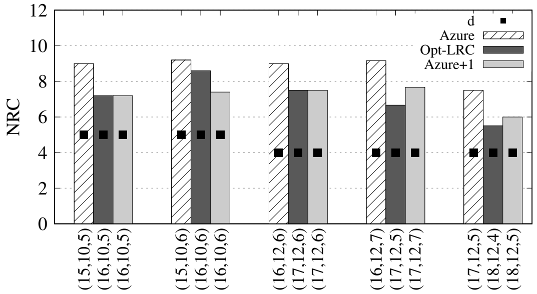

Figure 9: NRC for (n,k,r) Azure-LRC and $(n+1,k,r)$ Azure-LRC+1 and Optimal-LRC. Adding a local parity always reduces repair cost, despite the increase in overhead.

the code with the lowest *rd*-ratio may not be the optimal choice—a different code may have a higher ratio but provide the required level of fault tolerance at a lower overhead or repair cost.

We defined a threshold value of d, d_{th}, and compared the NRC of all the codes for which $d \geq d_{th}$. We considered $d_{th} \in \{3,4,5\}$, corresponding to the minimum distance of commonly deployed configurations. Figure 12 shows the NRC of all the LRCs whose $d \geq 4$. Many constructions do not provide the required fault tolerance, and are thus absent from this figure. Different codes achieved the lowest NRC for different k,n combinations. However, we note that a construction of Azure-LRC and Optimal-LRC with the required d was defined for every k,n combination. This demonstrates the flexibility of both codes. We observed similar results when setting the threshold d_{th} to 3 or 5, where increasing the threshold removed more codes from the comparison, and vice versa.

Our theoretical evaluation results demonstrate the challenges in comparing different LRC codes and approaches. Our metrics, NRC, degraded cost, and *rd*-ratio, provide a framework for directly comparing all codes in all parameter combinations. Our comparison demonstrates the benefit of full-LRCs, the flexibility of Optimal-LRC, and the realistic settings in which they may reduce the amount of data read and thus the system repair cost. In the following, we extend our notion of 'repair cost' to additional performance measures.

5 System-Level Evaluation Setup

The goal of our system-level evaluation was threefold: to validate the accuracy of NRC when predicting the amount of data read for node reconstruction, to evaluate its ability to estimate repair time and bandwidth, and to compare the recovery efficiency of the different LRCs in a real system. We omitted the minimum distance, d, from this part of our analysis, because it is not measured empirically. We focused on four representative (n,k) combinations, and compared Reed-Solomon codes, Azure-LRC, Azure-LRC+1, and Optimal-LRC in these setups. We excluded Xorbas from this part of our analysis due to design limi-

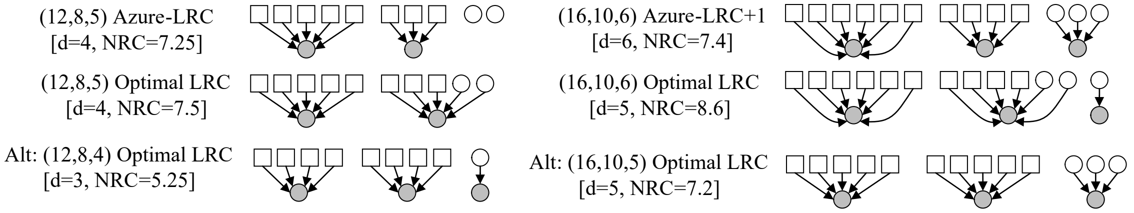

Figure 10: Examples where (n,k,r) Optimal-LRC does not achieve the lowest NRC. In both cases, an alternative $(n,k,r-1)$ Optimal-LRC achieves a lower NRC, possibly at the cost of reducing d.

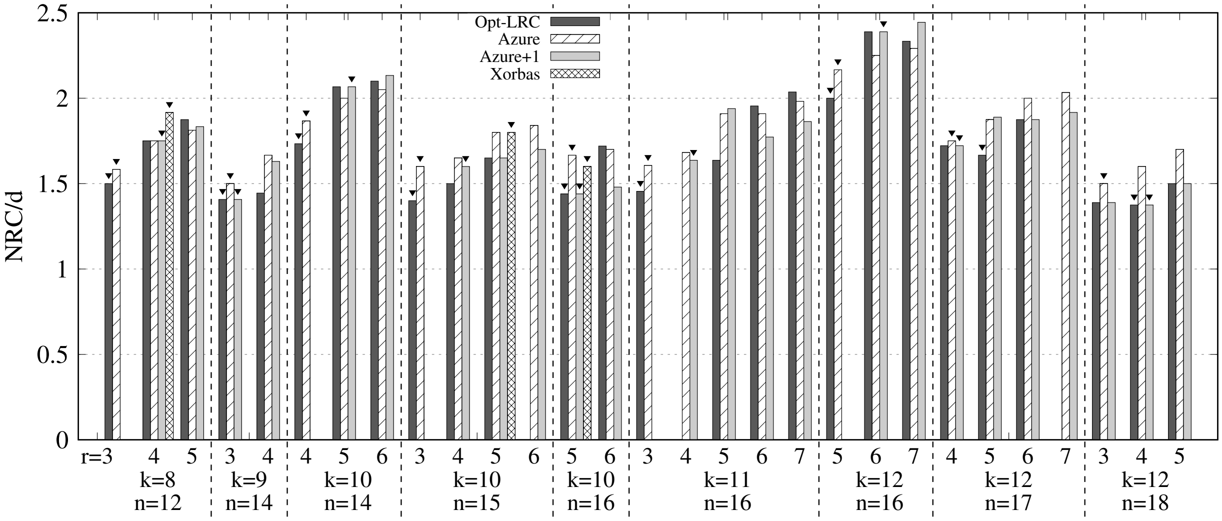

Figure 11: Repair-distance ratio ($\frac{NRC}{d}$). For each (n,k), different codes achieve their minimal rd-ratio (marked by the small triangle) with different values of r.

tations described below.

We performed our evaluation in Ceph—a distributed open-source storage system [34]. Ceph's object storage service, RADOS [36], is responsible for object placement, failure detection and failure recovery. Ceph's nodes are called *object storage devices (OSDs)*. Objects in Ceph are assigned to *placement groups*, which define the allocation of blocks to OSDs. The mapping of placement groups to OSDs is implemented by a pseudo-random mechanism, CRUSH, to ensure load balancing [35].

The *primary OSD* in each placement group is responsible for encoding the data and distributing the data and parity blocks to the remaining, *secondary*, OSDs. When one of the OSDs in a placement group fails, a *replacement OSD* is assigned to it. The primary OSD is responsible for reading the required data from the surviving OSDs, reconstructing the missing block, and sending it to the replacement OSD for permanent storage.

Ceph's design imposes certain limitations on our evaluation. When the failed OSD and the primary OSD belong to different *locality groups*, the repair data must be transferred across groups. In complex network topologies, this might incur cross-rack or cross-zone traffic that LRCs were designed to avoid. In addition, degraded reads are currently implemented by reconstructing the entire object at the primary OSD. This means that all k data blocks are read, even if only r blocks are required to repair the missing block. As a result, for degraded reads, there is no observable difference between MDS codes and LRCs.

We chose to use Ceph despite these limitations. As far as we know, it is the only open-source distributed storage system that implements LRCs as part of its main distribution. Furthermore, at the time we began this research, it was the only system to support online erasure coding, without requiring that objects are first replicated and then erasure-coded in the background.

LRC plugin. In Ceph, erasure codes are implemented as plugins. We used the Jerasure Erasure Code plugin [4], which contains an implementation of Reed-Solomon based on the Jerasure [21] and GF-Complete [20] libraries. We used the Locally Repairable Erasure Code plugin (LRC plugin) [5] to implement Azure-LRC and Azure-LRC+1[1]. This plugin first attempts to reconstruct the missing blocks from the surviving blocks in its locality group. If the block does not belong to any group, or if other blocks in the group are unavailable, it will be reconstructed from the global parities.

We made two adjustments in the LRC plugin. First,

[1] Ceph's LRC plugin actually implements Pyramid codes, and not Azure-LRC. However, the data read by these two codes in all single-node failure scenarios is identical. The precise parity calculations and fault tolerance of Azure-LRC are outside the scope of this study.

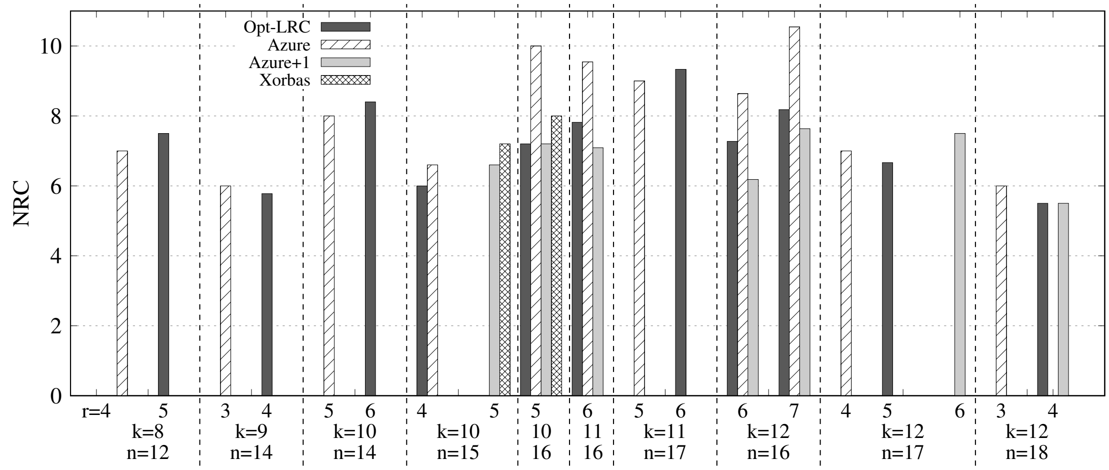

Figure 12: NRC of codes with $d \geq 4$. Azure-LRC and Optimal-LRC are the most flexible codes, defined for all (k,n) combinations.

we prevented CRUSH from rebalancing the placement groups after a node failure. This prevented the primary OSD from reading data that was not strictly required for repair. Second, we adjusted the LRC plugin to read the minimum amount of required blocks for recovery with global parities. The original implementation greedily reads *all* the remaining blocks in the stripe, which artificially increased the repair cost.

Optimal-LRC implementation. We implemented the encoding in Optimal-LRC as a multiplication by a $k \times n$ generator matrix created from the polynomial described in [13]. When creating the matrix, we transformed the k columns corresponding to the data blocks to ensure *systematic encoding* in which the data blocks are not encoded and are stored on the storage nodes in their original form. We further optimized the generator matrix to ensure that the decoding process of local recovery would consist only of XOR operations, avoiding finite field operations. We used Matlab to construct the generator matrix for each (n,k,r) Optimal-LRC in our evaluation.[2]. Beyond these initial calculations, the encoding and decoding processes of Optimal-LRC are equivalent to those of the original Ceph LRC implementation. The differences in encoding and decoding complexities are negligible compared to the I/O and network times of a large-scale storage system [6, 11, 12, 15, 19]. Similarly, there is no significant difference in the overhead of their implementation and metadata storage and maintenance.

Amazon EC2 deployment. We deployed our Ceph cluster on 20 instances in the Amazon Elastic Compute Cloud (EC2). We used `t2.medium` instances, each equipped with two Intel Xeon processors and 4GiB RAM [2]. We allocated two storage volumes to each instance, and used them to initialize two OSDs, resulting in a cluster of 40 OSDs. An additional `t2.2xlarge` instance hosted the monitor, metadata server, and client.

EC2 data centers belong to different *regions*, which correspond to distinct geographical locations. Each region contains several *availability zones*, which are connected by low latency links and guarantee failure tolerance within the region [3]. We deployed our cluster in a single availability zone in the Frankfurt region in all experiments except the multi-zone one. Unless stated otherwise, we use General Purpose SSD as storage devices [1].

In our basic "node repair" experiment, we populated the cluster with 200GB of data, written as 64MB objects. These objects are distributed across 512 placement groups. Thus, each OSD stored, on average, 5GB of data, and additional parity blocks according to the evaluated code. We killed one OSD daemon on one instance and removed this OSD from the cluster. This initialized the repair process, which was performed by the primary OSD in each affected placement group. We recorded the amount of data read from each device and the CPU utilization of each instance, until the full recovery of the cluster. We describe variations of this experiment with foreground workload and with slower storage below.

6 Results

Amount of data read and transferred. Figure 13 shows the number of blocks read by each code during repair, normalized to the number of data blocks on the failed OSD. We also present the ARC and NRC of each code, for comparison. We use an (n,k) Reed-Solomon in each configuration as our baseline. The results show the considerable reduction in repair cost achieved by LRCs, and that full-LRCs achieve a larger reduction, as shown in our theoretical evaluation.

For a given (n,k,r) combination, both ARC and NRC can predict which code will incur the the highest and lowest repair costs. At the same time, they are both inaccurate in their prediction of the actual repair cost. The reason for this inaccuracy is different for each metric. ARC in-

[2] Our implementation of Optimal-LRC in Ceph and its construction in Matlab will be made available as open-source projects.

Code	ARC	Adjusted ARC	NRC	Adjusted NRC	Data read	Time (s)
(13,10) RS	10	10	13	13	11.71	89
(14,10,5) Azure	5.71 (0.57)	5.5 (0.55)	8 (0.62)	7.7 (0.59)	6.74 (0.58)	59 (0.66)
(14,10,6) Azure	5.85 (0.58)	5.6 (0.56)	8.2 (0.63)	7.84 (0.6)	6.86 (0.59)	57 (0.64)
(15,10,5) Azure+1	4.4 (0.44)	4.5 (0.45)	6.6 (0.51)	6.75 (0.52)	5.96 (0.51)	57 (0.64)
(15,10,6) Azure+1	4.53 (0.53)	4.59 (0.46)	6.8 (0.52)	6.88 (0.53)	6.08 (0.52)	57 (0.64)

Table 1: Adjusted ARC and NRC according to block distribution on the failed OSD. The adjusted NRC corresponds to the actual amount of data read for recovery. The values in parenthesis show the costs normalized to Reed-Solomon with the same *k* and *d*.

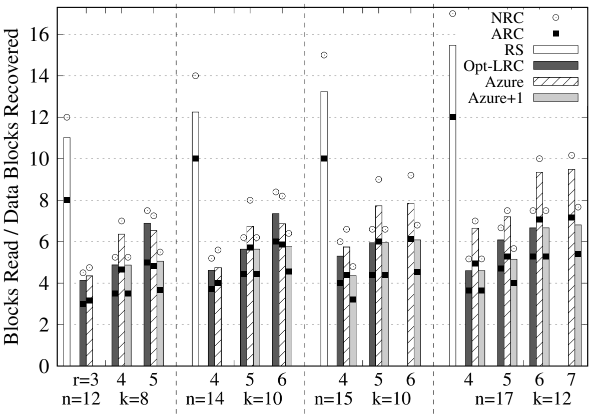

Figure 13: The number of average read blocks per data block repaired, compared to expected ARC and NRC.

herently underestimates the absolute cost, because it does not take into account the code's overhead. As a result, it is not useful for comparing codes with different storage overheads. For example, the ARC of (14,10) Reed-Solomon and (15,10) Reed-Solomon is 10 for both, but they read 12.53 and 13.24 blocks per data block recovered, respectively.

The inaccuracy of NRC is the result of our limited evaluation setup. Although CRUSH attempts to uniformly distribute data and parity blocks on all OSDs, its mapping is deterministic, and the actual distribution with 40 OSDs is not perfectly uniform. As a result, some OSDs store more blocks than others, and the percentage of data and parity blocks on each OSD is different. We verified that this is the cause of the inaccuracy - by distinguishing between the blocks on the failed OSD according to the number of blocks required for their repair and observing that their percentage is different than expected. We adjusted the NRC and ARC in several setups according to the observed distribution, although we still assumed 5GB of data on each OSD[3].

Table 1 shows the detailed metric and results for Reed-Solomon, Azure-LRC, and Azure-LRC+1, when $k = 10$, and $d = 4$. The required storage overhead is different for each code, which makes it difficult to directly compare their repair costs. The mapping of OSDs to placement groups is also different for each *n*. The table shows the calculated and the adjusted ARC and NRC of all codes,

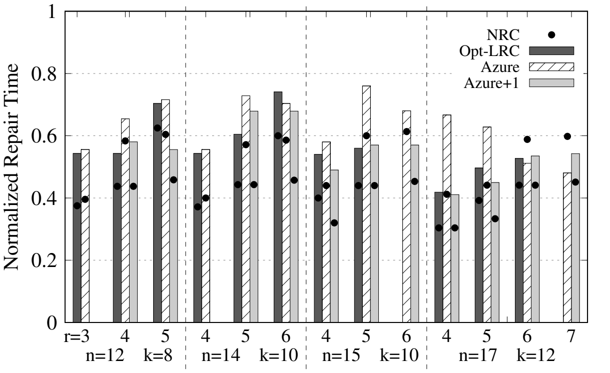

Figure 14: Recovery time of LRCs normalized to Reed-Solomon with the same *k* and *n*.

with the repair cost of each LRC compared to that of Reed-Solomon in parenthesis. The adjusted NRC provides a fairly accurate prediction of the amount of data read for recovery (we discuss the recovery time below). This confirms that in a large-scale storage system with uniform block distribution, the NRC can accurately predict the average repair cost of an entire storage node.

The amount of data transferred between nodes was almost identical to the amount of data read. We verified that the differences were caused by the role of the primary OSD in the reconstruction process: when the primary stored one of the blocks required for reconstruction, it did not have to transfer this block to another OSD. On the other hand, the primary always had to transfer the reconstructed block to the replacement OSD. In light of this simple correlation, we omit the amount of data transferred from the rest of our discussion.

Repair time. Figure 14 shows the recovery time of LRCs normalized to Reed-Solomon with the same *k* and *n* (normalizing to Reed-Solomon with the same *d* yields equivalent results). Our results show that the reduction in the amount of data read for repair does not directly translate to a reduction in repair time. This is the result of additional bottlenecks in the system, such as queuing and batching delays. We verified that the CPU utilization is the same for all codes, ruling out encoding costs as a bottleneck. However, the I/O bandwidth utilized by the codes was slightly different. Reed-Solomon typically achieved a higher throughput than the LRCs—it reads considerably more data than the other codes, which allows it to saturate the storage devices. Thus, the reduction in repair time achieved by the LRCs was smaller than that predicted by NRC. Overall, the full-LRCs achieved the greatest reduc-

[3] Ceph does not report the number of data blocks stored on each OSD, and we could not distinguish between data blocks and local parity blocks because they require the same number of blocks for repair.

Code	NRC	SSD	Opt HDD	Cold HDD
Reed-Solomon	15	100	115	303
Azure-LRC	6.6 (0.44)	58 (0.58)	65 (0.56)	134 (0.44)
Azure-LRC+1	4.8 (0.32)	49 (0.49)	53 (0.46)	134 (0.44)
Optimal-LRC	6 (0.4)	54 (0.54)	57 (0.49)	143 (0.47)

Table 2: NRC of all codes and their recovery time in seconds. $n = 15$ and $k = 10$ for all codes and $r = 4$ for the LRCs, with the repair time normalized to Reed-Solomon in parentheses.

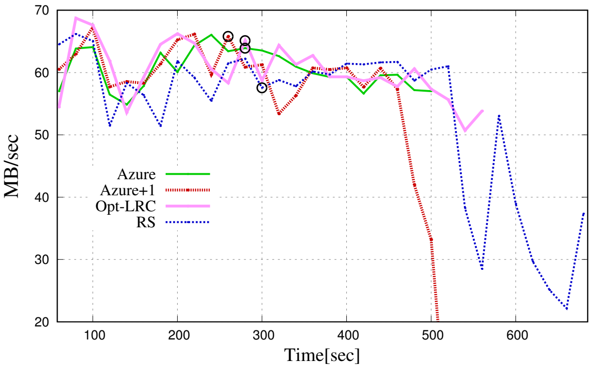

Figure 15: Throughput of RADOS benchmark during repair with LRC in (15,10,4) and RS(15,10).

tion in repair time.

Different storage types. LRCs reduce the amount of data read during recovery, and thus their benefit is expected to increase with the cost of storage I/O. We repeated our repair experiment for one configuration, replacing the SSD storage volumes with two types of hard drives, Optimized HDD and Cold HDD, with a maximum throughput of 500 and 250 IOPS, respectively [1]. The amount of data read from all storage types was the same. Table 2 shows the repair time, in seconds, for all the codes and storage types. As we expected, in the setups where the repair time of Reed-Solomon was longer, the reduction in repair time achieved by all LRCs was higher and closer to the reduction predicted by NRC.

Foreground workloads. Local repair is also designed to minimize the interference with application workloads running in the system at the time of failure. To evaluate this interference, we repeated the repair experiment with the (15,10,4) configuration, in which each LRC has a different NRC. We ran a Ceph benchmark called RADOS Bench [32], which writes objects for a given amount of time (220 seconds in our experiment), reads all the objects, and terminates. For this experiment, we increased the number of outstanding recovery requests allowed per OSD from 15 to 150. We killed one OSD 100 seconds after the benchmark started to read. The repair process took place while the benchmark was still reading the data, but the system recovered before the benchmark terminated.

Figure 15 shows the throughput of the benchmark's I/O requests during its read phase. The black circles mark the time at which recovery was fully completed, and the measurements continue until the benchmark terminates. The differences between the codes were smaller than we expected. This is the result of Ceph's restrictions on repair throughput, and of the high I/O parallelism of SSDs. Nevertheless, the results show that the different codes completed their repair in the order of their NRC: Azure-LRC+1 was the fastest and Reed-Solomon the slowest. The throughput reduction experienced by the benchmark was greatest with Reed-Solomon and smallest with the full-LRCs—Azure-LRC+1 and Optimal-LRC.

Multiple zones. The first LRCs were motivated by the goal of restricting the repair cost to the locality of the failed node. In production systems, this means that blocks in the same group are assigned to a group of nodes on the same rack or in the same zone of the datacenter [11]. To evaluate the different LRCs in a similar environment, we repeated the repair experiment when our instances were deployed on three availability zones in the same EC2 region (N. Virginia). In this experiment, we deployed six instances in each zone, with a total of 18 instances running 36 OSDs. To make up for the reduced I/O bandwidth within in each zone, we replaced the General Purpose SSDs with Provisioned IOPS SSDs, which increased the maximum IOPS per volume from 150 to 2500.

We edited the CRUSH map, instructing CRUSH to assign placement groups to OSDs such that groups are allocated in the same zone [35]. We also ensured that the primary OSD resides in the same zone as the failed OSD. We ran this experiment twice. In the first setup, both the primary OSD and the failed OSD belonged to a data group. In the second setup, both the primary OSD and the failed OSD belonged to a global-parity group.

For full-LRCs, both setups are equivalent: all blocks are reconstructed from blocks in the same group. For Reed-Solomon, all recovery scenarios follow the second setup: recovery requires blocks from different groups. For data-LRCs, data and local parity blocks are recovered according to the first setup, and global parities are recovered according to the second setup. We calculated the weighted average of these two setups to obtain the expected recovery time for each code.

We used (15,8,4) as our configuration, having excluded it from our previous analysis due to its high overhead. Nevertheless, it has the desirable property that all the groups in all codes have the same size (5). This ensures that all placement groups include the same number of OSDs in each zone. In this configuration, the full LRCs are equivalent in their distribution of data and parity blocks to groups. We use Azure-LRC+1 as our full-LRC in this experiment.

For comparison, we repeated this experiment with all OSDs in a single zone, but with the same restriction on the allocation of OSDs to groups. This setup eliminates the cross-zone network bottleneck, with I/O parallelism limited as in the three-zone experiment. Our baseline is

Code	NRC	Reads	1 zone		3 zones
			Baseline	3 groups	
Reed-Solomon	15	14.42	121	179	190
Azure-LRC	10	9.73	88 (0.73)	158 (0.88)	162 (0.85)
Azure-LRC+1	7.5	7.21	80 (0.66)	148 (0.82)	148 (0.78)

Table 3: Number of blocks read per lost data block and repair time when running on one zone and on three zones, with the repair time normalized to Reed-Solomon in parentheses.

the unrestricted setup we used in the rest of this section.

Table 3 shows the amount of data read and the weighted average of the repair time in this experiment. It shows that restricting the number of nodes that participate in the repair process significantly reduces its throughput. When all the OSDs are deployed in the same zone, this restriction increases the repair time by 48% to 85%. The increase is lower for Reed-Solomon because it can still utilize twice as many OSDs than the LRCs. The addition of the cross-zone network bottleneck further reduces the repair time of Reed-Solomon (by 6%) and of Azure-LRC (by 2.5%), but does not affect Azure-LRC+1 which does not incur any cross-zone transfers for repair.

These results demonstrate the well-known tradeoff between I/O parallelism and locality. They confirm that data-LRCs and full-LRCs are expected to achieve the highest benefit in large-scale deployments, where sufficient I/O parallelism can be achieved within a single zone.

7 Related Work

Efforts to reduce the repair cost can be classified into two main lines of research: LRCs, which attempt to reduce the repair cost by reducing the number of nodes participating in the repair process [8, 10, 11, 17, 28], and Regenerating Codes, which strive to attain the same goal by reducing the network bandwidth utilized during repair [6, 24, 25].

The benefits of codes with locality were first realized in [10] before the actual notion was isolated into a standalone concept in the information-theory community [8]. The basic code construction of Pyramid codes [10] assumes that a global parity relation of an MDS code is subdivided into two (or more) local parity check equations which can be used for local repair. Importantly, this work indicated possible savings in repair cost, thereby propelling further research on LRC codes.

In particular, [11] developed LRC codes and observed substantial savings in the repair cost of Microsoft Azure storage attained by using them, and [8] developed the coding-theoretic side of the notion of LRCs. Another relevant work [37] builds on Azure-LRC to dynamically adjust the system's overall storage overhead and average recovery speed by migrating hot and cold data to arrays with more or fewer parity nodes, respectively. Finally, a family of non-MDS codes called Sector Disk codes [15, 19] addresses the recovery of a failed block within an otherwise healthy node. The codes constructed in these works add parity blocks that allow efficient recovery of bad hard-disk sectors or SSD blocks. The above codes were implemented and evaluated independently of one another. Our study is the first to present a comparative framework for codes designed with different properties and overheads, and for different sets of parameters.

Minimum storage regenerating (MSR) codes [6,25] are a class of MDS codes designed to optimize recovery network bandwidth rather than the number of accessed storage devices. MSR codes and related families, such as RotatedRS [12], Hitchhiker-XOR [23], Butterfly [7] and Zigzag [31] codes, divide each data and parity block into smaller chunks, such that only a subset of each block's chunks are required for the repair of a failed node. Paper [22] constructs an MSR code that reduces the amount of data read from some of the surviving nodes but is applicable only for clusters with $n = 2 \times k$. These codes reduce the *rebuilding ratio*—the portion of the surviving nodes' data that must be read during recovery. All MDS codes with the same d have the same overhead, and can be directly compared by their rebuilding ratio. However, this metric is also limited in its ability to predict recovery costs in a real system: these costs depend on the granularity of the non-sequential I/O accesses incurred when reading arbitrary chunks from each block [18].

Alternative approaches reduce recovery costs of existing codes. An approach introduced in [33] and developed in [9] considers linear repair schemes of Reed-Solomon codes for reducing their network repair bandwidth. *Repair pipelining* improves the utilization of the network bandwidth of all nodes participating in the recovery [16]. *Lazy repair* delays node recovery to amortize its costs over more than one failure [29]. This reduces the fault tolerance of the system, which is equivalent to reducing d. LSTOR relies on attached non-volatile memory for caching additional parity blocks [27], effectively increasing the storage overhead of the system. Our comparative framework, using NRC, can also be extended to evaluate the above approaches.

8 Conclusions

In this study, we performed the first systematic comparison of full-LRCs and data-LRCs. To that end, we implemented a new full-LRC, Azure-LRC+1, and extended and implemented Optimal-LRC for a comparison covering a wide range of system parameters. We demonstrated the limitations of existing metrics and introduced NRC—a new metric that successfully models full-node repair cost. Our theoretical analysis demonstrated the non-trivial correlation between NRC and the cost of degraded reads, and the tradeoff between them and the code's fault tolerance. Our evaluation in a Ceph cluster on Amazon EC2 further showed how this benefit of full-LRCs and data-LRCs depends on the underlying storage devices, network topology, and foreground application load.

TxFS: Leveraging File-System Crash Consistency to Provide ACID Transactions

Yige Hu[1], Zhiting Zhu[1], Ian Neal[1], Youngjin Kwon[1], Tianyu Cheng[1]

[1]*University of Texas at Austin* [2]*VMware Research*

Abstract

We introduce TxFS, a novel transactional file system that builds upon a file system's atomic-update mechanism such as journaling. Though prior work has explored a number of transactional file systems, TxFS has a unique set of properties: a simple API, portability across different hardware, high performance, low complexity (by building on the journal), and full ACID transactions. We port SQLite and Git to use TxFS, and experimentally show that TxFS provides strong crash consistency while providing equal or better performance.

1 Introduction

Modern applications store persistent state across multiple files [21]. Some applications split their state among embedded databases, key-value stores, and file systems [27]. Such applications need to ensure that their data is not corrupted or lost in the event of a crash. Unfortunately, existing techniques for crash consistency, such as logging or using atomic rename, result in complex protocols and subtle bugs [21].

Transactions present an intuitive way to atomically update persistent state [6]. Unfortunately, building transactional systems is complex and error-prone. In this paper, we introduce a novel approach to building a transactional file system. We take advantage of a mature, well-tested piece of functionality in the operating system: the file-system journal, which is used to ensure atomic updates to the internal state of the file system. We use the atomicity and durability provided by journal transactions and leverage it to build ACID transactions available to user-space transactions. Our approach greatly reduces the development effort and complexity for building a transactional file system.

We introduce TxFS, a transactional file system that builds on the ext4 file system's journaling mechanism. We designed TxFS to be practical to implement and to use. TxFS has a unique set of properties: it has a small implementation (5,200 LOC) by building on the journal (for example, TxFS has 25% the LOC of the TxOS transactional operating system [22]); it provides high performance unlike various solutions which built a transactional file system over a user-space database [5, 16, 18, 31]; it has a simple API (just wrap code in `fs_tx_begin()` and `fs_tx_commit()`) compared to solutions like Valor [28] or TxF [24] which require multiple system calls per transaction and can require the developer to understand implementation details like logging; it provides all ACID guarantees unlike solutions such as CFS [15] and AdvFS [30] which only offer some of the guarantees; it provides transactions at the file level instead of at the block level unlike Isotope [26], making several optimizations easier to implement; finally, TxFS does not depend upon specific properties of the underlying storage unlike solutions such as MARS [3] and TxFlash [23].

The advantage to building TxFS on the file-system journal is that TxFS transactions obtain atomicity, consistency, and durability by placing each one entirely within a single file-system journal transaction (which is applied atomically to the file system). Using well-tested journal code to obtain ACD reduces the implementation complexity of TxFS, while limiting the maximum size of transactions to the size of the journal.

The main challenge of building TxFS is providing isolation. Isolation for TxFS transactions requires that in-progress TxFS transactions are not visible to other processes until the transaction commits. At a high level, TxFS achieves isolation by making private copies of all data that is read or written, and updating global data during commit. However, the naive implementation of this approach would be extremely inefficient: global data structures such as bitmaps would cause conflicts for every transaction, causing high abort rates and excessive transaction retries. TxFS makes concurrent transactions efficient by collecting logical updates to global structures, and applying the updates at commit time. TxFS includes a number of other optimizations such as eager conflict detection that are tailored to the current implementation of file-system data structures in ext4.

We find that the transactional framework allows us to easily implement a number of file-system optimizations. For example, one of the core techniques from our earlier work, separating ordering from durability [2], is easily accomplished in TxFS. Similarly, we find TxFS transactions allow us to identify and eliminate redundant application IO where temporary files or logs are used to atomically update a file: when the sequence is simply enclosed in a transaction (and without any other changes), TxFS atomically updates the file (maintaining functionality) while eliminating the IO to logs or temporary files (provided the temporary files and logs are deleted inside the transaction). As a result, TxFS improves performance while simultaneously providing better crash-consistency semantics: a crash does not leave ugly temporary files or logs that need to be cleaned up.

To demonstrate the power and ease of use of TxFS transactions, we modify SQLite and Git to incorporate TxFS transactions. We show that when using TxFS transactions, SQLite performance on the TPC-C benchmark improves by 1.6× and a micro-benchmark which mimics Android Mail obtains 2.3× better throughput. Using TxFS transactions greatly simplifies Git's code while providing crash consistency without performance overhead. Thus, TxFS transactions increase performance, reduce complexity, and provide crash consistency.

Our paper makes the following contributions.

- We present the design and implementation of TxFS, a transactional file system for modern applications built by leveraging the file-system journal (§3). We have made TxFS publicly available at `https://github.com/ut-osa/txfs`.
- We show that existing file systems optimizations, such as separating ordering from durability, can be effectively implemented for TxFS transactions (§4).
- We show that real applications can be easily modified to use TxFS, resulting in better crash semantics and significantly increased performance (§5).

2 Background and motivation

We first describe the protocols used by current applications to update state in a crash-consistent manner. We then present a study of different applications and the challenges they face in maintaining crash consistency across persistent state stored in different abstractions. We describe the file-system optimizations enabled by transactions and finally summarize why we think transactional file systems should be revisited.

2.1 How applications update state today

Given that applications today do not have access to transactions, how do they consistently update state to multiple storage locations? Even if the system crashes or power fails, applications need to maintain invariants across state in different files (*e.g.,* an image file should match the thumbnail in a picture Gallery). Applications achieve this by using ad hoc protocols that are complex and error-prone [21].

In this section, we show how difficult it is to implement seemingly simple protocols for consistent updates to storage. There are many details that are often overlooked, like the persistence of directory contents. These protocols are complex, error prone, and inefficient. With current storage technologies, these protocols must sacrifice performance to be correct because there is no efficient way to order storage updates.

```

write(/dir/db)
fsync(/dir/db)
unlink(/dir/journal)
fsync(/dir/)
```

(c) Atomically adding a email message with attachments in Android Mail

Figure 1: Different protocols used by applications to make consistent updates to persistent data.

Currently, applications use the `fsync()` system call to order updates to storage [2]; since `fsync()` forces durability of data, the latency of a `fsync()` call varies from a few milliseconds to several seconds. As a result, applications do not call `fsync()` at all the places in the update protocol where it is necessary, leading to severe data loss and corruption bugs [21].

We now describe two common techniques used by applications to consistently update stable storage. Figure 1 illustrates these protocols.

Atomic rename. Protocol (a) shows how a file can be updated via atomic rename. The atomic rename approach is widely used by editors, such as Emacs and Vim, and by GNOME applications that need to atomically update dot configuration files. The application writes new data to a temporary file, persists it with an `fsync()` call, updates the parent directory with another `fsync()` call, and then renames the temporary file *over* the original file, effectively causing the directory entry of the original file to point to the temporary file instead. The old contents of the original file are unlinked and deleted. Finally, to ensure that the temporary file has been unlinked properly, the application calls `fsync()` on the parent directory.

Logging. Protocol (b) shows another popular technique for atomic updates, logging [8] (either write-ahead-logging or undo logging). The log file is written with new contents, and both the log file and the parent directory (with the new pointer to log file) are persisted. The application then updates the original file and persists the original file; the parent directory does not change during this step. Finally, the log is unlinked, and the parent directory is persisted.

The situation becomes more complex when applications store state across multiple files. Protocol (c) illustrates how the Android Mail application adds a new email with an attachment. The attachment is stored on the file system, while the email message (along with metadata) is stored in the database (which for SQLite, also resides on the file system). Since the database has a pointer to the attachment (i.e., a file name), the attachment must be persisted first. Persisting the attachment requires two `fsync()` calls (to the file and its containing directory) [1, 21]. SQLite's most performant mode uses write-ahead-logging to atomically update the database. It then follows a protocol similar to Protocol (b).

Removing `fsync()` calls in any of the presented protocols will lead to data loss or corruption. For instance, in Protocol (b), if the parent directory is not persisted with an `fsync()` call, the following scenario could occur: the application writes the log file, and then starts overwriting the original file in place. The system crashes at this point. Upon reboot, the log file does not exist, since the directory entry pointing to the log file was not persisted. Thus, the application file has been irreversibly partially edited, and cannot be restored to a consistent version. Many application developers avoid `fsync()` calls due to the resulting decrease in performance, leading to severe bugs that cause loss of data.

Safe update protocols for stable storage are complex and low performance (*e.g.,* Android Mail uses *six* `fsync()` calls to persist a single email with an attachment). System support for transactions will provide high performance for these applications.

2.2 Application case studies

We now present four examples of applications that struggle with obtaining crash consistency using primitives available today. Several applications store data across the file system, key-value stores, and embedded databases such as SQLite [27]. While all of this data ultimately resides in the file system, their APIs and performance constraints are different and consistently updating state across these systems is complex and error-prone.

Android mail. Android's default mail application stores mail messages using the SQLite embedded database [29]. Mail attachments are stored separately as a file, and the database stores a pointer to the file. The user requires both the file and the database to be updated atomically; SQLite only ensures the database is updated correctly. For example, a crash could leave the database consistent, but with a dangling pointer to a missing attachment file. The mail application handles this by first persisting the attachment (via `fsync()`), and then persisting a database transaction. Clearly, this harms performance – a transaction that spans both the database and the file system would need to persist data only at a single commit point.

Apple iWork and iLife. Analysis of the storage behavior of Apple's home-user, desktop applications [9] finds that applications use a combination of the file system, key-value stores, and SQLite to store data. iTunes uses SQLite to store metadata similar to the Android Mail application. When you download a new song via iTunes, the sound file is transferred and the database updated with the song's metadata. Apple's Pages application uses a combination of SQLite and key-value stores for user preferences and other metadata (two SQLite databases and 128 `.plist` key-value store files). Similar to Android Mail, Apple uses `fsync()` to order updates correctly.

Browsers. Mozilla Firefox stores user data in multiple SQLite databases. For example, addons, cookies, and download history are each stored in their separate SQLite database. Since downloads and other files are stored on the file system, a crash could leave a database with a dangling pointer to a missing file.

Version control systems. Git and Mercurial are widely-used version control systems. The `git commit` command requires two file-system operations to be atomic: a file append (`logs/HEAD`) and a file rename (to a lock file). Failure to achieve atomicity results in data loss and a corrupted repository [21]. Mercurial uses a combination of different files (`journal, filelog, manifest`) to consistently update state. Mercurial's `commit` command requires a long sequence of file-system operations including file creations, appends, and renames be atomic; if not, the repository is corrupted [21].

For these applications, transactional support would lead directly to more understandable and more efficient idioms. It is difficult for a user-level program to provide crash-consistent transactional updates using the POSIX file-system interface. A transactional file-system interface will also enable high-performance idioms like editors grouping updates into transactions rather than the less efficient process they currently use of making temporary file copies that are committed via `rename`.

Note that applications that use temporary files and techniques like atomic rename do achieve crash consistency; however, after a crash there may be temporary files which need to be cleaned up. After a crash, the application runs a recovery procedure and returns to a consistent state. Often, the "recovery procedure" forces a human user to look for and manually delete stale files. A transactional file system does not provide *new* crash-consistency guarantees for these applications; rather, transactional file systems remove the burden of recovery and cleanup, simplifying the application and eliminating bugs [21].

2.3 Optimizing transactions

A transactional file-system interface enables a number of interesting file-system optimizations. We now describe a few of them.

Eliminate temporary durable files. A number of applications such as Vim, Emacs, Git, and LevelDB provide reasonable crash semantics (*i.e.,* the user sees either the old version or the new version after an update) by making a temporary copy of a file, editing it, then renaming it atomically to the permanent name when the user updates data. The application can simply enclose its writes inside a transaction, avoiding the copy. For large files, the difference in performance can be significant. In addition, the file system will not be cluttered with temporary files in the event of a crash.

Group commit. Transactions buffer related file-system updates in memory, which can all be sent to the storage device at once. Batching updates is often more efficient, enabling efficient allocation of file-system data structures and better device-level scheduling. Without user-provided transaction boundaries, the file system provides uniform, best-effort persistence for all updates.

Eliminate redundant IO *within* transactions. Workloads often contain redundancy; for example, files are often updated several times at the same offset, or a file is created, written, read, and unlinked. Transaction boundaries allow the file system to eliminate some of this redundant work because the entire transaction is visible to the file system at commit time, which enables global optimization.

Consolidate IO *across* transactions. Transactions often update data written by prior transactions. When a workload anticipates data in its transaction will be updated by another transaction shortly, it can prioritize throughput over latency. Committing a transaction with a special flag allows the system to delay a transaction commit, anticipating that the data will be overwritten, and then it can be persisted once instead of twice. Note that consolidating IO in this manner is different from eliminating redundant IO within a transaction; this optimization operates across multiple transactions. Optimizing multiple transactions, especially from different applications, is best done by the operating system, not by an individual application. This non-work conserving strategy is similar to the anticipatory disk scheduler [12].

Separate ordering from durability. When ending a transaction, the programmer can specify if the transaction should commit durably. If so, the call blocks until all updates specified by the transaction have been written to a persistent journal. If we commit non-durable transaction A and then start non-durable transaction B, then A is ordered before B, but neither is durable. A subsequent transaction (*e.g.,* C), can specify that it and all previous transactions should be made durable. In this way we can use transactions to gain much of the benefit of splitting `sync` into ordering sync (`osync`), and durability sync (`dsync`) [2].

In summary, we believe transactional file systems should be revisited for two reasons. First, applications routinely store persistent state in multiple files and across different storage systems such as databases and key-value stores, and maintaining crash consistency of this state using techniques such as atomic rename results in complexity and bugs. Second, using a transactional API enables the file system to provide a number of optimizations that would be significantly harder to introduce in a non-transactional file system.

3 TxFS Design and implementation

We now present the design and implementation of TxFS. TxFS avoids the pitfalls from earlier transactional file systems (§6): it has a simple API; provides complete ACID guarantees; does not depend on specific hardware; and takes advantage of the file-system journal and how the kernel is implemented to achieve a small implementation (≈5,200 LOC).

3.1 API

A simple API was one of the key goals of TxFS. Thus, TxFS provides developers with only three system calls: `fs_tx_begin()`, which begins a transaction; `fs_tx_commit()`, which ends a transaction and attempts to commit it; and `fs_tx_abort()`, which discards all file-system updates contained in the current transaction. On commit, all file-system updates in an application-level transaction are persisted in an atomic fashion – after a crash, users see all of the transaction updates, or none of them. This API significantly simplifies application code and provides clean crash semantics, since temporary files or partially written logs will not need to be cleaned up after a crash.

`fs_tx_commit()` returns a value indicating whether the transaction was committed successfully, or if it failed, why it failed. A transaction can fail for three reasons: there was a conflict with another concurrent transaction, there is no journal space for the transaction, or the file system does not have enough resources for the transaction to complete (no space or inodes). Depending upon the error code, the application can choose to retry the transaction. Nested TxFS transactions are flattened into a single transaction, which succeed or fail as a unit. Flat nesting is a common choice in transactional systems [22, 28].

A user can surround any sequence of file-system related system calls with `fs_tx_begin()` and `fs_tx_commit()` and the system will execute those system calls in a single transaction. This interface is easy for programmers to use and makes it simple to incrementally deploy file-system transactions into existing applications. In contrast, some transactional file systems (*e.g.,* Window's TxF [24] and Valor [28]) have far more complex, difficult-to-use interfaces. TxF assigns a handle to each transaction, and requires users to explicitly call the transactional APIs with the handle. Valor exposes operations on the kernel log to user-level code.

TxFS isolates file-system updates only. The application is still responsible for synchronizing access to its own user-level data structures. A transactional file system is not intended to be an application's sole concurrency control mechanism; it only coordinates file-system updates which are difficult to coordinate without transactions.

3.2 Atomicity and durability

Most modern Linux file systems have an internal mechanism for atomically updating multiple blocks on storage. These mechanisms are crucial for maintaining file-system crash consistency, and thus have well-tested and mature implementations. TxFS takes advantage of these mechanisms to obtain three of the ACID properties: atomicity, consistency, and durability. This is the key insight which allows TxFS to have a small implementation.

TxFS builds upon the ext4 file system's journal. The journal provides the guarantee that each journal transaction is applied to the file system in an atomic fashion. We could have instead used a different mechanism such as copy-on-write [10] which provides the same guarantee in btrfs and F2FS. TxFS can be built upon any file system with a mechanism for atomic updates.

For each TxFS transaction, TxFS maintains a private `jbd2` transaction, and at commit, merges the private transaction into the global `jbd2` transaction. While the global `jbd2` transaction contains only metadata by default, TxFS also adds data blocks to the transaction to ensure atomic updates. If, by chance, a block added to the private `jbd2` transaction is also being committed by a previous global `jbd2` transaction, TxFS creates a shadow block. Ext4 also creates a shadow block when a block is shared between a running and a committing transaction. TxFS employs selective data journaling [2], only journaling data blocks that were already allocated (*i.e.,* data blocks that are being updated), and avoids journaling newly allocated data blocks (because it can write them directly). Selective data journaling provides the same guarantees as full data journaling at a fraction of the cost.

TxFS ensures that an entire transaction can be merged into a *single* journal transaction; otherwise, an error is returned to the user. As long as a TxFS transaction is added to a single journal transaction, the journal will ensure it is applied to the file system atomically. After merging a user's transaction into the journal transaction, TxFS persists the journal transaction, ensuring the durability of the TxFS transaction.

3.3 Isolation and conflict detection

Although the ext4 journal provides atomicity and durability, it does not provide isolation. Adding isolation for file-system data structures in the Linux kernel is challenging because a large number of functions all over the kernel modify file-system data structures without using a common interface. In TxFS, we tailor our approach to isolation for each data structure to simplify the implementation.

To provide isolation, TxFS has to ensure that all operations performed inside a transaction are not visible to other transactions or the rest of the system until commit time. TxFS achieves the isolation level of *repeatable reads* [7] using a combination of different techniques.

Split file-system functions. System calls such as `write()` and `open()` execute file-system functions which often result in allocation of file-system resources such as data blocks and inodes. TxFS splits such functions into two parts: one part which does file-system allocation, and one part which operates on in-memory structures. The part doing file-system allocation is moved to the commit point. The other part is executed as part of the system call, and the in-memory changes are kept private to the transaction.

Transaction-private copies. TxFS makes transaction-private copies of all kernel data structures modified during the transaction. File-system related system calls inside a transaction operate on these private copies, allowing transactions to read their own writes. In case of abort, these private copies are discarded; in case of commit, these private copies are carefully applied to the global state of the file system in an atomic fashion. During a transaction, file-system operations are redirected to the local in-memory versions of the data structures. For example, dentries updated by the transaction are modified to point to a local inode which maintains a local radix tree which has locally modified pages.

Two phase commit. TxFS transactions are committed using a two-phase commit protocol. TxFS first obtains a lock on all relevant file-system data structures using a total order. The following order prevents deadlock: inode mutexes, page locks, inode buffer head locks, the global `inode_hash_lock`, the global `inode_sb_list_lock`, inode locks, and dentry locks. The Linux kernel orders the acquiring of inode mutexes based on the pointer addresses of their inodes; we adopt this locking discipline in TxFS. Similarly, page locks are acquired in order of the address of the page. Acquiring the locks for directory data block buffers and inode metadata buffers is ordered by inode number.

After obtaining the locks, all allocation decisions are checked to see if they would succeed; for example, if the transaction creates inodes, TxFS checks if there are enough free inodes. Next, TxFS checks the journal to ensure there is enough space in the global `jbd2` transaction to allow the transaction to be merged. Finally, TxFS

Figure 2: TxFS relies on ext4's own journal for atomic updates and maintains local copies of in-memory data structures, such as inodes, dentries, and pages to provide isolation guarantees. At commit time, the local operations are made global and durable.

checks for conflicts with other transactions (as described below). If any of these checks fail, all locks are released, and the commit returns an error to the user. Otherwise, the in-memory data structures are updated, all file-system allocation is performed, and the private `jbd2` transaction is merged with the global `jbd2` transaction. At this point, the transaction is committed, locks are released and the changes are persisted to storage in a crash-consistent manner.

Conflict detection. Conflict detection is a key part of providing isolation. Since allocation structures such as bitmaps are not modified until commit time, they cannot be modified by multiple transactions at the same time, and do not give rise to conflicts; as a result, TxFS avoids false conflicts involving global allocation structures.

Conflict detection is challenging as file-system data structures are modified all over the Linux kernel without a standard interface. TxFS takes advantage of how file-system data structures are implemented to detect conflicts efficiently.

Conflict detection for pages. The `struct page` data structure holds the data for cached files. TxFS adds two fields to this structure: `write_flag` and `reader_count`. The `write_flag` indicates if there is another transaction that has written this page. The `reader_count` field indicates the number of other transaction that have read this page. Non-transactional threads will never see the in-flight un-committed data in transactions, and thus can always safely read data. TxFS does eager conflict detection for pages since there is a single interface to read and write pages that TxFS interposes. The following rules are followed on a page read or write:

1. When a transaction reads a page, it increments `reader_count` by one. If the page has the `write_flag` set, the transaction aborts.
2. If a transaction attempts to write a page that has either the `write_flag` set or `reader_count` greater than zero, it aborts. Otherwise, it sets the `write_flag`.
3. If a non-transactional thread attempts to write to a page with `reader_count` or `write_flag` set, it is put to sleep until the transaction commits or aborts.
4. When the transaction commits or aborts, `write_flag` is reset and `reader_count` is decremented.

Aborting transactions in this manner can lead to livelock, but we have not found it a problem with our benchmarks and the policy can be easily changed to resolve conflicts in favor of the oldest transaction (which does not livelock). TxFS favors transactional throughput, but for greater fairness between transactional and non-transactional threads, TxFS could allow a non-transactional thread to proceed by aborting all transactions conflicted by its operation [22].

Conflict detection for dentries and inodes. Apart from pages, TxFS must detect conflicts on two other data structures: dentries (directory entries) and inodes. Unfortunately, unlike pages, inodes and dentries do not have a standard interface and are modified throughout kernel code. Therefore, TxFS uses lazy conflict detection for inodes and dentries, detecting conflicts at commit time. At commit time, TxFS needs to detect if the global copy of the data structure has changed since it was copied into the local transaction. Doing a byte-by-byte comparison of each modified data structure would significantly increase commit latency; instead, TxFS takes advantage of the inode's `i_ctime` field that is changed whenever the inode is changed; TxFS simply has to check that the `i_ctime` has not changed for each inode that TxFS has read or written (writes are performed to a transaction-local copy of the inode). TxFS similarly adds a new `d_ctime` field to the dentry data structure to track its last modified time. We added kernel code in a number of places to update `d_ctime` whenever a dentry is changed. Creating different named entries within a directory does not create a conflict because the names are checked at commit time. By taking advantage of `i_ctime` and `d_ctime`, TxFS is able to perform conflict detection for these structures without radically changing the Linux kernel.

Summary. Figure 2 shows how TxFS uses ext4's journal for atomically updating operations inside a transaction, and maintaining local state to provide isolation guarantees. File operations inside a TxFS transaction are redirected to the transaction's local copied data structures, hence they do not affect the file system's global state, while being observable by subsequent operations in the same transaction. Only after a TxFS transaction finishes its commit (by calling `fs_tx_commit()`) will its modifications be globally visible.

3.4 Implementation

We modified Linux version 3.18 and the ext4 file system. The implementation requires a total of 5,200 lines of code, with 1,300 in TxFS internal bookkeeping, 1,600 in the VFS layer, 900 in the journal (JBD2) layer, 1,200 for ext4 and 200 for memory management (all measurements with SLOCCount [4]). Except for the ext4 and jbd2 extensions, all other code could be reused to port TxFS to other file systems, such as ZFS, in the future.

3.5 Limitations

TxFS has two main limitations. First, the maximum size of a TxFS transaction is limited to one fourth the size of the journal (the maximum journal transaction size allowed by ext4). We note that the journal can be configured to be as large as required. Multi-gigabyte journals are common today. Second, although parallel transactions can proceed with ACID guarantees, each transaction can only contain operations from a single process. Transactions spanning multiple processes are future work.

4 Accelerating program idioms with TxFS

We now explore a number of programming idioms where a transactional API can improve performance because transactions provide the file system a sequence of operations which can be optimized as a group (§2). Whole transaction optimization can result in dramatic performance gains because the file system can eliminate temporary durable writes (such as the creation, use and deletion of a log file). In some cases, we show that benefits previously obtained by new interfaces (such as `osync` [2]) can be obtained easily with transactions.

4.1 Eliminating file creation

When an application creates a temporary file, syncs it, uses it, and then unlinks it (*e.g.,* logging shown in Figure 1b), enclosing the entire sequence in a transaction allows the file system to optimize out the file creation and all writes while maintaining crash consistency.

Workload	FS	TX
Create/unlink/sync	37.35s	0.28s (133×)
Logging	5.09s	4.23s (1.20×)
Ordering work	2.86 it/s	3.96 it/s (1.38×)

Table 1: Programming idioms sped up by TxFS transactions. Performance is measured in seconds (s), and iterations per second (it/s). Speedups for the transaction case are reported in parentheses.

The create/unlink/sync workload spawns six threads (one per core) where each thread repeatedly creates a file, unlinks it, and syncs the parent directory. Table 1 shows that placing the operation within a transaction increases performance by 133× because the transaction completely eliminates the workload's IO. While this test is an extreme case, we next look at using transactions to automatically convert a logging protocol into a more efficient update protocol.

4.2 Eliminating logging IO

Figure 1b shows the logging idiom used by modern applications to achieve crash consistency. Enclosing the entire protocol within a transaction allows the file system to transparently optimize this protocol into a more efficient direct modification. During a TxFS transaction, all sync-family calls are functional nops. Because the log file is created and deleted within the transaction, it does not need to be made persistent on transaction commit. Eliminating the persistence of the log file greatly reduces the amount of user data but also file system metadata (*e.g.,* block and inode bitmaps) that must be persisted.

Table 1 shows execution time for a microbenchmark that writes and syncs a log, and a version that encloses the entire protocol in a single TxFS transaction. Enclosing the logging protocol within a transaction increases performance by 20% and cuts the amount of IO performed in half because the log file is never persisted. Rewriting the code increases performance by 55% (3.28s, not shown in the table). In this case getting the most performance out of transactions requires rewriting the code to eliminate work that transactions make redundant. But even without a programmer rewrite, by just adding two lines of code to wrap a protocol in a transaction achieves 47% of the performance of doing a complete rewrite.

Optimizing SQLite logging with TxFS. Table 3 reports results for SQLite. "Rollback with TxFS" represents SQLite's default logging mode encased within a TxFS transaction. Just enclosing the logging activity with a transaction increases performance for updates by 14%. Modifying the code to eliminate the logging work that transactions make redundant increases the performance for updates to 31%, in part by reducing the number of

Experiment	TxFS benefit	Speed
Single-threaded SQLite	Faster IO path, Less sync	1.31×
TPC-C	Faster IO path, Less sync	1.61×
Android Mail	Cross abstraction	2.31×
Git	Crash consistency	1×

Table 2: The table summarizes the micro- and macro-benchmarks used to evaluate TxFS, and the speedup obtained in each experiment.

system calls by 2.5×.

4.3 Separating ordering and durability

Table 1 shows throughput for a workload that creates three 10MB files and then updates 10MB of a separate 40MB file. The user would like to create the files first, then update the data file. This type of ordering constraint often occurs in systems like Git that create log files and other files that hold intermediate state.

The first version uses `fsync()` to order the operations, while the second uses transactions that allow the first three file create operations to execute in any order, but they are all serialized behind the final data update transaction (using flags to `fs_tx_begin()` and `fs_tx_commit()`). The transactional approach has 38% higher throughput because the ordering constraints are decoupled from the persistence constraints. The work that first distinguished ordering from persistence suggests adding different flavor sync system calls [2], but TxFS can achieve the same result with transactions.

5 Evaluation

We evaluate the performance and durability guarantees of TxFS on a variety of micro-benchmarks and real workloads. The micro-benchmarks help point out how TxFS achieves specific design goals while the larger benchmarks validate that transactions provide stronger crash semantics and improved performance to a variety of large applications with minimal porting effort.

Testbed. Our experimental testbed consists of a machine with a 4 core Intel Xeon E3-1220 CPU and 32 GB DDR3 RAM and a machine with a 6 core Intel Xeon E5-2620 CPU and 8 GB DDR3 RAM. All experiments are performed on Ubuntu 16.04 LTS (Linux kernel 3.18.22). The kernel is installed on a Samsung 850 (512 GB) SSD and all experiments are done on a Samsung 850 (250 GB) SSD. The experimental SSD is run at low utilization (around 20%) to prevent confounding factors from wear leveling firmware.

Table 2 presents a summary of the different experiments used to evaluate TxFS and the speedup obtained in each experiment. In the Git experiment, TxFS provides strong crash-consistency guarantees without degrading performance. Note that if not explicitly mentioned, all our baselines run on ext4 with its default journaling mode, the ordered journaling mode.

5.1 Crash consistency

TxFS's ACID transactions should be recoverable after a system crash. In order to verify this crucial correctness property, we boot a virtual machine and run a script that creates many types of transactions in multiple threads with random amounts of contained work and conflict probabilities. We crash the VM at a random time and make sure the file system journal is recoverable and that the file system passes all fsck checks. We have run over 100 random crashes and can recover the file system in all cases. An alternate way to test crash consistency would use a testing framework such as CrashMonkey [13].

5.2 Stress testing TxFS

We performed stress testing on TxFS to ensure its correctness in the face of conflicts and multi-threaded operations. Our stress tests had two main workloads. Our first workload was a micro-benchmark with six threads starting TxFS transactions and performing file-system operations picked at random across two files before committing. These threads generate a lot of conflicts, stressing TxFS conflict detection and isolation mechanisms. Our second workload uses the SQLite embedded database, performing a number of database operations with multiple threads. We were able to run both workloads for over 24 hours on TxFS without a kernel crash or our unit tests failing, giving us a measure of confidence in the correctness and stability of the codebase.

5.3 SQLite

We modified SQLite to use TxFS transactions. Data and metadata are first written safely to the journal and then checkpointed in-place into the file system. Note that all metadata is written into the file system exactly once. With SQLite in write-ahead-logging (WAL) mode, metadata is written twice: once to SQLite's log and once to the actual database file. The size and frequency of metadata updates for SQLite is significant because in order to be recoverable, it must update the parent directory whenever log files are created or deleted [29]. We use `PRAGMA synchronous=NORMAL` (default) for all modes, and `PRAGMA wal_checkpoint(FULL)` for WAL mode to guarantee all ACID properties.

When SQLite uses TxFS transactions, crashes do not leave any residual files on storage. Currently, users often must remove these residual files by hand which is tedious and error-prone. TxFS transactions eliminate user-visible log files; user-level code sees only the before and after state of the database, not messy in-flight data.

Single-threaded SQLite. Table 3 shows that TxFS is the best performing option for SQLite updates. Data is

	Performance (kOps/s)		IO (GB)		Sync/tx	
Journal mode	Insert	Update	Insert	Update	Insert	Update
Rollback (default)	53.9	28.0	1.9	3.9	4	10
Truncate	53.5 (0.99×)	28.9 (1.03×)	1.9	3.9	4	10
WAL	39.8 (0.74×)	34.6 (1.23×)	3.9	3.8	3	3
TxFS	51.4 (0.95×)	36.7 (1.31×)	1.9	3.8	1	1
Rollback with TxFS	52.1 (0.97×)	31.9 (1.14×)	1.9	3.8	1	1
No journal (**unsafe**)	54.9 (1.02×)	50.6 (1.81×)	1.9	1.9	1	1

Table 3: The table compares operations per second (larger is better) and total amount of IO for SQLite executing 1.5M 1KB operations grouping 10K operations in a transaction using different journaling modes (including TxFS). The database is pre-populated with 15M rows. All experiments use SQLite's synchronous mode (its default).

	Rollback (default)	Truncate	WAL	TxFS	No journal (**unsafe**)
Delivery	110.52	123.33	157.01	188	300.4
New Order	142.38	165.15	216.8	240.34	445.14
Order Status	1998.53	2067.29	3317.1	2489.94	3141.13
Payment	198.45	240.21	367.26	300.61	909.91
Stock levl	575.03	602.33	765.41	684.06	1079.85
Total	172.97	203.3 (1.18×)	280.01 (1.62×)	278.97 (1.61×)	600.15 (3.47×)
Syscall/tx	208.0	207.95	138.26	100.35	146.9
Sync/tx	2.76	2.75	2.76	0.92	0.92
R MB/tx	0.018	0.016	0.013	0.013	0.007
W MB/tx	0.17	0.158	0.131	0.129	0.066
T MB/tx	0.187	0.174 (0.93×)	0.144 (0.77×)	0.142 (0.76×)	0.073 (0.39×)

Table 4: Rates (in transactions per second) for the TPC-C workload using different SQLite journaling modes. Each workload runs continuously for a fixed amount of time.

the average of five trials with standard deviations below 2.2% of the mean. For the update workload, TxFS is 31% faster than the default. We report IO totals as part of our validation that TxFS correctly writes all data in a crash-consistent manner. Several choices for SQLite logging mode, including TxFS, result in similar levels of IO that resemble the no-journal lower bound. Write-ahead logging mode (WAL) writes more data for the insert workload, which harms its performance. Note that TxFS does not suffer WAL's performance shortfall on insert, and TxFS surpasses WAL's performance on update, making it a better alternative. Although the file system journal shares similarity with a WAL log, TxFS does not generate redundant IO on insert because of its selective data journaling.

We run similar experiments with small updates (16 bytes) and find that there is little difference in performance between SQLite's different modes and TxFS. This shows that small transactions do not have significant overhead in TxFS.

TxFS's improves performance for the update workload is due to several factors. TxFS reduces the number of data syncs from 10 (in Rollback and Truncate mode) or 3 (in WAL mode) to only 1, which leads to better batching and re-ordering of writes inside a single transaction. It performs half of its IO to the journal, which is written sequentially. The remaining IO is done asynchronously via a periodic file-system checkpoint that writes the journaled blocks to in-place files. Since TxFS uses the file-system journal instead of an application-level journal for logging the transaction, it avoids the *journaling on journal* problem [25], where the journaling of the application-level log causes a significant slowdown. Even in realistic settings where performance is at a premium, transactions provide a simple, clean interface to get significantly increased file-system performance, while maintaining crash safety.

5.4 TPC-C

We run a version of the TPC-C benchmark [17], ported to use single-threaded SQLite[1]. TPC-C is a standard online transaction processing benchmark for an order-entry environment. R MB/tx is the amount of read IO per transaction, W is written IO and T is total.

Table 4 shows that TxFS outperforms SQLite's default mode by 1.61×. The performance advantage comes from two sources. First, TxFS writes less data and batches its writes. TxFS writes much of its data sequentially to the file system journal on `fs_tx_commit()` and writes back the journal data asynchronously. SQLite's default mode must write data to the SQLite journal and to the database file on `fsync()`. Therefore, TxFS writes only once in the critical path (to the journal), while SQLite (as configured in Section 5.3) must write to the journal plus database in the critical path. Second, TxFS decreases the number of system calls, especially sync-family calls. Table 4 shows that TxFS reduces the number of sync-family calls per transaction by 3×. By reducing the sync-familly calls, TxFS can batch writes in a transaction, reducing the amount of writes by 31.7% compared to default mode.

The performance of TxFS and WAL is similar. When transactions contain writes, TxFS has better performance than WAL, but it has worse performance for read-only

[1] `https://github.com/apavlo/py-tpcc/wiki/SQLite-Driver`

Journal mode	Throughput	IO(MB)
Rollback (default)	45.73	3269
Truncate	45.48 (0.99×)	3154
WAL	53.43 (1.17×)	3539
TxFS	105.68(2.31×)	6797
TxFS Small tx	60.85 (1.33×)	4052
No journal (**unsafe**)	61.88 (1.35×)	3995

Table 5: TxFS supports transactions across storage abstractions. Performance is measured in iterations per second.

transactions: WAL is 28% faster than TxFS for read-only transactions. “Order status” and “Stock level” consist of 3 select queries and 2 select queries respectively, resulting in lower throughput for TxFS compared with WAL. However, “Delivery” consists of 3 select, 3 update, and 1 delete queries, so TxFS outperforms WAL by 20%.

5.5 Abstractions built on files

Modern file systems support storage of not only files but databases (*e.g.,* SQLite) and key-value stores (*e.g.,* LevelDB and RocksDB). These abstractions are built on the file system and generally are a lower-performing, but easier to set up and maintain alternative to their dedicated counterparts.

TxFS supports transactions that span storage abstractions. Table 5 shows the throughput for a workload that models the core activity of Android mail, storing an image file and recording the path to that file in a SQLite database along with other metadata. The database is prepopulated with 100,000 1KB rows, image files are 1 MB. The workload creates the database record in one transaction, creates a uniquely named file where it stores the file data, syncs the data, and then updates the database record in a second transaction.

TxFS outperforms default SQLite by 2.31× and the best alternative (WAL mode) by 1.98×. It is essential to TxFS’s performance that both database transactions as well as the file system operation are all contained in a single transaction. When they are separate transactions (TxFS Small tx), performance is bounded by SQLite (i.e., it is close to no journaling). IO is not a bottleneck for this workload. The amount of IO performed is proportional to the amount of work done: TxFS has higher throughput, so it performs more IO.

5.6 Git

Git is a widely-used version control system. Git commands such as `git add` and `git commit` result in a large number of file-system operations. Git updates files by creating a temporary file, writing the desired data to it, and renaming it over the old file. To enable high performance, Git does not order its operations via `fsync()` [21], leaving it vulnerable to garbage files and outright data corruption on a system crash.

Category	System	Isolation	Durability	Easy-to-use API	Hardware independence	Performance	Complexity
In-kernel transactional FS	**TXFS**	✓	✓	✓	✓	H	L
	Valor	✓	✓	✗	✓	H	L
	TxF	✓	✓	✗	✓	H	H
Transactional OS	TxOS	✓	✓	✓	✓	H	H
FS over userspace databases	OdeFS Inversion DBFS Amino	Relying on databases		✗	✓	L	L
Transactional storage	CFS	✗	✓	✓	✗	H	L
	MARS	✓	✓	✗	✗	H	H
	Isotope	✓	✓	✓	✓	H	H
Failure atomicity	msync	✗	✓	✓	✓	H	L
	AdvFS	✗	✓	✓	✓	H	L

Table 6: The table compares prior work providing ACID transactions or failure atomicity in a local file system. Legend: ✓- supported, ✗- unsupported, L - Low, H - High. Note that only TxFS provides isolation and durability with high performance and low implementation complexity without restrictions or hardware modifications.

In our experiment, we run Git inside a virtual machine. We instrument the Git code to crash the VM at vulnerable points (such as after the temp file rename, but before the file is persistent). The workload first initializes a Git repository, populates it with 20,000 empty files, then adds all files at once.

After a VM restart, we find that the `.git/index` file has been truncated to zero bytes, resulting in a loss of the working tree. Running the Git recovery command `git fsck` simply reports a fatal error. Recovery is not possible unless the data has been backed up in another location. In contrast, when we change Git to use TxFS transactions, we find that crashes no longer produce such catastrophic errors. Furthermore, we do not find a significant difference in performance between the code that use TxFS transactions, and the code that does not. Thus, using TxFS transactions provides crash consistency for Git without any performance overhead.

6 Related work

There have been a number of efforts over the years to provide systems support for file-system transactions. Each of these systems failed to gain adoption due to one of the following reasons: they had severe restrictions on what could be placed inside a transaction, they were complicated to use, they added complexity to the kernel, or they caused significant performance degradation. Learning from prior systems, TxFS avoids all of these mistakes. Table 6 summarizes related work and demonstrates that TxFS is unique among transactional file systems.

Building file systems on top of user-space databases. One way to provide transactional updates for applications is to build a file system over a user-space transactional database. OdeFS [5], Inversion [18], and DBFS [16] use a database (such as Berkeley DB [19]) to provide ACID transactions to applications via NFS. Amino [31] tracks all user updates via `ptrace` and employs a user-level database to provide transactional updates. Such systems come with significant performance cost (*e.g.,* 50-80% for large operations in DBFS [16]).

In-kernel transactional file systems. An approach that leads to higher performance is adding transactions to in-kernel file systems. Valor [28] provides kernel support for file-system transactions. However, Valor does not provide a simple begin/end transaction interface, and it forces programmers to use seven new system calls to manage the transaction log.

Microsoft introduced Transactional NTFS (TxF), Transaction Registry (TxR), and the kernel transaction manager (KTM) in Windows Vista [24]. Using TxF requires all transactional operations be explicit (i.e., instead of using `read()` in a transaction, the programmer must add an explicit transactional read). Therefore TxF had a high barrier to entry and code that used it required separate maintenance. TxF also had significant limitations, like no transactions on the root file system.

Transactional operating systems. A third, somewhat heavyweight, approach is modifying the entire operating system to provide transactions. Our prior work, TxOS [22], is an operating system that provides transactions. This approach adds significant complexity to the kernel. For example, TxOS modified tens of thousands of lines of code and changed core OS data structures like the inode. Maintaining such a kernel will be tricky – Windows abandoned its transactional file system and kernel transaction manager [14].

The transactional capabilities of the file system supported by TxOS is similar in approach to TxFS. It also uses the file-system journal and modifies the virtual file system (VFS) code to provide isolation. One could view TxFS as specializing TxOS to the file system, achieving a transactional file system at significantly lower cost, while adding file-system specific optimizations like selective journaling and eliminating redundant work within transactions.

Transactional storage systems. Similar to our work, CFS [15] provides a lightweight mechanism for atomic updates of multiple files, building on top of transactional flash storage. MARS [3] builds on hardware-provided atomicity to build a transactional system. TxFlash [23] uses the copy-on-write nature of Flash SSDs to provide transactions at low cost. In contrast to these systems, TxFS provides transactions without assuming any hardware support (beside device cache flush and atomic sector updates). Isotope [26] uses multi-version concurrency control to provide isolation, significantly increasing its complexity. Isotope builds a user-space transactional file system using FUSE, which limits its performance for certain workloads. The higher abstraction level of TxFS makes implementing transactional optimizations and tailored isolation significantly easier than the lower level of Isotope.

Failure atomicity. Failure-atomic msync [20] is similar to TxFS in that it re-uses the journal for providing atomicity to application updates; in contrast, TxFS provides full ACID transactions at significantly higher complexity. AdvFS [30] is also limited in the same way, is specific to the Tru64 file system, and is not available as open-source (latest version available was from 2008). The principles behind TxFS could be used in any file system that has an internal mechanism for atomic updates.

We previewed the ideas behind TxFS at HotOS [11], but this paper reports on the completed system with comprehensive evaluation.

7 Conclusion

We present TxFS, a transactional file system built with less development effort than previous systems by leveraging the file-system journal. TxFS is easy to develop, it is easy to use, and it does not have significant overhead for transactions. We show that using TxFS transactions increases performance significantly for a number of different workloads.

Transactional file systems have not been successful for a variety of reasons. TxFS shows that it is possible to avoid the mistakes of the past, and build a transactional file system with low complexity. Given the power and flexibility of file-system transactions, we believe they should be examined again by file-system researchers and developers. Adopting a transactional interface would allow us to borrow decades of research on optimizations from the database community while greatly simplifying the development of crash-consistent applications.

Abstract

Modern computer systems come with a large number of configurable parameters that control their behavior. Tuning system parameters can provide significant gains in performance but is challenging because of the immense number of configurations and complex, nonlinear system behavior. In recent years, several studies attempted to automate the tuning of system configurations; but they all applied only one or few optimization methods. In this paper, for the first time, we apply and then perform comparative analysis of multiple black-box optimization techniques on storage systems, which are often the slowest components of computing systems. Our experiments were conducted on a parameter space consisting of nearly 25,000 unique configurations and over 450,000 data points. We compared these methods for their ability to find near-optimal configurations, convergence time, and instantaneous system throughput during auto-tuning. We found that optimal configurations differed by hardware, software, and workloads—and that no one technique was superior to all others. Based on the results and domain expertise, we begin to explain the efficacy of these important automated black-box optimization methods from a systems perspective.

1 Introduction

Storage is a critical element of computer systems and key to data-intensive applications. Storage systems come with a vast number of configurable parameters that control system's behavior. Ext4 alone has around 60 parameters with whopping 10^{37} unique combinations of values. Default parameter settings provided by vendors are often suboptimal for a specific user deployment; previous research showed that tuning even a small subset of parameters can improve power and performance efficiency of storage systems by as much as 9× [66].

Traditionally, system administrators pick parameter settings based on their expertise and experience. Due to the increased complexity of storage systems, however, manual tuning does not scale well [87]. Recently, several attempts were made to automate the tuning of computer systems in general and storage systems in particular [71, 78]. Black-box auto-tuning is an especially popular approach thanks to its obliviousness to a system's internals [86]. For example, Genetic Algorithms (GA) were applied to optimize the I/O performance of HDF5-based applications [5] and Bayesian Optimization (BO) was used to find a near-optimal configuration for Cloud VMs [3]. Other methods include Evolutionary Strategies [62], Smart Hill-Climbing [84], and Simulated Annealing [21]. The basic mechanism behind black-box auto-tuning is to iteratively try different configurations, measure an objective function's value—and based on the previously learned information—select the next configurations to try. For storage systems, objective functions can be throughput, energy consumption, purchase cost, or even a formula combining different metrics [50, 71]. Despite some appealing results, there is no deep understanding how exactly these methods work, their efficacy and efficiency, and which methods are more suitable for which problems. Moreover, previous works evaluated only one or few algorithms at a time. In this paper, for the first time (to the best of our knowledge), we apply and analytically compare *multiple* black-box optimization techniques on storage systems.

To demonstrate and compare these algorithms' ability to find (near-)optimal configurations, we started by exhaustively evaluating several storage systems under four workloads on two servers with different hardware and storage devices; the largest system consisted of 6,222 unique configurations. Over a period of 2+ years, we executed 450,000+ experimental runs. We stored all data points in a relational database for query convenience, including hardware and workload details, throughput, energy consumption, running time, etc. In this paper, we focused on optimizing for throughput, but our methodology and observations are applicable to other metrics as well. We will release our dataset publicly to facilitate more research into auto-tuning and better understanding of storage systems.

Next, we applied several popular techniques to the collected dataset to find optimal configurations under various hardware and workload settings: Simulated Annealing (SA), Genetic Algorithms (GA), Bayesian Optimization (BO), and Deep Q-Networks (DQN). We also tried Random Search (RS) in our experiments, which showed surprisingly good results in previous research [8]. We compared these techniques from various aspects, such as the ability to find near-optimal configurations, convergence time, and instantaneous system throughput during auto-tuning. For example, we found that several techniques were able to converge to good configurations given enough time, but their efficacy differed a lot. GA and BO outperformed SA and

DQN on our parameter spaces, both in terms of convergence time and instantaneous throughputs. We also showed that hyper-parameter settings of these optimization algorithms, such as mutation rate in GA, could affect the tuning results. We further compared the techniques across three behavioral dimensions: (1) *Exploration*: how much the technique searches the space randomly. (2) *Exploitation*: how much the technique leverages the "neighborhood" of the current candidate or previous search history to find even better configurations. (3) *History*: how much data from previous evaluations is kept and utilized in the overall search process. We show that all techniques employ these three key concepts to varying degrees and the trade-off among them plays an important role in the effectiveness and efficiency of the algorithms. Based on our experimental results and domain expertise, we provide explanations of efficacy of such black-box optimization methods from a storage perspective. We observed that certain parameters would have a greater effect on system performance than others, and the set of dominant parameters depends on file systems and workloads. This allows us to provide more insights into the auto-tuning process.

Auto-tuning storage systems is fairly complex and challenging. We made several necessary assumptions and simplifications while collecting our exhaustive data, which we detail in §3. Therefore, some of our observations might differ when applied to production systems. However, the main purpose of this paper is *not* to provide a complete solution; rather, we focus on comparing and understanding the efficacy of several popular optimization techniques when applied to storage systems. We believe this paves the way for practical auto-tuning storage systems in real-time.

The rest of the paper is organized as follows. §2 explains the challenges of auto-tuning storage systems and provides necessary background knowledge. §3 describes our experimental methodology and environments. In §4 we applied multiple optimization methods and evaluated and explained them from various aspects. §5 covers limitations and future plans for our work. §6 lists related work. We conclude and discuss future directions in §7.

2 Background

Storage systems are often a critical component of computer systems, and are the foundation for many data-intensive applications. Usually they come with a large number of configurable options that could affect or even determine the systems' performance [12, 74], energy consumption [66], and other aspects [47, 71]. Here we define a *parameter* as one configurable option, and a *configuration* as a combination of parameter values. For example, the parameter *block_size* of Ext4 can take 3 values: 1K, 2K, and 4K. Based on this, *[journal_mode="data=writeback", block_size=4K, inode_size=4K]* is one *configuration* with 3 specific parameters: *journal mode*, *block size*, and *inode size*. All possible configurations form a *parameter space*.

When configuring storage systems, users often stick with the default configurations provided by vendors because 1) it is nearly impossible to know the impact of every parameter across multiple layers; and 2) vendors' default configurations are trusted to be "good enough". However, previous studies [66] showed that tuning even a tiny subset of parameters could improve the performance and energy efficiency for storage systems by as much as 9×. As technological progress slows down, it becomes even more important to squeeze every bit of performance out of deployed storage systems.

In the rest of this section we first discuss the challenges of system tuning (§2.1). Then, §2.2 briefly introduces several promising techniques that we explore in this paper. §2.3 explains certain methods that we deem less promising. §2.4 provides a unified view of these optimization methods.

2.1 Challenges

The tuning task for storage systems is difficult, due to the following four challenges.

(1) Large parameter space. Modern storage systems are fairly complex and easily come with hundreds or even thousands of tunable parameters. One evaluation for storage systems can take multiple minutes or even hours, which makes exhaustive search impractical. Even human experts cannot know the exact impact of every parameter and thus have little insight into how to optimize. For example, Ext4+NFS would result in a parameter space consisting of more than 10^{22} unique configurations. IBM's General Parallel File System (GPFS) [64] contains more than 100 tunable parameters, and hence 10^{40} configurations. From the hardware perspective, SSDs [30, 53, 57, 65], shingled drives [1, 2, 32, 45], and non-volatile memory [40, 83] are gaining popularity, plus more layers (LVM, RAID) are added.

(2) Non-linearity. A system is *non-linear* when the output is not directly proportional to the input. Many computer systems are non-linear [16], including storage systems [74]. For example, Figure 1 shows the average operation latency of GPFS under a typical database server workload while changing only the value of the parameter *pagepool* from 32MB to 128MB, and setting all the others to their default. Clearly the average latency is not directly proportional to the *pagepool* size. In fact, through our experiments, we have seen many more parameters with similar behavior. Worse, the parameter space for storage systems is often sparse, irregular, and contains multiple peaks. This makes automatic optimization even more challenging, as it has to avoid

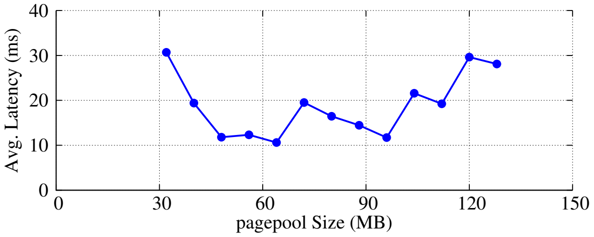

Figure 1: Storage systems are non-linear.

getting stuck in a local optima [36].

(3) Non-reusable results. Previous studies have shown that evaluation results of storage systems [12,66] and databases [78] are dependent on the specific hardware and workloads. One good configuration might perform poorly when the environment changes. Our evaluation results in Section 4 show similar observations.

(4) Discrete and non-numeric parameters. Some storage system parameters can take continuous real values, while many others are discrete and take only a limited set of values. Some parameters are not numeric (e.g., I/O scheduler name or file system type). This adds difficulty in applying gradient-based approaches.

Given these challenges, manual tuning of storage systems becomes nearly impossible while automatic tuning merely difficult. In this paper we focus on automatic tuning and treat it as an optimization problem.

2.2 Applied Methods

Several classes of algorithms have been proposed for similar optimization tasks, including automated tuning for hyper-parameters of machine learning systems [7, 8, 59] and optimization of physical systems [3, 78]. Examples include Genetic Algorithms (GA) [18, 34], Simulated Annealing (SA) [15, 41], Bayesian Optimization (BO) [11,68], and Deep Q-Networks (DQN) [46,54,55]. Although these methods were proposed originally in different scholarly fields, they can all be characterized as black-box optimizations. In this section we introduce several of these techniques that we successfully applied in auto-tuning storage systems.

Simulated Annealing (SA) is inspired by the annealing process in metallurgy, which involves the heating and controlled cooling of a material to get to a state with minimum thermodynamic free energy. When applied to storage systems, a *state* corresponds to one *configuration*. *Neighbors* of a state refer to new configurations achieved by altering only one parameter value of the current state. The thermodynamic free energy is analogous to optimization objectives. SA works by maintaining the *temperature* of the system, which determines the probability of accepting a certain move. Instead of always moving towards better states as hill-climbing methods do, SA defines an *acceptance probability distribution*, which allows it to accept some bad moves in the short run, that can lead to even-better moves later on. The system is initialized with a high temperature, and thus has high probability of accepting worse states in the beginning. The temperature is gradually reduced based on a pre-defined *cooling schedule*, thus reducing the probability of accepting bad states over time.

	FS	BG	Journal Option
Parent 1	NilFS2	8	order=strict
Parent 2	NilFS2	256	order=relaxed
Child 1	NilFS2	8	order=relaxed
Child 2	NilFS2	256	order=strict

Figure 2: Crossover in Genetic Algorithm (GA).

Genetic Algorithms (GA) were inspired by the process of natural selection [34]. It maintains a population of *chromosomes* (configurations) and applies several genetic operators to them. *Crossover* takes two parent chromosomes and generates new ones. As Figure 2 illustrates, two parent Nilfs2 configurations are cut at the same *crossover* point, and then the subparts after the crossover point are exchanged between them to generate two new child configurations. Better chromosomes will have a higher probability to "survive" in future *selection* phases. *Mutation* randomly picks a chromosome and mutates one or more parameter values, which produces a completely different chromosome.

Reinforcement Learning (RL) [72] is an area of machine learning inspired by behaviorist psychology. RL explores how software agents take actions in an environment to maximize the defined cumulative rewards. Most RL algorithms can be formulated as a model consisting of: (1) A set of environment states; (2) A set of agent actions; and (3) A set of scalar rewards. In case of storage systems, *states* correspond to *configurations*, *actions* mean changing to a different configuration, and *rewards* are differences in evaluation results. The agent records its previous experience (history), and makes it available through a *value function*, which can be used to predict the expected reward of state-action pairs. The *policy* determines how the agent takes action, which maintains the *exploration-exploitation* trade-off. The value function can take a tabular form, but this does not scale well to many dimensions. Function approximation is proposed to deal with high dimensionality, which is still known to be unstable or even divergent. With recent advances in Deep Learning [28], deep convolutional neural networks, termed Deep Q-Networks (DQN), were proposed to parameterize the value function, and have been successfully applied in solving various problems [54, 55]. Many variants of DQN have been proposed [46].

Bayesian Optimization (BO) [11, 68] is a popular framework to solve optimization problems. It models

Algorithm	Origin	Exploration	Exploitation	History
Simulated Annealing (SA)	Annealing technology in metallurgy	Allowing moving to worse neighbor states	Neighbor function	N/A
Genetic Algorithms (GA)	Natural evolution	Mutation	Crossover and selection	Current population
Deep Q-Networks (DQN)	Behaviorist psychology and neuroscience	Taking random actions	Taking actions based on action-reward function	Deep convolutional neural network
Bayesian Optimization (BO)	Statistics and experimental design	Selecting samples with high variances	Selecting samples with high mean values	Acquisition function & probabilistic model

Table 1: Comparison and summaries of optimization techniques.

the objective function as a stochastic process, with the argument corresponding to one storage configuration. In the beginning, a set of prior points (configurations) are given to get a fair estimate of the entire parameter space. BO works by computing the *confidence interval* of the objective function according to previous evaluation results, which is defined as the range of values that the evaluation result is most likely to fall into (e.g., with 95% probability). The next configuration is selected based on a pre-defined *acquisition function*. Both confidence intervals and the acquisition function are updated with each new evaluation. BO has been successfully applied in various areas, including hyper-parameter optimization [17] and system configuration optimization [3]. BO and its variants differ mainly in their form of probabilistic models and acquisition functions. In this paper we focus mainly on Gaussian priors and an Expected Improvement acquisition function [68].

Other promising techniques include Tabu Search [27], Particle Swarm Optimization [39], Ant Colony Optimization [20], Memetic Algorithms [52], etc. Due to space limits, we omit comparing all of them in this paper (part of our future work). In fact, as detailed in §2.4, most of these techniques actually share similar traits.

2.3 Other Methods

Although many optimization techniques have been proposed, we feel that not all of them make good choices for auto-tuning storage systems. For example, since many parameters of storage systems are non-numeric, most gradient-based methods (i.e., based on linear-regression) are less suitable to this task [29].

Control Theory (CT). CT was historically used to manage linear system parameters [19, 37, 44]. CT builds a controller for a system so its output follows a desired reference signal [33, 43]. However, CT has been shown to have the following three problems: 1) CT tends to be unstable in controlling non-linear systems [48, 49]. Although some variants were proposed, they do not scale well. 2) CT cannot handle non-numeric parameters; and 3) CT requires a lot of data during the learning phase, called *identification* to build a good controller.

Supervised Machine Learning (ML). Supervised ML has been successfully applied in various domains [9, 10, 56, 81]. However, the accuracy of ML models depends heavily on the quality and amount of training data [81], which is not available or impossible to collect for large parameter spaces such as ours.

Therefore, we feel that neither CT nor supervised ML, in their current state, are the first choice to *directly and efficiently* apply for auto-tuning storage systems. That said, they constantly evolve and new promising results appear in research literature [4, 67, 69, 86]; we plan to investigate them in the future.

2.4 Unified Framework

Most optimization techniques are known to follow the *exploration-exploitation* dilemma [23, 46, 68, 79]. Here we summarize the aforementioned methods by extending the unified framework with a third factor, the *history*. Our unified view thus defines three factors or dimensions: ■ **(1) Exploration** defines how the technique searches unvisited areas. This often includes a combination of pure random and also guided search based on *history*. ■ **(2) Exploitation** defines how the technique leverages *history* to find next sample. ■ **(3) History** defines how much data from previous evaluations is kept. History information can be used to help guide both future exploration and exploitation (e.g., avoiding less promising regions, or selecting regions that have never been explored before). Table 1 summarizes how the aforementioned techniques work by maintaining the balance among these three key factors. For example, GA keeps the evaluation results from the last generation, which corresponds to the concept of *history*. GA then *exploits* the stored information, applying selection and crossover to search nearby areas and pick the next generation. Occasionally, it also randomly mutates some chosen parameters, which is the idea of *exploration*. As shown in §4, the trade-off among exploration, exploitation, and history determines the effectiveness and efficiency of these optimization techniques.

3 Experimental Settings

We now describe details of the experimental environments, parameter spaces, and our implementations of optimization algorithms.

Param.	Abbr.	Values
File System	FS	Ext2, Ext3, Ext4, XFS, Btrfs, Nilfs2, Reiserfs
Block (Leaf) Size	BS	1K, 2K, 4K
Inode Size, Sector Size	IS	n/a, 128, 256, 512, 1024, 2048, 4096, 8192
Block Group	BG	n/a, 2, 4, 8, 16, 32, 64, 128, 256
Journal Option	JO	n/a, order=strict, order=relaxed, data=journal, data=ordered, data=writeback
Atime Option	AO	relatime, noatime
Special Option	SO	n/a, compress, nodatacow, nodatasum, notail
I/O Scheduler	I/O	noop, cfq, deadline

Table 2: Details of parameter spaces.

Hardware. We performed experiments on two sets of machines with different hardware categorized as low-end (M1) and mid-range (M2). We list the hardware details in Table 3. We also use Watts Up Pro ES power meters to measure the energy consumption [82].

Workload. We benchmarked storage configuration with four typical macro-workloads generated by Filebench [25, 75]. ■ **(1) Mailserver** emulates the I/O workload of a multi-threaded email server. ■ **(2) Fileserver** emulates the I/O workload of a server that hosts users' home directories. ■ **(3) Webserver** emulates the I/O workload of a typical static Web server with a high percentage of reads. ■ **(4) Dbserver** mimics the behaviors of Online Transaction Processing (OLTP) databases. Before each experiment run, we formatted and mounted the storage devices with the targeted file system.

The working set size affects the duration of an experiment [74]. Our goal in this study was to explore a large set of parameters and values quickly (although it still took us over two years). We therefore decided to trade the working set size in favor of increasing the number of configurations we could explore in a practical time period. We used the default working set sizes in Filebench, and ran each workload for 100 seconds; this is long enough to get stable evaluation results under this setting. The experiments demonstrate a wide range of performance numbers and are suitable for evaluating different optimization methods.

Parameter Space. Since the main goal of our paper is to compare multiple optimization techniques, we want our storage parameter spaces to be large and complex enough. Alas, evaluations for storage systems take a long time. Considering experimentation on multiple hardware settings and workloads, we decided to experiment with a reasonable subset of the most relevant storage system parameters. We selected parameters in close collaboration with several storage experts that have either contributed to storage stack designs or have spent years tuning storage systems in the field. We experimented with 7 Linux file systems that span a wide range of designs and features: *Ext2* [13], *Ext3* [77], *Ext4* [24], *XFS* [73], *Btrfs* [61], *Nilfs2* [42], and *Reiserfs* [60].

Hardware	M1	M2
Model	Dell PE SC1425	Dell PE R710
CPU	Intel Xeon single-core 2.8GHz CPU × 2	Intel Xeon quad-core 2.4GHz CPU × 2
Memory	2GB	24GB
Storage	HDD1 (73GB Seagate ST373207LW SCSI drive)	HDD2 (147GB SAS), HDD3 (500GB SAS), HDD4 (250GB SATA), SSD (200GB)

Table 3: Details of experiment machines.

Our experiments were mainly conducted on two sets of parameters, termed as *Storage V1* and *Storage V2*. We started with seven common file system parameters (shown in the first 7 rows of Table 2), and refer it as *Storage V1*. *Storage V1* was tested on M1 machines. We then extended our search space with one more parameter, the *I/O Scheduler*, and refer to it as *Storage V2*. *Storage V2* was evaluated on M2 servers. Note that certain combinations of parameter values could produce invalid configurations. For example, for Ext2, the journaling option makes no sense because Ext2 does not have a journal. To handle this, we added a value *n/a* to the existing range of parameters. Any parameter with *n/a* value is considered invalid. Invalid configurations will always come with evaluation results of zero (i.e., no throughput); this ensures they are purged in an upcoming optimization process. There are 2,074 valid configurations in *Storage V1* and 6,222 in *Storage V2* for each workload and storage device. We believe our search spaces are large and complex enough to demonstrate the difference in efficiency of various optimization algorithms. Furthermore, many of the chosen parameters are commonly tuned and studied by storage experts; having a basic understanding of such parameters helped us understand auto-tuning results.

Experiments and implementations. Our experiments and implementation consist of two parts. First, we exhaustively ran all configurations for each workload and device on M1 and M2 machines, and stored the results in a relational database. We collected the throughput in terms of I/O operations per second, as reported by Filebench, the running time (including setup time), as well as power and energy consumption. To acquire more accurate and stable results, we evaluated each configuration under the same environment for at least 3 runs, resulting in more than 450,000 total experimental runs. This data collection benefited our evaluation on auto-tuning as we can simply simulate a variety of algorithms by just querying the database for the evaluation results for different configurations, without having to rerun slow I/O experiments. The exhaustive search

Hardware-Workload-Device	File System	Block Size	Inode Size	BG Count	Journal Options	Atime Options	Special Options	I/O Scheduler	Through-put (IOPS)
M1-Mail-HDD1	Nilfs2	2K	n/a	256	order=relaxed	relatime	n/a	-	3,677
M2-Mail-HDD3	Ext2	4K	256	32	n/a	relatime	n/a	noop	18,744
M2-File-HDD3	Btrfs	4K	4,096	n/a	n/a	relatime	compress	deadline	16,549
M2-Mail-SSD	Ext2	4K	256	8	n/a	relatime	n/a	noop	18,845
M2-DB-SSD	Ext4	1K	128	2	data=ordered	noatime	n/a	noop	41,948
M2-Web-SSD	Ext4	4K	128	4	data=ordered	noatime	n/a	noop	16,185

Table 4: Global optimal configurations with different settings and workloads.

also lets us know exactly what the global optimal configurations are, so that we can calculate how close each optimization method gets to the global optimum.

Second, we simulated the process of auto-tuning storage systems by running the desired optimization method and querying the database for the average evaluation results from multiple (3+) repeated runs. We focused on optimizing for throughput in this paper. The computation cost of optimization algorithms are ignored in our experiments. We believe our observations are applicable to other optimization objectives as well. Our implementations of optimization methods are mostly based on open-source libraries. We use Pyevolve [58] for Genetic Algorithms, Scikit-Optimize [70] for Bayesian Optimization, and TensorFlow [76] for the DQN implementation. We implemented a simple version of Simulated Annealing, with both linear and geometric cooling schedules. (We also fixed bugs in Pyevolve and plan to release our patches.) Most of our implementation was done by converting storage-related concepts into algorithm-specific ones. For example, for GA, we defined each storage parameter as a *gene*, and each configuration as a *chromosome*. For DQN we provided storage-specific definitions for states, actions, and rewards. The complete implementation uses around 10,000 lines of Python code.

4 Evaluations

Our evaluation mainly focuses on comparing the effectiveness and speed of applying multiple optimization techniques on auto-tuning storage systems, and providing insights into our observations. §4.1 overviews the data sets that we collected for over two years. §4.2 compares five popular optimization techniques from several aspects. §4.3 uses GA as a case study to show that hyper-parameters of these methods can also impact the auto-tuning results. §4.4 takes the first step towards explaining these black-box optimization methods, based on our evaluation results and our storage expertise.

4.1 Overview of Data Sets

As per §3, our experimental methodology is to first exhaustively run all configurations under different workloads and test machines. We stored the results in a database for future use. This data collection benefits future experiments as we can simulate a variety of algorithms by querying the database for the evaluation results of different configurations. Due to space limits, in this section we show only 6 representative data sets out of 18: 2 workloads on M1 and 4 devices × 4 workloads on M2. They were picked to (1) show a wide range of hardware and workloads' impact on optimization results and (2) to present more SSD results, given SSDs' increasing popularity.

Figure 3 shows the throughput CDF among all configurations for each hardware setting and workload. The Y-axis is normalized by the maximum throughput under each experiment setting. The symbols on each line mark the default Ext4 configurations. As seen, for most settings, throughput values vary across a wide range. The ratios of the worst throughput to the best one are mostly between 0.2–0.4. In one extreme case, for *Fileserver* on *M2* machines and with the HDD3 device (abbreviated as *M2-Fileserver-HDD3*), the worst configuration only produces 1% I/O operations per unit time, compared with the global optimal one. This underlines the importance of tuning storage systems: an improperly configured system could be remarkably under-utilized, and thus wasting a lot of resources. However, *M2-Webserver-SSD* shows a much narrower range of throughput, with the worst-to-best ratio close to 0.9. This is attributed mainly to the fact that *Webserver* consists of mostly sequential read operations that are processed similarly by different I/O stack configurations. Figure 3 also shows that default Ext4 configurations are always sub-optimal and, under most settings, ranked lower than the top 40% configurations. For *M1-Mailserver-HDD1*, the default Ext4 configuration shows a normalized throughput of 0.39, which means that the optimal configuration performs 2.5 times better.

Table 4 lists optimal configurations for the same six hardware and workload settings. As we can see, optimal configurations depend on the specific hardware as well as the running workload. For *M1-Mailserver-HDD1*, the global best is a *Nilfs2* configuration. However, if we fix the workload, change the hardware, and get *M2-Mailserver-HDD3*, the optimum becomes an *Ext4* configuration. Similarly, fixing the hardware to *M2-*-SSD* and experimenting under different workloads leads to different optimal configurations. This proves our early

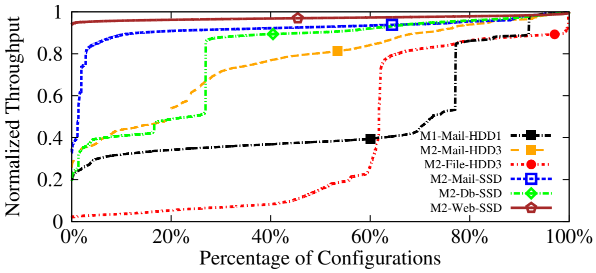

Figure 3: Throughput CDF with different hardware and workloads, with symbols marking the default Ext4 configurations.

claim that performance is sensitive to the environment (e.g., hardware, configuration, and workloads); this actually complicates the problem as results from one environment cannot be directly applied in another.

4.2 Comparative Analysis

Many optimization techniques have been applied to various auto-tuning tasks [71, 78]. However, previous efforts picked algorithms somewhat arbitrarily and evaluated only one algorithm at a time. Here we provide the first comparative study of multiple black-box optimization techniques on auto-tuning storage systems. As discussed in §2.2, we focus our evaluations on a representative set of optimization methods, and their common hyper-parameter settings, including 1) Simulated Annealing (SA), with a linear cooling schedule; 2) Genetic Algorithms (GAs) with population size of 8, mutation rate of 2%; 3) Deep Q-Networks (DQN) with experience replay [55] and $\epsilon = 0.2$, where ϵ; represents the probability of an agent taking random actions. 4) Bayesian Optimization (BO) with Expected Improvement (EI) and Gaussian prior; and 5) Random Search (RS), which merely performs random selection without replacement. We provide more discussion on the impact of hyper-parameters in §4.3. Note that SA, DQN, and RS experiments start with the default Ext4 configuration. GA and BO require several initial configurations (*prior points*), which we set to default configurations of all seven file systems. This allows us to simulate real-world use cases, where users often deploy their system with the default settings (and may manually optimize starting from the defaults). In the current experiments we assume that changing parameter values comes at no cost. In reality, parameters like *Block Size* may require re-formatting file systems.

Figure 4 presents one simulated run of each optimization method on *M2-Mailserver-HDD3*; the Y-axis shows the throughput value of the best configuration found so far, and the X-axis is the running time. All time-related metrics in this paper are based on the actual running time of evaluating each storage configuration, which is stored in our database. This includes both setup time and benchmarking time. We are not comparing the running

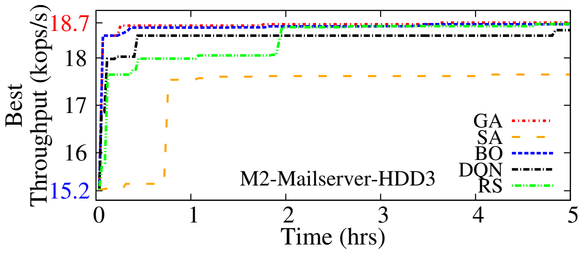

Figure 4: Highest throughput found over time, zooming in the $Y \in [15 : 19]$ range. The blue number (15.2) on the Y-axis shows the default, and the red one (18.7) shows the optimal.

costs (including any necessary training phases) for optimization methods here, which is our future work. Figure 4 is plotted by zooming in the range of $Y \in [15 : 19]$, with the blue number (15.2) on Y-axis represents the default, while the red one (18.7) shows the global optimal. Here we define a near-optimal configuration as one with throughput higher than 99% of the global optimal value. As shown in Figure 4, all five methods were able to gradually find higher performing configurations, but their effectiveness and speed differed a lot. SA performed the worst, and got stuck in a configuration with throughput value of less than 18K IOps. DQN was able to converge to a good configuration, but spent more time to achieve that than RS. GA and BO performed best out of these five tested optimization methods. They both successfully identified a near-optimal configuration within one hour. Interestingly, we observed that pure Random Search (RS) produced better results than some other optimization methods; the reason is that within the search space *M2-Mailserver-HDD3*, 4.5% of total configurations are near-optimal. RS needs only to hit one of them to reach good auto-tuning results.

Since exploration is one critical component of optimizations (see §2.4), their evaluation results could also exhibit some degree of randomness. To compare them more thoroughly, we ran each optimization technique on the same environment for 1,000 runs. Figure 5 shows the results, which evaluate the techniques' probability to find near-optimal configurations, defined the same as in Figure 4. The Y-axis shows the percentage of total runs that found a near-optimal configuration within a certain time (X-axis). Under *M2-Mailserver-HDD3*, seen in the upper part of Figure 5, SA had the lowest probability among 5 algorithms. Even after 5 hours, only around 80% of its runs found one near-optimal configuration, which shows that SA sometimes gets stuck in a local optimum. For other optimization methods, given enough time, over 90% of their runs converged to a near-optimal configuration, with BO outperforming GA, and GA outperforming DQN. RS shows the highest probability of finding near-optimal configurations when approaching 5 hours. This is reasonable because given enough time, a random selection will eventually hit near-optimal points.

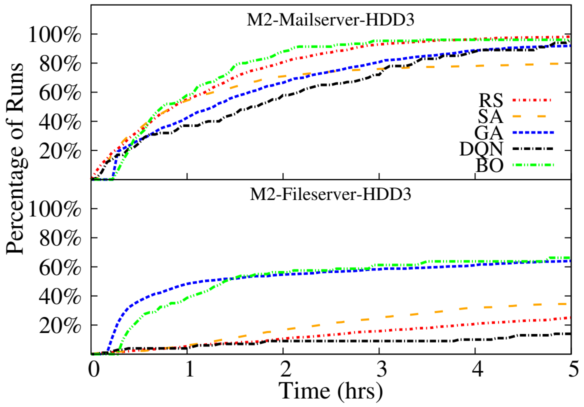

Figure 5: Comparing optimization methods' efficacy in finding near-optimal configurations. The Y-axis shows the percentage of total runs (1,000) that found near-optimal configurations within certain time (X-axis).

However, when conducting the same experiments under *M3-Fileserver-HDD3*, it becomes more difficult to find near-optimal configurations. GA and BO are still the best, though only 65% of their runs were able to find near-optimal configurations within 5 hours. SA, RS, and DQN have a probability of lower than 40% to do so, with DQN perform the worst. This is because the global optimum under *M2-Fileserver-HDD3* is a Btrfs configuration (see Table 4). It is more difficult for optimization algorithms to pick such configurations for the following reasons: 1) Few Btrfs configurations reside in the neighborhood of the default Ext4 configurations; 2) Fewer than 2% of all valid configurations are Btrfs ones, which make them less likely to be selected through mutation; 3) Only 0.2% of all configurations are considered near-optimal, compared with 4.5% in **Mailserver-HDD3**.

The above results focused on finding near-optimal configurations. However, another important aspect to compare is the system's performance *during* the auto-tuning process. This is especially important if the targeted system is deployed and online. Some randomness (exploration) is necessary when searching a complex parameter space, but ideally optimization algorithms should spend less time on bad configurations. To compare this, in Figure 6 we plotted the instantaneous throughput (Y-axis) over time (X-axis) for one run with each method under *M2-Mailserver-HDD3*.

BO and GA are still the best two methods in terms of instantaneous throughput. During the tuning process, occasionally they pick a worse configuration than the current one. However, they both possess the ability to quickly discard these unpromising configurations. GA achieves this by assigning the probability of surviving to next generation based on the fitness values (i.e., throughput). Configurations with low throughput values have a lower chance to be picked as parents, and thus their genes (parameter values) have a lower chance of appearing in configurations of the next generation (i.e., "survival of the fittest"). The reason for stable instantaneous throughputs with BO is that it uses an intelligent acquisition function to guide the selection of the next generation, with the goal of maximizing the potential gain; this makes BO less likely to choose a bad configuration. In contrast, SA performs poorly possibly because it lacks a history to guide the exploitation and exploration phases, and only uses its neighborhood information (and current temperature) to pick the next configuration. DQN shows similar results with RS, which is likely caused by the fact that DQN was originally designed as an agent interacting with an unknown environment, and thus a lot of exploration (randomness) occurs in the training phase [55,85].

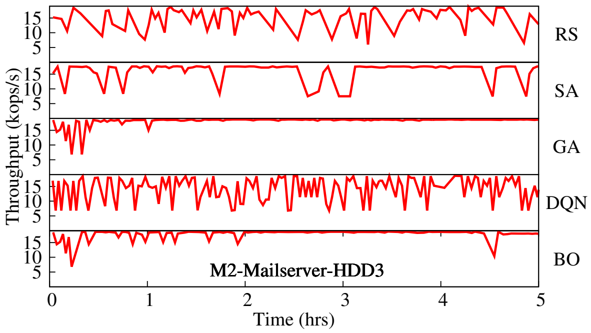

Figure 6: Comparing optimization methods' instantaneous performance (Y-axis) over time (X-axis).

In conclusion, our results demonstrated that the efficacy of different optimization algorithms vary a lot while applied in auto-tuning storage systems. The trade-off among *exploitation*, *exploration*, and *history* plays an important role in find near-optimal configurations efficiently. However, a well-known problem for many optimization techniques is that their performance depend heavily on hyper-parameter settings. Some of our observations may only apply to our specific settings and search spaces. This paper's main goal is not to provide guidelines on which methods are more suitable for auto-tuning storage systems; rather, we focused on comparing multiple methods and understanding their efficacy under different conditions.

4.3 Impact of Hyper-Parameters

Many optimization methods' efficacy depend on the specific hyper-parameter settings, and choosing the right hyper-parameters has caused headache to researchers for a long time [7, 8]. In this section we use GA as a case study, and show the impact of one hyper-parameter, the *mutation rate*, on auto-tuning results. The mutation rate controls the probability of randomly mutating one parameter to a different value, and aligns with the idea of *exploration*, as per §2.4.

Figure 7 shows the results from 7 sets of GA exper-

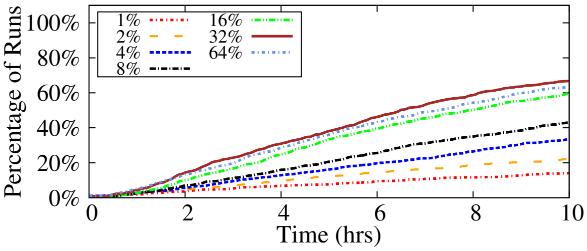

Figure 7: Impact of mutation rates on GA.

iments with different mutation rates (from 1% to 64%) under *M2-Mailserver-HDD3*. Each experiment was repeated for 1,000 runs. It is similar to Figure 5, but with the goal of finding near-optimal configurations whose throughput values are higher than **99.5%** of the global optimal. This makes the optimization more challenging, as GA already performs quite well on easier tasks (§4.2). As shown in the figure, when increasing the mutation rate, GA has a higher probability to converge to near-optimal configurations within a shorter time period. This is because GA works by identifying promising combination of alleles (parameter values) for the subset of dominant genes (parameters). We define dominant parameters as those having a higher impact on performance than all others. A higher mutation rate means a higher chance of exploration, and thus finding combinations of well-performing alleles for the dominant genes within a shorter time. We explain this effect more in §4.4. However, a mutation rate of 64% actually performs worse than 32%. This is because in order to reach near-optimal configurations, GA needs both exploration and exploitation. Exploration lets GA identify processing subspaces (i.e., combinations of certain parameter values) while exploitation helps GA search within promising subspaces. In this case, with a mutation rate of 64%, GA spends too much time on exploration (too much randomness), resulting in fewer chances for exploitation.

4.4 Peering into the Black Box

Despite some successful applications of black-box optimization on auto-tuning system parameters, few have explained how and why some techniques work better than others for certain problems. Here we take the first step towards unpacking the "black box" and provide some insights into their internals based on our evaluation results and storage domain knowledge.

Our attempts for explanations stem from a somewhat unexpected but beneficial behavior of GA in the experiments. We found that as GA runs, there is often a small set of alleles (parameter values) that dominate the current population and are unlikely to change. We present and explain this observation in Figure 8. The experiment was conducted on a parameter space consisting of 2,208 Ext3 configurations under *M2-Fileserver-SSD*. The X-axis shows 5 genes (parameters) separated by red gridlines, while one column represents one allele (parameter value). The parameters are denoted with their abbreviations from Table 2. The Y-axis shows the generation number, and we plotted only the first 8 generations. Cells were colored based on the number of alleles in each generation. More frequent alleles are colored with darker colors. In the first generation, the gene's alleles (parameter values) were quite diverse. For example, there were 3 alleles (1K, 2K, 4K) for the *Block Size* gene, and 3 alleles (journal, ordered, writeback) for the *Journal Option* gene. However, the diversity of alleles decreased in later generations, and several genes began to dominate and even converged to a single allele. For the *Block Size* gene, only the 4K allele survived and other two became extinct. Since GA was proposed by simulating the process of natural selection, where alleles with better fitness are more likely to survive, this suggests that GA works by identifying the combination of good alleles (storage parameter values), and producing offspring with these alleles. As shown in Figure 8, in the 8^{th} generation, all configurations have a *Block Size* of 4K and *Journal Option* of writeback.

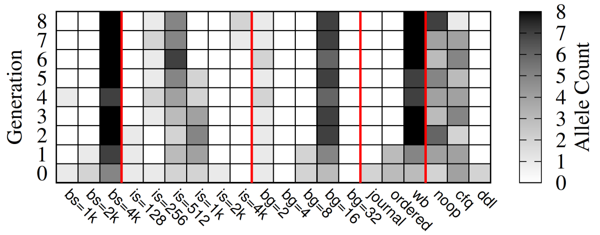

Figure 8: Number of alleles in the first 8 GA generations, with more frequent ones colored with darker colors.

To confirm the above observations, in Figure 9 we plotted all Ext3-SSD configurations, with one dot corresponding to one configuration. Configurations are separated based on the *Journal Option*, shown as the X-axis, and colored based on their *Block Size*. To clearly see all points within each X-axis section, we ordered configurations by their unique identification number in our database. The Y-axis represents throughput values. This resulted in the formation of nine "clusters" on the graph, each corresponding to a fixed ⟨*Journal Option*, *Block Size*⟩ pair. We can see that configurations with *data=ordered* tend to produce higher throughput than those with *data=journal*, and *data=writeback* produces the best throughput. This is somewhat expected from a storage point of view, as Ext3's more fault tolerant journal option (*data=journal*) may hurt throughput by writing data as well as meta-data to the journal first. Moreover, among journal configurations with *data=writeback*, those with a 4K *Block Size* turn out to produce the highest throughput. This aligns with our observation from Figure 8 that GA works by identifying a subset of genes that have a greater impact

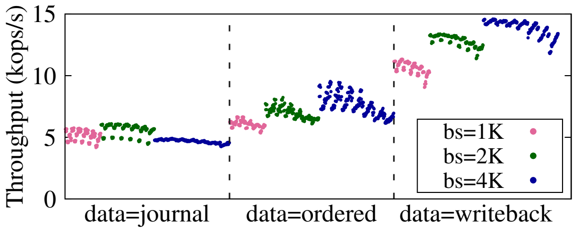

Figure 9: Scatter plot for all Ext3-SSD configurations, with one dot corresponding to one configuration.

on performance—*Block Size* and *Journal Option*—and finding the best alleles for them ([*4K, data=writeback*]).

Based on these observations, one interesting question to ask is whether the conclusion that a subset of parameters have greater impact on performance than other parameters, also holds for other file systems and workloads. To answer this question, we quantified the correlation between each parameter and throughput values. As most of our parameters are categorical or discrete numeric, whereas the throughput is continuous, we took a common approach to quantify the correlation between categorical and continuous variables [14]. We illustrate with the *Block Size* parameter as an example. Since it can take 3 values, we convert this parameter to three binary variables x_1, x_2, and x_3. If the *Block Size* is 1K, we assign $x_1 = 1$ and x_2 and x_3 are set to 0. Let Y represent the throughput values. We then do a linear regression with ordinary least squares (OLS) on Y and x_1, x_2, x_3. R^2 is a common metric in statistics to measure how the data fits a regression line. In our approach, R^2 actually quantifies the correlation between the selected parameter and throughput. We consider $R^2 > 0.6$ as an indication that the parameter has significant impact on performance, as is common in statistics [14]. The same calculation is applied to all parameters for each file system under *M2-Fileserver-SSD* and *M2-Dbserver-SSD*. Parameters with the highest R^2 values are colored in yellow background in Table 5. If all R^2 values are below 0.6, we simply leave the entries blank, meaning no highly correlated parameters were found. To find the second important parameter, the same process is applied to the remaining parameters, but with the value of the most important one fixed (to isolate its effect on the remaining parameters' importance). Taking Ext4 under *M2-Fileserver-SSD* as an example, we calculate R^2 values for all other parameters among configurations with the same *Journal Option*. For one parameter, 3 *Journal Options* lead to three R^2 values; we then take the maximum one as the R^2 value for this parameter. We color the parameter with the highest R^2 in Table 5 with a green background.

We can see that the correlated parameters are quite diverse, and depend a lot on file systems. For example, under *M2-Fileserver-SSD*, the two most important parameters for Ext3 (in descending order) are *Journal Option* and *Block Size*; this aligns with our observation in Figures 8 and 9. However, for Reiserfs, the top 2 changes to *I/O Scheduler* and *Journal Option*. Interestingly, all parameters for Btrfs come with low R^2 values, which indicates that no parameter has significant impact on system performance under *M2-Fileserver-SSD* with Btrfs. Correlation of parameters can also depend on the workloads. For instance, the two dominant parameters for XFS under *M2-Fileserver-SSD* are *Block Size* and *Allocation Group*. When the workload changes to *M2-Dbserver-SSD*, all parameters for XFS seem to have minor impact on performance. In this paper we are isolating the impact of each parameter, thus assuming that their effect on throughput is independent. Note that the above observations are made based on our collected data sets, and might change on different workloads and hardware. However, our methodology is generally applicable. Moreover, this paper's main goal is *not* to suggest guidelines on what specific storage configurations to deploy under certain workloads; rather, we focus on comparing multiple optimization methods and providing insights into their operation.

Table 5: Importance of parameters (measured by R^2), with the most important one colored in yellow and second in green.

The fact that parameters have varied impact on performance can also help explain the auto-tuning results in §4.2. Although our parameter space comes with 8 parameters, only a subset of them are highly correlated with performance. As long as the optimization algorithm identifies the "correct" combination of values for these dominant parameters, it will be able to find a near-optimal configuration. Similar behavior has been reported in hyper-parameter optimization problems [7]. For the experiments shown in Figure 4, near-optimal configurations take up 4.5% of the whole search space. Random Search (RS) needs to hit only one of them to achieve good auto-tuning results. GA's efficacy comes from assigning a higher chance of survival to configurations with a certain combination of values for the dominant parameters. BO stores its previous search experience (history) in a probabilistic surrogate model that it is building, which eventually encodes the combination of dominant parameter values that can result in good throughput values. SA does not work as well because it lacks history information to identify the dominant parameters: it wastes time changing less useful parameters and converges slowly. Similarly, DQN also spends lots of its effort on exploring unpromising spaces, which slows its ability to find near-optimal configurations.

5 Limitations and Future Work

In this paper we provided the first comparative analysis of applying multiple optimization methods on auto-tuning storage systems. However, auto-tuning is a complex topic and more effort is required. We list some limitations of this work and our future research directions below. ■ **(1)** We plan to extend the scope of evaluation with more complex workloads and search spaces. We will investigate more techniques, such as experiment design [80], as will as the impact of algorithm hyper-parameter settings [8]. ■ **(2)** We plan to improve traditional optimization techniques with new features, such as penalty functions to cope with costly parameter changes, stopping/restarting criteria, workload identification, handling noisy and unstable results [12], etc., which makes auto-tuning algorithms more robust to environment changes and more generally applicable in production systems.

6 Related Work

Auto-tuning computer systems. In recent years, several attempts were made to automate the tuning of storage systems. Strunk et al. [71] proposed to use utility functions combining different system metrics and applied GA to automate storage system provisioning. Babak et al. [5] utilized GA to optimize I/O performance of HDF5 applications. GA has also been applied for storage recovery problems [38]. More recently, Deep Q-Networks has been successfully applied in optimizing performance for Lustre [85]. Auto-tuning is also a hot topic in other computer systems: Bayesian Optimization was applied to find near-optimal configurations for databases [78] and Cloud VMs [3]. Other applied techniques include Evolutionary Strategies [62], Simulated Annealing [26, 35], Tabu Search [63], and more. However, previous work all focused on one or a few techniques. One contribution of our work is to provide the first comparative study of multiple, applicable optimization methods on their efficacy in auto-tuning storage systems from various aspects. We also provide some insights into the working mechanism of auto-tuning.

Hyper-parameter tuning. Evolutionary Algorithms [59], Reinforcement Learning [6], and Bayesian Optimization [22] have been applied to hyper-parameter optimization for ML algorithms. Bergstra and Bengio [8] found that randomly chosen trials are more efficient for hyper-parameter optimization than trials on a grid, and explained the cause as the objective function having a low effective dimensionality. Another direction of research focuses on eliminating all hyper-parameters and tries to propose non-parametric versions of optimization methods. Examples of this include GA [31,51] and BO [68].

7 Conclusions

Optimizing storage systems can provide significant benefits especially in improving I/O performance. Alas, storage systems are getting more complex, contain many parameters and an immense number of possible configurations; manual tuning is therefore impractical. Worse, many of those parameters are non-linear or non-numeric; traditional linear-regression-based optimization techniques do not work well for such problems. Several efforts were made to apply black-box optimization techniques to auto-tune storage systems, but they all used only one or few techniques. In this work, we performed the first comparative study, and offered the following four contributions. **(1)** We evaluated *five* popular but different auto-tuning techniques, varied some of their hyper-parameters, and applied them to storage and file systems. **(2)** We show that the speed at which the techniques can find optimal or near-optimal configurations (in terms of throughput) depends on the hardware, software, and workload; this means that no single technique can "rule them all." **(3)** We explain why some techniques appear to work better than others. **(4)** For more than two years, we have collected a large data set of over 450,000 data points; this data set was used in this study and we plan to release it.

Abstract

[1] Finding top-*k* elephant flows is a critical task in network traffic measurement, with many applications in congestion control, anomaly detection and traffic engineering. As the line rates keep increasing in today's networks, designing accurate and fast algorithms for online identification of elephant flows becomes more and more challenging. The prior algorithms are seriously limited in achieving accuracy under the constraints of heavy traffic and small on-chip memory in use. We observe that the basic strategies adopted by these algorithms either require significant space overhead to measure the sizes of all flows or incur significant inaccuracy when deciding which flows to keep track of. In this paper, we adopt a new strategy, called *count-with-exponential-decay*, to achieve space-accuracy balance by actively removing small flows through decaying, while minimizing the impact on large flows, so as to achieve high precision in finding top-*k* elephant flows. Moreover, the proposed algorithm called HeavyKeeper incurs small, constant processing overhead per packet and thus supports high line rates. Experimental results show that HeavyKeeper algorithm achieves 99.99% precision with a small memory size, and reduces the error by around 3 orders of magnitude on average compared to the state-of-the-art.

1 Introduction

1.1 Background and Motivation

Finding the largest *k* flows, also referred to as the top-*k* elephant flows, is a fundamental network management function, where a flow's ID is usually defined as a combination of certain packet header fields, such as source IP address, destination IP address, source port, destination port, and protocol type, and the size of a flow is defined as the number of packets of the flow. Elephant flows contribute a large portion of network traffic. Many management applications can benefit from a function that can find them efficiently, such as congestion control by dynamically scheduling elephant flows [1], network capacity planning [2], anomaly detection [3], and caching of forwarding table entries [4]. Such a function also has applications beyond networking in areas such as data mining [5–7], information retrieval [8], databases [9], and security [10, 11].

In real network traffic, it is well known that the distribution of flow sizes (the number of packets in a flow), is highly skewed [12–21], *i.e.*, the majority are mouse flows, while the minority are elephant flows. most flows are small while a few flows are very large. The small flows are usually called *mouse flows*, while the large ones are called *elephant flows*.

Finding the top-*k* elephant flows (or top-*k* flows for short) in high-speed networks is a challenging task. [22] Extremely high line rates of modern networks make it practically impossible to accurately track the information of all flows. Consequently, approximate methods have been proposed in the literature and gained wide acceptance [14, 23–27]. In order to keep up with the line rates, these algorithms are expected to use on-chip memory such as SRAM whose latency is around 1ns [28, 29], in contrast to a latency of around 50ns when off-chip DRAM is used [29]. However, on-chip memory is small. Adding to the challenge, it is highly desirable to keep per-packet processing overhead small and constant, which helps pipelining.

Traditional solutions to finding the top-*k* flows follow two basic strategies: *count-all* and *admit-all-count-some*. The count-all strategy relies on a sketch (*e.g.*, CM sketch [14]) to measure the sizes of all flows, while us-

ing a min-heap to keep track of the top-k flows. For each incoming packet, it records the packet in the sketch and retrieves from the sketch an estimate $\hat{n}_i$ for the size of the flow f_i that the packet belongs to. If $\hat{n}_i$ is larger than the smallest flow size in the min-heap, it replaces the smallest flow in the heap by flow f_i. As a large sketch is needed to count all flows, these solutions are not memory efficient.

The *admit-all-count-some* strategy is adopted by Frequent [30], Lossy Counting [26], Space-Saving [24] and CSS [23]. These algorithms are similar to each other. To save memory, Space-Saving only maintains a data structure called Stream-Summary to counts only some flows (m flows). Each new flow will be inserted into the summary, replacing the smallest existing flow. The initial size of the new flow is set as $\hat{n}_{min}+1$, where $\hat{n}_{min}$ is the size of the smallest flow in the summary. By keeping m flows in the summary, the algorithm will report the largest k flows among them, where $m > k$. It assumes every new incoming flow is an elephant, and expels the smallest one in the summary to make room for the new one. But most flows are mouse flows. Such an assumption causes significant error, especially under tight memory (for a limited value of m).

1.2 Our Proposed Solution

In this paper, we propose a new algorithm, HeavyKeeper, based on a different strategy, called *count-with-exponential-decay*, which keeps all elephant flows while drastically reducing space wasted on mouse flows. Unlike *count-all*, our strategy only keeps track of a small number of flows. Unlike *admit-all-count-some*, we do not automatically admit new flows into our data structure and the vast majority of mouse flows will be by-passed. For a small number of mouse flows that do enter our data structure, they will decay away to make room for true elephants. The decay is not uniform for the flows in our data structure. The design of exponential decay is biased against small flows, and it has a smaller impact on larger flows. This design works extremely well with real traffic traces under small memory where the previous strategies will fail.

Main experimental results: As shown in Table 1, when compared with *Space-Saving*, *Lossy counting*, *CSS*, and *CM sketch*, HeavyKeeper achieves 99.99% percent precision, and much smaller error than all of them.

Table 1: Main experimental results.
Precision is defined as the ratio between the number of correctly reported elephant flows and the total number of reported flows.

Algorithm	**Top-k precision**	**Avg. relative error of flow sizes**
Space-Saving [24]	0.27	172.7222
Lossy counting [26]	0.39	54.8440
CSS [23]	0.49	18.9356
CM sketch [14]	0.93	0.2951
HeavyKeeper	0.9999	0.0011

Contributions: This paper makes the following contributions.

1. We propose a new data structure, named HeavyKeeper, which achieves high precision for finding top-k flows, and achieves constant and fast speed as well as high memory efficiency.

2. We develop a mathematical analysis for HeavyKeeper, to theoretically prove its high precision.

3. We conduct extensive experiments on real network streams and synthetic datasets, and results show that HeavyKeeper reduces the error by around 3 orders of magnitude on average compared to the state-of-the-art.

4. We integrate HeavyKeeper and other related algorithms with Open vSwitch (OVS) platform. We also conduct experiments on throughput on OVS platform to show the impact of the algorithms. The results show that HeavyKeeper has little impact on the throughput, while other algorithms decrease the throughput significantly. We release the source code of HeavyKeeper and related algorithms at GitHub [31].

2 Preliminaries

2.1 Problem Statement

Simply speaking, finding top-k flows refers to finding the largest k flows. Let $\mathscr{P} = \mathbb{P}_1, \mathbb{P}_2, \cdots, \mathbb{P}_N$ be a network stream with N packets. Each packet $\mathbb{P}_l$ ($1 \leqslant l \leqslant N$) belongs to a flow f_i, where $f_i \in \mathscr{F} = \{f_1, f_2, \cdots, f_M\}$ and $\mathscr{F}$ is the set of flows. Let n_i be the real flow size of flow f_i in $\mathscr{P}$. We order all flows ($f_1, f_2, \cdots, f_M$) so that $n_1 \geqslant n_2 \geqslant \cdots \geqslant n_M$.

Given an integer k and a network stream $\mathscr{P}$, the output of top-k is a list of k flows from $\mathscr{F}$ with the largest flow sizes, *i.e.*, $f_1, f_2, \cdots, f_k$.

2.2 Prior Art and Limitations

The count-all strategy: As mentioned above, the *count-all* strategy uses sketches (such as the CM sketch [14] or the Count sketch [25]) to record the sizes of all flows, and uses a min-heap to keep track of the top-k flows, including the flow IDs and their flow sizes. Take the CM sketch as an example. It records packets in a CM sketch, consisting of a pool of counters. For each arrival packet, it hashes the packet's flow ID f to d counters and increases these d counters by one. The smallest value of the d counters is used as the estimated size of the flow.

If this estimated flow size is larger than the smallest flow size in the min-heap, we replace the smallest flow in the heap by flow f.

The problem is that all flows are pseudo-randomly mapped to the same pool of counters through hashing. Each counter may be shared by multiple flows, and thus record the sum of sizes of all these flows. Consequently, the CM sketch has an over-estimation problem, which will become severe in a tight memory space where the number of counters is far smaller than the number of flows, resulting in aggressive sharing. In such a case, a small flow may be treated as an elephant flow if all its d counters are shared with real elephant flows.

The admit-all-count-some strategy: As mentioned above, quite a few algorithms use the *admit-all-count-some* strategy, including Frequent [30], Lossy counting [26], and Space-Saving [24], with Space-Saving being the most widely used among them. Take Space-Saving as an example. Recognizing that it is infeasible to count the sizes of all flows, Space-Saving counts only the sizes of some flows in a data structure called Stream-Summary, which incurs $O(1)$ overhead to search or update a flow, or find the smallest flow. The selection of which flows to store in the summary is rather simple: For each arrival packet, if its flow ID is not in the summary, the flow will be admitted into the summary, replacing the smallest existing flow. The new flow's initial size is set to $\hat{n}_{min}+1$, where $\hat{n}_{min}$ is the smallest flow size in the summary before replacement. Therefore, later incoming mouse flows will be largely over-estimated, which is drastically inaccurate. In the end, the largest k flows in the summary will be reported. A recent work CSS [23] is proposed based on Space-Saving. It inherits the above strategy of Space-Saving, and redesigns the data structure of Stream-Summary by using TinyTable [32] to reduce memory usage.

The strategy of *admit-all-count-some* is to admit all new flows while expelling the smallest existing ones from the summary. To give new flows a chance to stay in the summary, their initial flow sizes are set as $\hat{n}_{min}+1$. Such a strategy drastically over-estimates sizes of flows, and we show an example here. Assume $\hat{n}_{min} = 10,000$. Given an new incoming flow, its size will be over-estimated as $10,001$. Early arrived elephant flows with flow sizes less than $10,008$ will be expelled. Therefore, massive mouse flows will cause significant over-estimation errors.

3 The Design of HeavyKeeper

In this section, we present the data structure and algorithm of our HeavyKeeper, and show how to find the top-k flows accurately and efficiently.

3.1 Rationale

We aim to use a small hash table to store all elephant flows. As there are a great number of flows, each bucket of the hash table will be mapped by many flows, and we aim to store only the largest flow with its size, which cannot be achieved with no error when using small memory. To address this problem, we propose a probabilistic method called *exponential-weakening decay*. Specifically, when the incoming flow is different from the flow in the hashed bucket, we decay the flow size with a decay probability, which is exponentially smaller as the flow size grows larger. If the flow size is decayed to 0, it replaces the original flow with the new flow. In this way, mouse flows can easily be decayed to 0, while elephant flows can easily keep stable in the bucket. There are two shortcomings: 1) With a small probability we elect the wrong flow as the largest flow; 2) The stored flow size is a little smaller than the true frequency because of the decay operations. To address these problems, we use multiple hash tables with different hash functions. An elephant flow could be stored in multiple hash tables, we choose the recorded largest size, minimizing the error of flow sizes.

3.2 The HeavyKeeper Structure

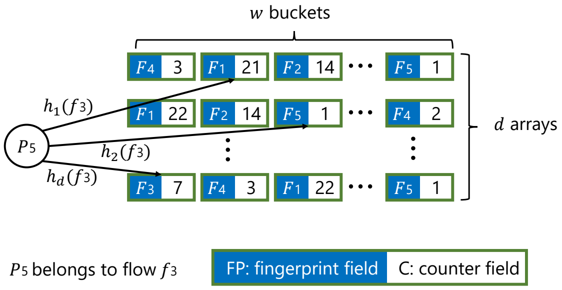

Figure 1: The data structure of HeavyKeeper.

As shown in Figure 1, HeavyKeeper is comprised of d arrays, and each array is comprised of w buckets. Each bucket consists of two fields: a fingerprint field and a counter field.[2] For convenience, we use $A_j[t]$ to represent the t^{th} bucket in the j^{th} array, and use $A_j[t].FP$ and $A_j[t].C$ to represent its fingerprint field and counter field, respectively. Arrays $A_1...A_d$ are associated with hash functions $h_1(.)...h_d(.)$, respectively. These d hash functions $h_1(.)...h_d(.)$ need to be pairwise independent.

Insertion: Initially, all fingerprint fields are *null*, and all counter fields are 0. For each incoming packet $\mathbb{P}_l$ belong-

[2] The fingerprint of a flow is a hash value generated by a certain function (for example, if we use $h_f(.)$ as the fingerprint hash function, the fingerprint of flow f_j is $h_f(f_j)$). Although there can be hash collisions among flows, the probability is quite small. For example, if we set the fingerprint size to 16 bits, and there are 10000 buckets in the array, the probability of fingerprint collisions is $1.52*10^{-3}$.

ing to flow f_i, HeavyKeeper computes the d hash functions, and maps f_i to d buckets $A_j[h_j(f_i)]$ $(1 \leqslant j \leqslant d)$ (one bucket in each array), which we call ***d* mapped buckets** for convenience. As shown in Figure 2, for each mapped bucket, HeavyKeeper applies different strategies for the following three cases:

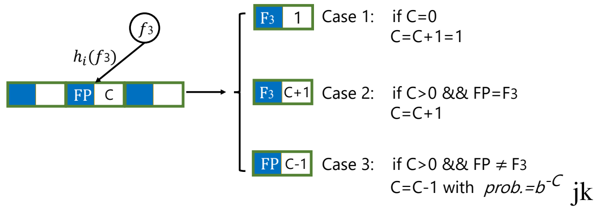

Figure 2: The main insertion cases of HeavyKeeper. Note: 1) $\mathbb{F}_3$ is the fingerprint of flow f_3. 2) $b > 1$ and $b \approx 1$ (*e.g.*, $b = 1.08$). 3) In Case 3, when C is decayed to 0, the fingerprint field will be replaced by $\mathbb{F}_3$, and then counter C is set to 1.

Case 1: When $A_j[h_j(f_i)].C = 0$. It means that no flow has been mapped to this bucket, then HeavyKeeper sets $A_j[h_j(f_i)].FP = \mathbb{F}_i$ and $A_j[h_j(f_i)].C = 1$, where $\mathbb{F}_i$ represents the fingerprint of f_i.

Case 2: When $A_j[h_j(f_i)].C > 0$ and $A_j[h_j(f_i)].FP = \mathbb{F}_i$. It means $A_j[h_j(f_i)].C$ is probably the estimated size of f_i. In this case, HeavyKeeper increments $A_j[h_j(f_i)].C$ by 1.

Case 3: When $A_j[h_j(f_i)].C > 0$ and $A_j[h_j(f_i)].FP \neq \mathbb{F}_i$. It means that $A_j[h_j(f_i)].C$ is not the estimated size of f_i. In here, HeavyKeeper applies the *exponential-weakening decay* strategy to this bucket: it decays $A_j[h_j(f_i)].C$ by 1 with a probability P_{decay}. After decay, if $A_j[h_j(f_i)].C = 0$, HeavyKeeper replaces $A_j[h_j(f_i)].FP$ with $\mathbb{F}_i$, and sets $A_j[h_j(f_i)].C$ to 1. Therefore, as long as flows are mapped to a bucket, its counter field will never be 0.

Query: To query the size of a flow f_i, HeavyKeeper first computes the d hash functions to get d buckets $A_j[h_j(f_i)]$ $(1 \leqslant j \leqslant d)$. Among the d mapped buckets, it chooses those buckets whose fingerprint fields are equal to $\mathbb{F}_i$. It then reports the maximum counter field of those buckets, *i.e.*, $max_{1 \leqslant j \leqslant d}\{A_j[h_j(f_i)].C\}$ where $A_j[h_j(f_i)].FP = \mathbb{F}_i$.

For convenience, for those d mapped buckets of f_i, if $A_j[h_j(f_i)].FP = \mathbb{F}_i$, we say that f_i is ***held*** at bucket $A_j[h_j(f_i)]$. Ignoring the limited impact of fingerprint collisions, we prove that *the reported size for each flow is equal to or smaller than the real flow size* in Section 4.1. If a flow is *held* at no mapped bucket, it reports that it is a mouse flow. If a flow is *held* at multiple buckets, HeavyKeeper reports the maximum counter field.

Decay probability: The decay probability P_{decay} in the exponential-weakening decay strategy is an important parameter. Here, we use the following exponential function to calculate the probability:

$$P_{decay} = b^{-C} \quad (b > 1)$$

where C is the value in the current counter field, and where b ($b > 1$ and $b \approx 1$, *e.g.*, $b = 1.08$) is a pre-defined exponential base number. Therefore, the larger size a flow has, the harder its size is decayed. For elephant flows, it is held at several buckets, and the corresponding counter fields are incremented regularly, while decayed with a very small probability. Therefore, the error rate for estimated sizes of elephant flows is very small.

Note: Our data structure of d arrays may show some similarity with that of CM [14]. But similarity stops there. CM records the sizes of all flows; we record the sizes of a small number of flows. CM does not store flow IDs; we do. CM stores information of each flow in d counters; we keep each flow mostly in one bucket, while d-hashing helps find an empty bucket. CM does not have to worry about the issue of kicking out existing flows to make room for new ones, which is what our exponential delay does.

Example: As shown in Figure 1, given an incoming packet $\mathbb{P}_5$ belonging to flow f_3, we compute the d hash functions to obtain one bucket in each array. In the mapped bucket of the first array, the fingerprint field is not equal to $\mathbb{F}_3$ and the counter field is 21, thus we decay the counter field from 21 to 20 with a probability of 1.08^{-21} (assume $b = 1.08$). In the second mapped bucket, the fingerprint field is not $\mathbb{F}_3$ yet, and with a probability of 1.08^{-1}, we decay the counter field from 1 to 0. If the counter field is decayed to 0, we set the fingerprint field to $\mathbb{F}_3$, and set the counter field to 1. In the last mapped bucket, the fingerprint field is $\mathbb{F}_3$, we increment the counter field from 7 to 8.

Analysis: HeavyKeeper uses fingerprint to identify and keep elephant flows. If a mouse flow with a small flow size is held at a bucket, it will be replaced by other flows mapped to this bucket soon, because each flow mapped to this bucket with a different fingerprint will decay the counter field with a high probability ($b^{-C} \to 1$ when C is small). If an elephant flow is held at a bucket, the corresponding counter field can easily be incremented to a large value since elephant flows have many incoming packets. Moreover, the decay probability becomes very small ($b^{-C} \to 0$ when C is large) as the counter field increases to a large value. Therefore, mouse flows can hardly be held in HeavyKeeper for a long time, and thus have a large probability to be *passers-by* of HeavyKeeper. However, elephant flows can keep stable in HeavyKeeper, and the estimated sizes of elephant flows are accurate.

3.3 Basic Version for Finding the Top-*k* Elephant Flows

To find top-*k* elephant flows, our basic version just uses a HeavyKeeper and a min-heap. The min-heap is used to store the IDs and sizes of top-*k* flows. For each incoming packet $\mathbb{P}_l$ belonging to flow f_i, we first insert it into HeavyKeeper. Suppose that HeavyKeeper reports the size of f_i as $\hat{n}_i$. If f_i is already in the min-heap, we update its estimated flow size with $max(\hat{n}_i, min\_heap[f_i])$, where $min\_heap[f_i]$ is the recorded size of f_i in min-heap. Otherwise, if $\hat{n}_i$ is larger than the smallest flow size which is in the root node of the min-heap, we expel the root node from the min-heap, and insert f_i with $\hat{n}_i$ into the min-heap. To query top-k flows, we simply report the k flows in the min-heap with their estimated flow sizes.

3.4 Optimizations

In this section, we propose further optimization methods to avoid accidental errors and improve speed.

Optimization I: Fingerprint Collisions Detection.
Problems: Assume that there is a bucket in HeavyKeeper where flow f_i is held, and a mouse flow f_j mapped to the same bucket has the same fingerprint as f_i, *i.e.*, $\mathbb{F}_i = \mathbb{F}_j$ due to hash collisions. Then, the mouse flow f_j is also held at this bucket, and its estimated size is drastically over-estimated. In the worst case, if flow f_j has a fingerprint collision in all d arrays, the mouse flow f_j will probably be inserted into the min-heap. It can hardly be expelled due to its drastically over-estimated size. To address this problem, we propose a solution based on the following Theorem.

Theorem 1. *When there is no fingerprint collision, after a flow f_i is inserted into HeavyKeeper, if its estimated size $\hat{n}_i$ is larger than n_{min}, then we must have*

$$\hat{n}_i = n_{min} + 1$$

The proof of this Theorem is not hard to derive and we skip it due to space limitations.

Solution: Based on Theorem 1, if f_i is not in the min-heap but $\hat{n}_i > n_{min} + 1$, then f_i is a mouse flow whose size is drastically over-estimated due to fingerprint collision. Therefore, we should not insert f_i into the min-heap in this case.

Optimization II: Selective Increment.
Problem: If a flow f_i is not in the min-heap, then the estimated flow size should be no larger than n_{min}. However, due to fingerprint collisions, there could be some mapped buckets of flow f_i where the fingerprint field is $\mathbb{F}_i$ and the counter field is larger than n_{min}. In this case, flow f_i is not the flow that is held at this bucket, and thus increasing the corresponding counter field can only incur extra error.

Solution: In this case, instead of incrementing or decaying the corresponding counter field, we make no change.

Optimization III: Speed Acceleration.
Problem: Our basic version of using the min-heap is the most memory efficient solution. However, the processing speed is limited, because the time complexity for updating and searching a flow in the min-heap is $O(log(k))$ and $O(k)$ respectively, which are time-consuming.

Solution: The min-heap is actually used to record the flow IDs of elephant flows and their estimated flow sizes. In this optimization version, instead of using the min-heap, we use a single array to record the flow IDs. Specifically, we define a flow size threshold η (*e.g.*, $\eta = 1000$). For each incoming flow, if its estimated size is equal to η, we record the flow ID in the array. As we record the fingerprints of elephant flows, the flow size will increases at most by 1 for each incoming packet when assuming there is no fingerprint collision. Therefore, any flow whose estimated size is larger than or equal to η is recorded in this array once in most cases. Further, this optimization of using an array is only suitable for sketches that record flow IDs or fingerprints.

Algorithm 1: Insertion process for finding top-k flows.

```
Input: A packet $\mathbb{P}_l$ belonging to flow $f_i$
$flag \leftarrow false$;
if $f_i \in min\_heap$ then
    $flag \leftarrow true$;
$maxv \leftarrow 0$;
for $j \leftarrow 1$ to $d$ do
    $C \leftarrow A_j[h_j(f_i)].C$;
    if $A_j[h_j(f_i)].FP = \mathbb{F}_i$ then
        if $flag = true$ or $C < min\_heap.n_{min}$ then
            $A_j[h_j(f_i)].C++$;
        $maxv \leftarrow max(maxv, A_j[h_j(f_i)].C)$;
    else
        if $rand(1) < b^{-C}$ then
            $A_j[h_j(f_i)].C--$;
            if $A_j[h_j(f_i)].C = 0$ then
                $A_j[h_j(f_i)].FP \leftarrow \mathbb{F}_i$;
                $A_j[h_j(f_i)].C \leftarrow 1$;
                $maxv \leftarrow max(maxv, 1)$;
if $flag = true$ then
    $min\_heap[f_i] \leftarrow max(maxv, min\_heap[f_i])$;
else
    if $min\_heap$ has empty buckets or $maxv - n_{min} = 1$ then
        $min\_heap.insert(f_i)$;
```

3.5 Final Version

Based on the basic version, we propose the common final version using the first two optimization methods, and propose the accelerated final version using the third optimization methods. The insertion and query processes of the common final version of our algorithm are as follows (see pseudo-code in Algorithm 1).

Insertion: All counters and fingerprints in HeavyKeeper and the min-heap are initialized to 0. For each incoming packet $\mathbb{P}_l$ belonging to flow f_i, these are the following three steps for each insertion:

Step 1: Check whether flow f_i is already monitored by the min-heap. For convenience, we use a boolean variable $flag$ to represent the result.

Step 2: Insert f_i into HeavyKeeper. According to Optimization II, for each mapped bucket, if the fingerprint field is equal to $\mathbb{F}_i$, increment the counter field only when $flag = true$ or $C < n_{min}$, where C is the original value in the counter field.

Step 3: Get an estimated size $\hat{n}_i$ of flow f_i from HeavyKeeper. According to Optimization III, if $flag = true$, we update the estimated size of flow f_i in the min-heap with $\hat{n}_i$. If $flag = false$, insert flow f_i into the min-heap with $\hat{n}_i$ in only two cases: 1) the number of flows that are in the min-heap is less than k; 2) $\hat{n}_i = n_{min} + 1$.

Query top-k flows: It reports the k flows recorded in the min-heap and their estimated flow sizes.

Analysis: Since HeavyKeeper achieves very small error rate on the flow size estimation of elephant flows, it can significantly reduce the error in finding top-*k* elephant flows. Furthermore, the first two optimizations reduce the impact of fingerprint collisions, and enhance the precision of finding top-*k* elephant flows and their flow size estimation. The third optimization method has a constant processing time for insertions: 1) For most incoming packets, they are only inserted into HeavyKeeper, which requires d (*e.g.*, $d = 2$) memory accesses. 2) For some packets belonging to elephant flows, they are inserted into both HeavyKeeper and the array. It requires $d+1$ memory accesses in the worst case. Therefore, the time complexity of insertion process is $O(d)$. Therefore, the processing speed of the accelerated final version is fast on average and constant in the worst case.

3.6 Other uses of HeavyKeeper

Besides finding top-*k* flows in a network stream, HeavyKeeper can also perform other tasks in network traffic measurement, such as heavy hitter detection and change detection. Due to space limitations, here we only briefly introduce how to perform these tasks using HeavyKeeper.

Heavy hitter detection: Given a threshold θ, a heavy hitter [13] is a flow whose size $n_i > \theta N$, where N is the number of packets in total. The heavy hitter detection algorithm is very similar to that of finding top-*k* flows. The only difference is that when querying heavy hitters, it reports those flows whose estimated size is larger than θN in min-heap.

Change detection: The network stream is divided into fixed-size time bins. Given a flow, if the difference of its flow sizes in two adjacent time bins is larger than a predefined threshold, then the flow is called a heavy change [13, 33]. We use the very flow ID as the fingerprint of each flow. For two adjacent time bins, we insert their packets into two different HeavyKeepers. By comparing buckets in the corresponding location in the two HeavyKeepers, we obtain the estimated difference of sizes of the flows, and report the heavy changes by checking if the difference is larger than the threshold.

4 Mathematical Analysis

In this section, we first prove that there is no over-estimation in HeavyKeeper, and then derive the formula of its error bounds.

4.1 Proof of No Over-estimation Error of HeavyKeeper

Theorem 2. *Let $n_i(t)$ be the real size of flow f_i at time t, and let $A_j[h_j(f_i)](t).C$ be the counter field of the mapped bucket of flow f_i in the j^{th} array at time t. If there is no fingerprint collision, then*

$$\forall j,t,\ A_j[h_j(f_i)](t).C \leqslant n_i(t) \tag{1}$$

Proof. When $t = 0$, no packet maps into this bucket, so $n_i(0) = 0$ and $A_j[h_j(f_i)](t).C = 0$. Therefore, the theorem holds at time 0. Let's now prove by induction that the theorem holds at any time.

When $t = 0$, the theorem holds.

If the theorem holds when $t = v$, let's prove that the theorem also holds when $t = v+1$. There are three cases when $t = v+1$:

Case 1: The new incoming packet is not mapped to bucket $A_j[h_j(f_i)]$. Then $n_i(v+1) = n_i(v)$ and $A_j[h_j(f_i)](v+1).C = A_j[h_j(f_i)](v).C$. Therefore, $A_j[h_j(f_i)](v+1).C \leqslant n_i(v+1)$.

Case 2: The new incoming packet belongs to flow f_i. Then $n_i(v+1) = n_i(v)+1$ and $A_j[h_j(f_i)](v+1).C = A_j[h_j(f_i)](v).C+1$. Therefore, $A_j[h_j(f_i)](v+1).C \leqslant n_i(v+1)$.

Case 3: The new incoming packet is mapped to bucket $A_j[h_j(f_i)]$ but does not belong to flow f_i. Then $A_j[h_j(f_i)](v+1).C = A_j[h_j(f_i)](v).C$ or $A_j[h_j(f_i)](v+1).C = A_j[h_j(f_i)](v).C-1$, and $n_i(v+1) = n_i(v)$. Therefore, $A_j[h_j(f_i)](v+1).C \leqslant n_i(v+1)$.

Therefore, for any time t,

$$A_j[h_j(f_i)](t).C \leqslant n_i(t)$$

□

4.2 Error Bound of HeavyKeeper

Definition 4.1. *Given a small positive number ε, $Pr\{n_i - \hat{n}_i \geqslant \lceil \varepsilon N \rceil\}$ ($n_i \geqslant \hat{n}_i$) represents the probability that the error of the estimated flow size $n_i - \hat{n}_i$ is larger than εN. If $Pr\{n_i - \hat{n}_i \geqslant \lceil \varepsilon N \rceil\} \leqslant \delta$, the algorithm is said to achieve (ε,δ)-counting.*

(ε,δ)-counting is a metric to evaluate the error rate of the algorithm. Here HeavyKeeper is proved to achieve (ε,δ)-counting, showing that HeavyKeeper achieves a low error rate in estimating the sizes of top-*k* flows.

Theorem 3. *Let's assume that there is no fingerprint collision and the fingerprint of an elephant flow is held at its mapped bucket all the time. Let's focus on one single array of HeavyKeeper. Given a small positive number ε, and an elephant flow f_i whose size is n_i is held at that bucket,*

$$Pr\{n_i - \hat{n}_i \geqslant \lceil \varepsilon N \rceil\} \leqslant \frac{1}{\varepsilon w n_i (b-1)} \tag{2}$$

where w is the width of each array, N the total number of packets, and b the exponential base.

Proof. Let's focus on the j^{th} array. Flow f_i is correctly reported, so at the end, the fingerprint of flow f_i is held in the $h_j(f_i)^{th}$ bucket of the j^{th} array. Let $I_{i,j,i'}$ be a binary random variable, defined as

$$I_{i,j,i'} = \begin{cases} 0 & (f_i = f_{i'}) \vee (h_j(f_i) \neq h_j(f_{i'})) \\ 1 & (f_i \neq f_{i'}) \wedge (h_j(f_i) = h_j(f_{i'})) \end{cases} \tag{3}$$

$I_{i,j,i'} = 1\ iff$ different flows f_i and $f_{i'}$ are held at the same bucket in the j^{th} array. We define random variable $X_{i,j}$ as:

$$X_{i,j} = \sum_{v=1}^{M} I_{i,j,i'} n_{i'} \tag{4}$$

$X_{i,j}$ represents the sum of the sizes of the flows held at the same bucket as flow f_i, except for the size of flow f_i itself. Assume that for each incoming packet, if it belongs to flow f_i, the counter field is incremented by 1; if not, the counter field is decayed with a certain probability. We have

$$n_i - X_{i,j} \leqslant A_j[h_j(f_i)].C \leqslant n_i \tag{5}$$

Specifically, if all packets that do not belong to flow f_i decay the counter field, then $A_j[h_j(f_i)].C = n_i - X_{i,j}$. If those packets do not decay the counter field, then $A_j[h_j(f_i)].C = n_i$. Let's define another random variable $P_{i,j,l}$. Among the $X_{i,j}$ packets defined above, $P_{i,j,l}$ is defined as the probability that the l^{th} packet decays the counter field. Therefore,

$$A_j[h_j(f_i)].C = n_i - \sum_{l=1}^{X_{i,j}} P_{i,j,l} \tag{6}$$

Given a small positive number ε, the following formula based on the Markov inequality holds

$$\begin{aligned} &Pr\{A_j[h_j(f_i)].C \leqslant n_i - \varepsilon N\} \\ &= Pr\{n_i - \sum_{l=1}^{X_{i,j}} P_{i,j,l} \leqslant n_i - \varepsilon N\} \\ &= Pr\{\sum_{l=1}^{X_{i,j}} P_{i,j,l} \geqslant \varepsilon N\} \leqslant \frac{E(\sum_{l=1}^{X_{i,j}} P_{i,j,l})}{\varepsilon N} \end{aligned} \tag{7}$$

Now let's focus on $E(\sum_{l=1}^{X_{i,j}} P_{i,j,l})$. Assume that all packets are uniformly distributed, we have the following formula:

$$Pr\{P_{i,j,l} = \frac{1}{b^{\mathrm{C}}}\} = \frac{1}{A_j[h_j(f_i)].C} = \frac{1}{n_i - E(\sum_{l=1}^{X_{i,j}} P_{i,j,l})} \tag{8}$$

where $1 \leqslant \mathrm{C} \leqslant n_i - E(\sum_{l=1}^{X_{i,j}} P_{i,j,l})$. Let β be $n_i - E(\sum_{l=1}^{X_{i,j}} P_{i,j,l})$ for convenience. As a result,

$$\begin{aligned} E(\sum_{l=1}^{X_{i,j}} P_{i,j,l}) &= \sum_{l=1}^{E(X_{i,j})} E(P_{i,j,l}) \\ &= E(X_{i,j}) \sum_{\mathrm{C}=1}^{\beta} \frac{1}{b^{\mathrm{C}}} \frac{1}{\beta} = \frac{E(X_{i,j})}{\beta} \cdot \sum_{\mathrm{C}=1}^{\beta} \frac{1}{b^{\mathrm{C}}} \\ &= \frac{E(X_{i,j})}{\beta} \cdot \frac{\frac{1}{b}(1-(\frac{1}{b})^{\beta})}{1-\frac{1}{b}} \\ &\leqslant \frac{E(X_{i,j})}{n_i b} \cdot \frac{1-(\frac{1}{b})^{n_i}}{1-\frac{1}{b}} = \frac{E(X_{i,j})(1-(\frac{1}{b})^{n_i})}{n_i(b-1)} \end{aligned} \tag{9}$$

Furthermore, for $E(X_{i,j})$, based on Equation 4,

$$E(X_{i,j}) = E(\sum_{v=1}^{M} I_{i,j,i'} n_{i'}) \quad \leqslant \sum_{i'=1}^{M} n_{i'} E(I_{i,j,v}) = \frac{N}{w} \tag{10}$$

Therefore, based on Equation 9,

$$E(\sum_{l=1}^{X_{i,j}} P_{i,j,l}) \leqslant \frac{N(1-(\frac{1}{b})^{n_i})}{w n_i (b-1)} \leqslant \frac{N}{w n_i (b-1)} \tag{11}$$

then

$$\begin{aligned} Pr\{A_j[h_j(f_i)].C \leqslant n_i - \varepsilon N\} &\leqslant \frac{E(\sum_{l=1}^{X_{i,j}} P_{i,j,l})}{\varepsilon N} \\ &\leqslant \frac{N}{\varepsilon N w n_i (b-1)} = \frac{1}{\varepsilon w n_i (b-1)} \end{aligned}$$

Note that for an elephant flow f_i, n_i is very large, and $(\frac{1}{b})^{n_i} \approx 0$. The estimated size of f_i is the maximum value of $A_j[h_j(f_i)].C$, so we have

$$Pr\{n_i - \hat{n}_i \geqslant \lceil \varepsilon N \rceil\} \leqslant Pr\{\hat{n}_i \leqslant n_i - \varepsilon N\} \leqslant \frac{1}{\varepsilon w n_i (b-1)}$$

□

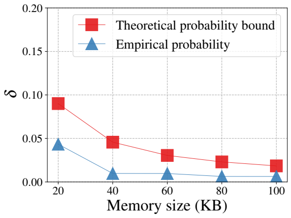

Figure 3: Theoretical bound and empirical probability of HeavyKeeper ($\varepsilon = 2^{-16}$).

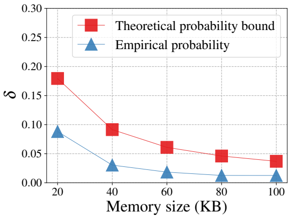

Figure 4: Theoretical bound and empirical probability of HeavyKeeper ($\varepsilon = 2^{-17}$).

To validate the correctness of this error bound, we conduct experiments on the dataset mentioned in Section 5.1. Here, we let $N = 10^7$, $\varepsilon = 2^{-16}$ and 2^{-17}, and vary memory size from 20KB to 100KB. As shown in Figure 3 and Figure 4, the empirical probability of HeavyKeeper is always lower than the theoretical probability bound, confirming the correctness of Theorem 3. Moreover, for the CSS algorithm, achieving such a (ε,δ)-counting requires at least $O(\varepsilon^{-1})$ buckets (*i.e.*, $m = O(\varepsilon^{-1})$), which requires a memory size much larger than 100KB. Therefore, HeavyKeeper is much more memory efficient than CSS.

5 Experimental Results

5.1 Experiment Setup

Platform: Our experiments are run on a server with dual 6-core CPUs (24 threads, Intel Xeon CPU E5-2620 @2 GHz) and 62 GB total system memory. Each core has two L1 caches with 32KB memory (one instruction cache and one data cache) and one 256KB L2 cache. All cores share one 15MB L3 cache.

Dataset:

1) Campus dataset: The first dataset is comprised of IP packets captured from the network of our campus. We rely on the usual definition of a flow, through its 5-tuple, *i.e.*, source IP address, destination IP address, source port, destination port, and protocol type. There are 10M packets in total, belonging to 1M flows. For convenience, we use *campus dataset* to denote this dataset.

2) CAIDA dataset: The second dataset is a CAIDA Anonymized Internet Trace from 2016 [34], made of anonymized IP packets. Each flow in this dataset is identified by the source and destination IP address. We use the first 10M packets, belonging to about 4.2M flows.

3) Synthetic datasets: We generate 10 different synthetic datasets according to a Zipf [35] distribution with different skewness (from 0.3 to 3.0). Each dataset is comprised of 32M packets, belonging to 1 $\sim$ 10M flows depending on the skewness. Each packet is 4 bytes long. The code of the dataset generator is the one from Web Polygraph [36].

Implementation: The implementation of HeavyKeeper is done in C++. We also implemented in C++ the other related algorithms including Space-Saving (SS), Lossy counting (LC), and CM sketch. The source code of CSS was provided by its author [23], and is written in Java. It is much slower than Space-Saving written in C++. Therefore, we do not include CSS in our speed experiments. For Space-Saving, Lossy counting, and CSS, the **number of buckets** m is determined by the memory size, which is usually much larger than k. When querying top-k flows, they report the largest k flows of them. For CM sketch, the size of the heap is k, the number of arrays is 3, and the width of each array is determined by the memory size. In our algorithm, the number of buckets m in Stream-Summary is equal to k, and HeavyKeeper occupies the rest memory size. Here we set $d = 2$, and w depends on the memory size. Both the fingerprint field and the counter field are 16-bit long. For experiments on throughput, we ignore operations on the min-heap for the CM sketch, because we can only record flows whose estimated size is larger than a pre-defined threshold.

5.2 Metrics

Precision: Precision is defined as $\frac{\mathscr{C}}{k}$. Only $\mathscr{C}$ flows belong to the real top-k flows.

Average Relative Error (ARE): ARE is defined as $\frac{1}{|\Psi|}\sum_{f_i\in\Psi}\frac{|\hat{n}_i - n_i|}{n_i}$, where Ψ is estimated set of top-k flows, $\hat{n}_i$ is the estimated size of flow f_i, and n_i is the real size of flow f_i. ARE evaluates the error rate of the estimated flow size reported by the algorithm.

Average Absolute Error (AAE): AAE is defined as $\frac{1}{|\Psi|}\sum_{f_i\in\Psi}|\hat{n}_i - n_i|$, similarly to ARE.

Throughput: We perform insertions of all packets, record the total time used, and calculate the throughput. The throughput is defined as $\frac{N}{T}$, where N is the total number of packets, and T is the total measured time. We use Million of insertions per second (Mps) to measure the throughput.

5.3 Experiments on Precision

To achieve a head-to-head comparison, we use the same memory size for each algorithm. We perform the experiments for varying memory size and k on the campus and CAIDA datasets, and varying skewness on the synthetic datasets. For experiments of varying memory size, we set $k = 100$. For experiments of varying k, we set the memory size to 100KB. For experiments of varying skewness, we set the memory size to 100KB and set $k = 1000$.

Precision vs. memory size: As shown in Figure 5, for the campus dataset, when memory size is 10KB, the precision of Space-Saving, Lossy counting, CSS, and CM

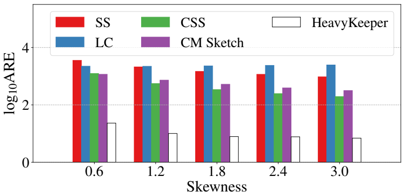

Figure 19: AAE vs. skewness (Synthetic).

sketch is respectively 10%, 11%, 19%, and 41%, while the one of HeavyKeeper is 82%. Furthermore, we find that the precision of HeavyKeeper reaches 100% for a memory size of 30KB, while the corresponding precision of Space-Saving, Lossy counting, CSS, and CM sketch is 27%, 39%, 49%, and 93%. This implies that HeavyKeeper has indeed much better precision than the other three algorithms. We find that Lossy counting is more accurate than Space-Saving. However, as will be mentioned later, Lossy counting is much slower than the other algorithms. For the CAIDA dataset (see Figure 6), we find that the precision of HeavyKeeper reaches 99.99% when memory size is larger than 20KB, while for Space-Saving, Lossy counting, CSS, and CM sketch, precision is respectively 18%, 33%, 34%, and 89% when memory size is 50KB.

Precision vs. *k*: As shown in Figure 7, for the campus dataset, as *k* becomes larger, the precision of HeavyKeeper stays high, while it degrades for other algorithms. For the campus dataset, as *k* becomes larger, the precision of HeavyKeeper is always higher than 95.9%, while that of Space-Saving, Lossy counting, CSS, and CM sketch reaches 32.7%, 44.1%, 50.1%, and 77.9% respectively when $k = 1000$. This happens for two main reasons: 1) larger *k* requires larger memory usage to store information about more flows; 2) as *k* increases, the difference of flow sizes among flows becomes smaller, so it is easy to mistake other flows for top-*k* flows. For the CAIDA dataset (Figure 8), we find that the precision of HeavyKeeper is always above 94%, while for Space-Saving, Lossy counting, CSS, and CM sketch, it is 26.6%, 37.1%, 44%, and 70% respectively when $k = 1000$.

Precision vs. skewness: As shown in Figure 9, the precision of HeavyKeeper reaches 99.99%. For all considered values of skewness, the precision of HeavyKeeper does not go below 94.9%, while the highest precision for Space-Saving, Lossy counting, CSS, and CM sketch is 46.8%, 41.3%, 74.5%, and 85.7%, respectively.

5.4 Experiments on AAE and ARE

In this section, we focus on the ARE and the AAE of the estimated frequency of reported top-*k* flows. We also conduct experiments with varying memory size, *k*, and skewness. The parameter settings are the same as in Section 5.3.

ARE vs. memory size: As shown in Figure 10, for the campus dataset, we find that the ARE of HeavyKeeper is smaller than 0.01 when memory size is larger than 20KB, while for Space-Saving, Lossy counting, CSS, and CM sketch, it is larger than 100. Furthermore, we find that the ARE of HeavyKeeper is between 100158 and 648291 times smaller than the one of Space-Saving, between 8450 and 78209 times smaller than the one of Lossy counting, between 945 and 49561 times smaller than the one of CSS, and between 279 and 226986 times smaller than the one of CM sketch. For the CAIDA dataset (see Figure 11), we find that the ARE of HeavyKeeper is between 21119 and 1190365 times smaller than the one of Space-Saving, between 2955 and 456275 times smaller than the one of Lossy counting, between 950 and 154047 times smaller than the one of CSS, and between 238 and 656145 times smaller than the one of CM sketch.

ARE vs. *k*: As shown in Figure 12, for the campus dataset, we find that the ARE of HeavyKeeper is between 25579 and 56791 times smaller than the one of Space-Saving, between 852 and 9312 times smaller than the one of Lossy counting, between 142 and 3132 times smaller than the one of CSS, and between 293 and 20370 times smaller than the of of CM sketch. For the CAIDA dataset (see Figure 13), we find that the ARE of HeavyKeeper is between 4506 and 121912 times smaller than the one of Space-Saving, between 383 and 23666 times smaller than the one of Lossy counting, between 137 and 8816 times smaller than the one of CSS, and between 66 and 27290 times smaller than the one of CM sketch.

ARE vs. skewness: As shown in Figure 14, for all considered values of skewness, we find that the ARE of HeavyKeeper is between 15566 and 27829 times smaller than that of Space-Saving, between 11915 and 41575 times smaller than that of Lossy counting, between 2174 and 6099 times smaller than that of CSS, and between 3819 and 10080 times smaller than that of CM sketch.

AAE vs. memory size: As shown in Figure 15, for the campus dataset, we find that the AAE of HeavyKeeper is between 433 and 3013 times smaller than that of Space-Saving, between 267 and 1221 times smaller than that of Lossy counting, between 200 and 758 times smaller than that of CSS, and between 155 and 428 times smaller than that of CM sketch. When memory size is 50KB, the AAE of HeavyKeeper is only 2.73, confirming that the estimated flow sizes of almost all reported flows are accurate. For the CAIDA dataset (see Figure 16), we find that the AAE of HeavyKeeper is between 697 and 1810 times smaller than that of Space-Saving, between 421 and 928 times smaller than that Lossy counting, between 289 and 647 times smaller than the one of CSS, and between 86 and 284 times smaller than that of CM sketch.

AAE vs. *k*: As shown in Figure 17, for the campus dataset, we find that the AAE of HeavyKeeper is between 271 and 1382 times smaller than that of Space-Saving, between 142 and 346 times smaller than that of Lossy counting, between 93 and 196 times smaller than that of CSS, and between 74 and 318 times smaller than that of CM sketch. For CAIDA dataset (see Figure 18), we find that the AAE of HeavyKeeper is between 206 and 694 times smaller than that of Space-Saving, between 118 and 329 times smaller than that of Lossy counting, between 73 and 199 times smaller than that of CSS, and between 67 and 121 times smaller than that of CM sketch.

AAE vs. skewness: From Figure 19, we find that the AAE of HeavyKeeper is between 137 and 209 times smaller than that of Space-Saving, between 96 and 355 times smaller than that of Lossy counting, between 28 and 55 times smaller than that of CSS, and between 45 and 73 times smaller than that of CM sketch.

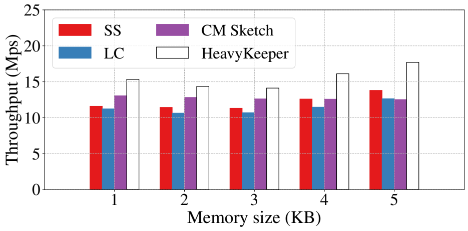

Figure 20: Throughput vs. memory size.

5.5 Experiments on Throughput

We now turn to the throughput of the algorithms. We only report results for the campus dataset due to space limitations. We set $k = 100$, and vary memory size from 10KB to 50KB. Here we use CAIDA datasets.

Throughput vs. memory size: As shown in Figure 20, we find that the throughput of HeavyKeeper is always higher than other algorithms. Indeed, the average throughput of HeavyKeeper is 15.52Mps, while it is 12.15Mps, 11.34Mps, and 12.72Mps for Space-Saving, Lossy counting, and CM sketch. These results show that HeavyKeeper not only is more accurate than previous work, but also achieves higher throughput as well.

6 Open vSwitch Deployment

In this section, we implement our HeavyKeeper algorithm on a software switch platform: Open vSwitch (OVS). We first present details of our implementation, and then present experimental results to show the performance of our algorithm running on Open vSwitch.

6.1 OVS Implementation

The OVS implementation of our HeavyKeeper algorithm consists of three components: 1) the modified OVS datapath, 2) the shared memory buffering flow IDs, and 3) the user-space program of HeavyKeeper processing flow IDs. For each incoming packet, it will be first inserted into the OVS datapath for forwarding. Besides, we modify the source codes of OVS datapath to parse the flow ID of the incoming packet, and then insert its flow ID into the shared memory (the shared memory is created initially). Finally, the user-space program will read the flow IDs from the shared memory, and process them as incoming packets.

In order to improve the performance of OVS, we integrate OVS with DPDK (Data Plane Development Kit). DPDK implements the datapath entirely in the user-space, and thus it eliminates the overhead of a context switch and memory copies between user-space and kernel-space.

6.2 OVS Evaluation

To evaluate the performance of HeavyKeeper implemented in OVS, we conduct experiments to evaluate the throughput of HeavyKeeper and other algorithms. Besides, we also show the throughput of OVS without using any algorithm to show the impact of algorithms. We set the memory size to 50KB.

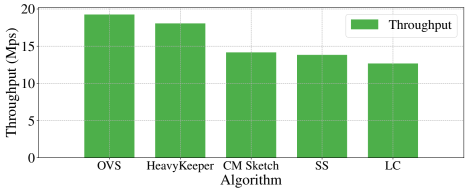

Figure 21: Throughput on OVS platform.

As shown in Figure 21, the throughput of HeavyKeeper is near the original throughput of OVS. Specifically, the throughput of the original OVS is 19.22Mps, and that of HeavyKeeper is 18.03Mps. However, the throughput of CM sketch, Space-Saving, and Lossy Counting is 14.14Mps, 13.80Mps, and 12.64Mps, respectively. The results show that our HeavyKeeper algorithm has little impact to the performance of OVS, while other algorithms decrease the throughput significantly.

7 Conclusion

Finding the top-k elephant flows is a critical task for network traffic measurement. As the line rate increases, it is more and more challenging to design an accurate algorithm that achieves fast and constant speed. Existing algorithms for finding top-k flows cannot achieve high precision when traffic speed is high and memory usage is small, because they do not handle massive mouse flows effectively. In this paper, we propose a novel data structure, called HeavyKeeper, which achieves a much higher precision on top-k queries and a much lower error rate on flow size estimation, compared to previous algorithms. The key idea of HeavyKeeper is that it intelligently omits mouse flows, and focuses on recording the information of elephant flows by using the exponential-weakening decay strategy. Our evaluation confirms that HeavyKeeper achieves 99.99% precision for finding the top-k elephant flows, while also achieving a reduction in the error rate of the estimated flow size by about 3 orders of magnitude compared to the state-of-the-art algorithms.

SAND: Towards High-Performance Serverless Computing

Istemi Ekin Akkus, Ruichuan Chen, Ivica Rimac, Manuel Stein
Klaus Satzke, Andre Beck, Paarijaat Aditya, Volker Hilt
Nokia Bell Labs

Abstract

Serverless computing has emerged as a new cloud computing paradigm, where an application consists of individual functions that can be separately managed and executed. However, existing serverless platforms normally isolate and execute functions in separate containers, and do not exploit the interactions among functions for performance. These practices lead to high startup delays for function executions and inefficient resource usage.

This paper presents SAND, a new serverless computing system that provides lower latency, better resource efficiency and more elasticity than existing serverless platforms. To achieve these properties, SAND introduces two key techniques: 1) application-level sandboxing, and 2) a hierarchical message bus. We have implemented and deployed a complete SAND system. Our results show that SAND outperforms the state-of-the-art serverless platforms significantly. For example, in a commonly-used image processing application, SAND achieves a 43% speedup compared to Apache OpenWhisk.

1 Introduction

Serverless computing is emerging as a key paradigm in cloud computing. In serverless computing, the unit of computation is a function. When a service request is received, the serverless platform allocates an ephemeral execution environment for the associated function to handle the request. This model, also known as Function-as-a-Service (FaaS), shifts the responsibilities of dynamically managing cloud resources to the provider, allowing the developers to focus only on their application logic. It also creates an opportunity for the cloud providers to improve the efficiency of their infrastructure resources.

The serverless computing paradigm has already created a significant interest in industry and academia. There have been a number of commercial serverless offerings (e.g., Amazon Lambda [1], IBM Cloud Functions [5], Microsoft Azure Functions [11], and Google Cloud Functions [15]), as well as several new proposals (e.g., OpenLambda [24] and OpenFaaS [19]).

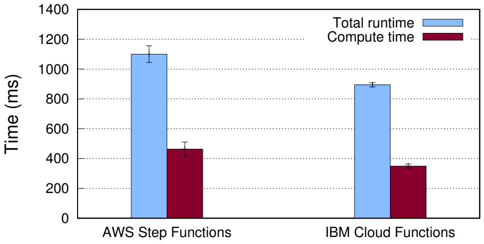

Figure 1: Total runtime and compute time of executing an image processing pipeline with four functions on existing commercial serverless platforms. Results show the mean values with 95% confidence interval over 10 runs, after discarding the initial (cold) execution.

Although existing serverless platforms work well for simple applications, they are not well-suited for more complex services due to their overheads, especially when the application logic follows an execution path spanning multiple functions. Consider an image processing pipeline that executes four consecutive functions [51]: extract image metadata, verify and transform it to a specific format, tag objects via image recognition, and produce a thumbnail. We ran this pipeline using AWS Step Functions [10] and IBM Cloud Functions with Action Sequences [29], both of which provide a method to connect multiple functions into a single service.[1] On these platforms, we found that the total runtime is significantly more than the actual time required for function executions (see Figure 1), indicating the overheads of executing such connected functions. As a result of these overheads, the use and adoption of serverless computing by a broader range of applications is severely limited.

We observe two issues that contribute to these over-

[1] As of this writing, other major serverless providers, e.g., Microsoft and Google, do not support Python, which was used for this pipeline.

heads and diminish the benefits of serverless computing. Our first observation is that most existing serverless platforms execute each application function within a separate container instance. This decision leads to two common practices, each with a drawback. First, one can start a new, 'cold' container to execute an associated function every time a new request is received, and terminate the container when the execution ends. This approach inevitably incurs long startup latency for each request. The second practice is to keep a launched container 'warm' (i.e., running idle) for some time to handle future requests. While reducing the startup latency for processing, this practice comes at a cost of occupying system resources unnecessarily for the idle period (i.e., resource inefficiency).

Our second observation is that existing serverless platforms do not appear to consider interactions among functions, such as those in a sequence or workflow, to reduce latency. These platforms often execute functions wherever required resources are available. As such, external requests (e.g., user requests calling the first function in a workflow) are treated the same as internal requests (e.g., functions initiating other functions during the workflow execution), and load is balanced over all available resources. This approach causes function interactions to pass through the full end-to-end function call path, incurring extra latency. For example, in Apache OpenWhisk [5] (i.e., the base system of IBM Cloud Functions [29]), even for functions that belong to the same workflow defined by the Action Sequences, all function calls pass through the controller. We also observe that, for functions belonging to the same state machine defined by AWS Step Functions [10], the latencies between functions executing on the same host are similar to the latencies between functions running on different hosts.

In this paper, we design and prototype a novel, high-performance serverless platform, SAND. Specifically, we propose two mechanisms to accomplish both low latency and high resource efficiency. First, we design a *fine-grained application sandboxing mechanism* for serverless computing. The key idea is to have two levels of isolation: 1) isolation between different applications, and 2) isolation between functions of the same application. This distinction enables SAND to quickly allocate (and deallocate) resources, leading to low startup latency for functions and efficient usage of cloud resources. We argue that stronger mechanisms (e.g., containers) are needed only for the isolation among applications, and weaker mechanisms (e.g., processes and light-weight contexts [37]) are well-suited for the isolation among functions within the same application.

Second, we design a *hierarchical message queuing and storage mechanism* to leverage locality for the interacting functions of the same application. Specifically, SAND orchestrates function executions of the same application as local as possible. We develop a local message bus on each host to create shortcuts to enable fast message passing between interacting functions, so that functions executing in a sequence can start almost instantly. In addition, for reliability, we deploy a global message bus that serves as a backup of locally produced and consumed messages in case of failures. The same hierarchy is also applied for our storage subsystem in case functions of the same application need to share data.

With these two mechanisms, SAND achieves low function startup and interaction latencies, as well as high resource efficiency. Low latencies are crucial for serverless computing and play a key role in broadening its use. Otherwise, application developers would merge functions to avoid the latency penalty, making the applications less modular and losing the benefits of serverless computing. In addition, the cloud industry is increasingly interested in moving infrastructure to the network edge to further reduce network latency to users [18, 26, 36, 50, 52]. This move requires high resource efficiency because the edge data centers typically have fewer resources than the core.

We implemented and deployed a complete SAND system. Our evaluation shows that SAND outperforms state-of-the-art serverless platforms such as Apache OpenWhisk [5] by 8.3× in reducing the interaction latency between (empty) functions and much more between typical functions. For example, in a commonly-used image processing application, these latencies are reduced by 22×, leading to a 43% speedup in total runtime. In addition, SAND can allocate and deallocate system resources for function executions much more efficiently than existing serverless platforms. Our evaluation shows that SAND improves resource efficiency between 3.3× and two orders of magnitude compared to the state-of-the-art.

2 Background

In this section, we give an overview of existing serverless platforms, their practices, and the implications of these practices. We summarize how these platforms deploy and invoke functions in parallel as well as in sequence. Our observations are based on open-source projects, but we think they still reflect many characteristics of commercial platforms. For example, the open-source Apache OpenWhisk is used in IBM Cloud Functions [29]. In addition, we augment these observations with our experiences using these platforms and with publicly available information from the commercial providers.

2.1 Function Deployment

In serverless computing, the cloud operator takes the responsibility of managing servers and system resources to run the functions supplied by developers. To our knowledge, the majority of serverless platforms use containers and map each function into its own container to achieve this goal. This mapping enables the function code to be portable, so that the operator can execute the function wherever there are enough resources in the infrastructure without worrying about compatibility. Containers also provide virtually isolated environments with namespaces separating operating system resources (e.g., processes, filesystem, networking), and can isolate most of the faulty or malicious code execution. Serverless platforms that employ such a mapping include commercial platforms (e.g., AWS Lambda, Microsoft Azure Functions, Google Cloud Functions, and IBM Cloud Functions) as well as open-source platforms (e.g., Apache OpenWhisk, OpenLambda [24], Greengrass [7], and OpenFaaS [19]).

Note that there are also other platforms that employ NodeJS [45] to run functions written in JavaScript [25, 49, 54, 58]. These platforms offer alternatives for serverless computing, but are not as widely used as the container-based platforms. For this reason, hereafter we describe in detail serverless platforms that employ containers and use them in our evaluation.

2.2 Function Call

The most straightforward approach to handle an incoming request is to start a new container with the associated function code and then execute it. This approach, known as 'cold' start, requires the initialization of the container with the necessary libraries, which can incur undesired startup latency to the function execution. For example, AWS Lambda has been known to have delays of up to a few seconds for 'cold' function calls [8]. Similarly, Google has reported a median startup latency of 25 seconds on its internal container platform [55], 80% of which are attributed to library installation. Lazy loading of libraries can reduce this startup latency, but it can still be on the order of a few seconds [23].

To improve startup latency, a common practice is to reuse launched containers by keeping them 'warm' for a period of time. The first call to a function is still 'cold', but subsequent calls to this function can be served by the 'warm' container to avoid undesired startup latency. To also reduce the latency of the first function call, Apache OpenWhisk can launch containers even before a request arrives via the 'pre-warming' technique [5].

The above 'warm' container practice, however, unnecessarily occupies resources with idling containers. Note that this practice also relaxes the original isolation guarantee provided by the containers, because different requests may be handled inside the same container albeit sequentially (i.e., one execution at a time).

2.3 Function Concurrency

Another aspect in which various serverless platforms can differ is how they handle concurrent requests. Apache OpenWhisk and commercial platforms such as AWS Lambda [1], Google Cloud Functions and Microsoft Azure Functions allow only one execution at a time in a container for performance isolation. As a result, concurrent requests will either be handled in their individual containers and experience undesired startup latencies for each container, or the requests will be queued for a 'warm' container to become available and experience queuing delays. In contrast, OpenFaaS [19] and OpenLambda [24] allow concurrent executions of the same function in a single container.

2.4 Function Chaining

Application logic often consists of sequences of multiple functions. Some existing serverless platforms support the execution of function sequences (e.g., IBM Action Sequences [29], AWS Step Functions [10]). In a function sequence, the events that trigger function executions can be categorized as external (e.g., a user request calling a function sequence) and internal (e.g., a function initiating other functions during the workflow execution). Existing serverless platforms normally treat these events the same, such that each event traverses the full end-to-end function call path (e.g., event passing via a unified message bus or controller), incurring undesired latencies.

3 SAND Key Ideas and Building Blocks

This section describes the key ideas and building blocks of SAND. We first present the design of our application sandboxing mechanism (§3.1) that enables SAND to be resource-efficient and elastic as well as to achieve low-latency function interactions. Then, we describe our hierarchical message queuing mechanism (§3.2) that further reduces the function interaction latencies.

3.1 Application Sandboxing

The key idea in our sandboxing design is that we need two levels of fault isolation: 1) isolation between different applications, and 2) isolation between functions of the same application. Our reasoning is that different applications require strong isolation from each other. On the other hand, functions of the same application may not need such a strong isolation, allowing us to improve the performance of the application. Note that some existing serverless platforms reuse a 'warm' container to execute calls to the same function, making a similar trade-off to improve the performance of a single function.

To provide a two-level fault isolation, one can choose from a variety of technologies, such as virtual machines (VMs), LightVMs [40], containers [21, 53], unikernels [38, 39], processes, light-weight contexts [37] and threads. This choice will impact not only performance but also the dynamic nature of applications and functions as well as the maintenance effort by cloud operators. We discuss these implications in §9.

In SAND, we specifically separate applications from each other via containers, such that each application runs in its own container. The functions that compose an application run in the same container but as separate processes. Upon receiving an incoming request, SAND forks a new process in the container to execute the associated function, such that each request is handled in a separate process. For example, Figure 2 shows that the two functions f_1 and f_2 of the same application are run in the same application sandbox on a host, but different applications are separated.

Our application sandboxing mechanism has three significant advantages. First, triggering a function execution by forking a process within a container incurs short startup latency, especially compared to launching a separate container per request or function execution — up to three orders of magnitude speedup (§6.1). Second, the libraries shared by multiple functions of an application need to be loaded into the container only once. Third, the memory footprint of an application container increases in small increments with each incoming request and decreases when the request has been processed, with the resources allocated for a single function execution being released immediately (i.e., when the process terminates). As a result, the cloud operator can achieve substantially better resource efficiency and has more flexibility to divert resources not only among a single application's functions but also among different applications (i.e., no explicit pre-allocation). This effect becomes even more critical in emerging edge computing scenarios where cloud infrastructure moves towards the network edge that has only limited resources.

3.2 Hierarchical Message Queuing

Serverless platforms normally deploy a unified message bus system to provide scalable and reliable event dispatching and load balancing. Such a mechanism works well in scenarios where individual functions are triggered via (external) user requests. However, it can cause unnecessary latencies when multiple functions interact with each other, such that one function's output is the input to another function. For example, even if two functions of an application are to be executed in a sequence and they reside on the same host, the trigger message between the two functions still has to be published to the unified message bus, only to be delivered back to the same host.

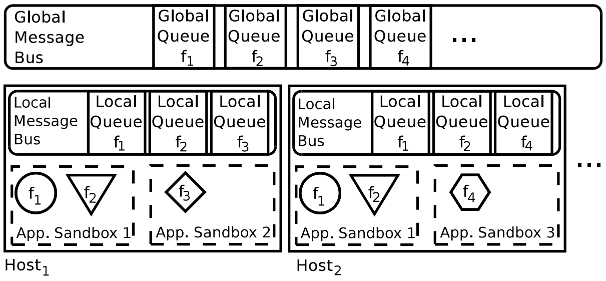

Figure 2: SAND's key building blocks: application sandboxing and hierarchical message queuing.

To address this problem, we design a *hierarchical* message bus for SAND. Our basic idea is to create shortcuts for functions that interact with each other (e.g., functions of the same application). We describe the hierarchical message bus and its coordination with two levels.[2]

In a two-level hierarchy, there is a *global* message bus that is distributed across hosts and a *local* message bus on every host (Figure 2). The global message bus serves two purposes. First, it delivers event messages to functions across different hosts, for example, when a single host does not have enough resources to execute all desired functions or an application benefits from executing its functions across multiple hosts (e.g., application sandbox 1 in Figure 2). Second, the global message bus also serves as a backup of local message buses for reliability.

The local message bus on each host is used to deliver event messages from one function to another if both functions are running on the same host. As a result, the interacting functions (e.g., an execution path of an application spanning multiple functions, similar to the application sandbox 1 in Figure 2) can benefit from reduced latency because accessing the local message bus is much faster than accessing the global message bus (§6.2).

The local message bus is first-in-first-out, preserving the order of messages from one function to another. For global message bus, the order depends on the load balancing scheme: if a shared identifier of messages (e.g., key) is used, the message order will also be preserved.

Coordination. To ensure that an event message does not get processed at the same time on multiple hosts, the local and global message buses coordinate: a backup of the locally produced event message is published to the global message bus with a *condition flag*. This flag indicates that the locally produced event message is being processed on the current host and should not be delivered to another host for processing. After publishing the backup message, the current host tracks the progress of the forked process that is handling the event message and

[2] This hierarchy can be extended to more than two levels in a large network; we omit the description due to space limit.

updates its flag value in the global message bus accordingly (i.e., ‘processing’ or ‘finished’). If the host fails after the backup message is published to the global message bus but before the message has been fully processed, another host takes over the processing after a timeout.

This coordination procedure is similar to write-ahead-logging in databases [57], whereby a locally produced event message would be first published to the global message bus before the local message bus. While guaranteeing that there are no lost event messages due to host failures, this ‘global-then-local’ publication order can add additional latency to the start of the next (locally available) function in a sequence. In SAND, we relax this order, and publish event messages to the global message bus asynchronously with the publication to the local message bus in parallel. In serverless computing, functions are expected to, and usually, finish execution fast [9,12]. In case of a failure, SAND can reproduce the lost event messages by re-executing the functions coming after the last (backup) event message seen in the global message bus. Note that, in SAND, the output of a function execution becomes available to other functions at the end of the function execution (§4.1). As such, the coordination and recovery procedures work for outputs that are contained within SAND. SAND does not guarantee the recovery of functions that make externally-visible side effects *during* their executions, such as updates to external databases.

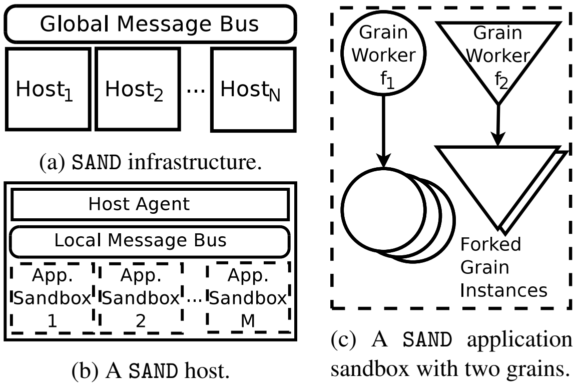
4 SAND System Design

This section presents the detailed design of SAND utilizing the aforementioned key ideas and building blocks. We also illustrate how an example application runs on SAND, and describe some additional system components.

4.1 System Components

The SAND system contains a number of hosts, which can exchange event messages via a global message bus (Figure 3a). Figure 3b shows the system components on a single host. Here, we describe these components.

Application, Grain, and Workflow. In SAND, a function of an application is called a *grain*. An *application* consists of one or multiple grains, as well as the *workflows* that define the interactions among these grains. The interaction between grains can be *static* where the grains are chained (e.g., Grain_2's execution always follows Grain_1's execution), or *dynamic* where the execution path is determined during the execution (e.g., the execution of Grain_2 and/or Grain_3 may follow Grain_1's execution, according to Grain_1's output). The grain code and workflows are supplied by the application developer. A grain can be used by multiple applications by copying it to the respective application sandboxes.



(a) SAND infrastructure.

(b) A SAND host.

(c) A SAND application sandbox with two grains.

Figure 3: High-level architecture of SAND.

Sandbox, Grain Worker, and Grain Instance. An application can run on multiple hosts. On a given host, the application has its own container called *sandbox*. The set of grains hosted in each sandbox can vary across hosts as determined by the application developer[3], but usually includes all grains of the application.

When a sandbox hosts a specific grain, it runs a dedicated OS process called *grain worker* for this grain. The grain worker loads the associated grain code and its libraries, subscribes to the grain's queue in the host's local message bus, and waits for event messages.

Upon receiving an associated event message, the grain worker forks itself to create a *grain instance* that handles the event message (Figure 3c). This mechanism provides three significant advantages for SAND. First, forking grain instances from the grain worker is quite fast and lightweight. Second, it utilizes OS mechanisms that allow the sharing of initialized code (e.g., loaded libraries), thus reducing the application's memory footprint. Third, the OS automatically reclaims the resources assigned to a grain instance upon its termination. Altogether, by exploiting the process forking, SAND becomes fast and efficient in allocating and deallocating resources for grain executions. As a result, SAND can easily handle load variations and spikes to multiplex multiple applications (and their grains) elastically even on a single host.

When a grain instance finishes handling an event message, it produces the output that includes zero or more event messages. Each such message is handled by the next grain (or grains), as defined in the workflow of the application. Specifically, if the next grain is on the same host, the previous grain instance directly publishes the output event message into the local message queue that is subscribed to by the next grain worker, which then forks a grain instance to handle this event message. In parallel, a backup of this message is asynchronously published to the global message bus.

[3] Or automatically by SAND via strategies or heuristics (e.g., a sandbox on each host should not run more than a certain number of grains).

Local and Global Message Buses. A *local message bus* runs on each host, and serves as a shortcut for local function interactions. Specifically, in the local message bus, a separate message queue is created for each grain running on this host (Figure 2). The local message bus accepts, stores and delivers event messages to the corresponding grain worker when it polls its associated queue.

On the other hand, the *global message bus* is a distributed message queuing system that runs across the cloud infrastructure. The global message bus acts as a backup for locally produced and consumed event messages by the hosts, as well as delivers event messages to the appropriate remote hosts if needed. Specifically, in the global message bus, there is an individual message queue associated with each grain hosted in the entire infrastructure (see Figure 2). Each such message queue is partitioned to increase parallelism, such that each partition can be assigned to a different host running the associated grain. For example, the widely-used distributed message bus Apache Kafka [3] follows this approach.

Each host synchronizes its progress on the consumption of the event messages from their respective partitions with the global message bus. In case of a failure, the failed host's partitions are reassigned to other hosts, which then continue consuming the event messages from the last synchronization point.

Host Agent. Each host in the infrastructure runs a special program called *host agent*. The host agent is responsible for the coordination between local and global message buses, as well as launching sandboxes for applications and spawning grain workers associated with the grains running on this host. The host agent subscribes to the message queues in the global message bus for all the grains the host is currently running. In addition, the host agent tracks the progress of the grain instances that are handling event messages, and synchronizes it with the host's partitions in the global message bus.

4.2 Workflow Example

The SAND system can be best illustrated with a simple workflow example demonstrating how a user request to a SAND application is handled. Suppose the application consists of two grains, Grain_1 and Grain_2. Host_x is running this application with the respective grain workers, GW_1 and GW_2. The global message bus has an individual message queue associated with each grain, GQ_1 and GQ_2. In addition, there is an individual partition (from the associated message queue in the global message bus) assigned to each of the two grain workers on Host_x, namely $\text{GQ}_{1,1}$ and $\text{GQ}_{2,1}$, respectively.

Assume there is a user request for Grain_1 (Step 0 in Figure 4), and the global message bus puts this event message into the partition $\text{GQ}_{1,1}$ within the global message queue GQ_1, according to a load balancing strategy. As a result, the host agent on Host_x can retrieve this event message (Step 1) and publish it into the local queue LQ_1 (associated with Grain_1) in Host_x's local message bus (Step 2). The grain worker GW_1, which is responsible for Grain_1 and subscribed to LQ_1, retrieves the recently added event message (Step 3) and forks a new grain instance (i.e., a process) to handle the message (Step 4).

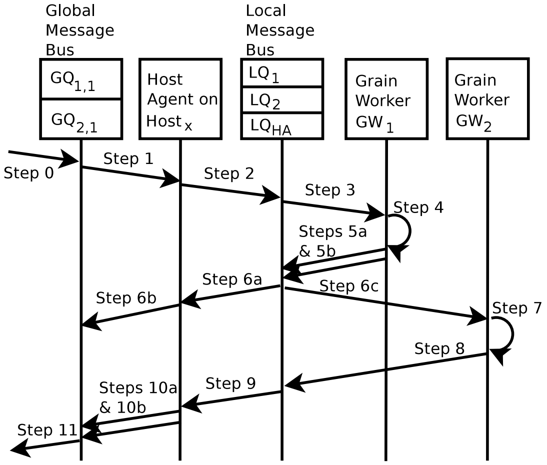


Figure 4: Handling of a user request to a simple application that consists of two grains in a workflow.

Assume Grain_1's grain instance produces a new event message for the next grain in the workflow, Grain_2. The grain instance publishes this event message directly to Grain_2's associated local queue LQ_2 (Step 5a), because it knows that Grain_2 is locally running. A copy of the event message is also published to the local queue LQ_{HA} for the host agent on Host_x (Step 5b). The host agent retrieves the message (Step 6a) and publishes it as a backup to the assigned partition $\text{GQ}_{2,1}$ in Grain_2's associated global queue with a condition flag 'processing' (Step 6b).

Meanwhile, the grain worker GW_2 for Grain_2 retrieves the event message from the local queue LQ_2 in the local message bus on Host_x (Step 6c). GW_2 forks a new grain instance, which processes the event message and terminates after execution (Step 7). In our example, GW_2 produces a new event message to the local queue of the host agent LQ_{HA} (Step 8), because Grain_2 is the last grain in the application's workflow and there are no other locally running grains to handle it. The host agent retrieves the new event message (Step 9) and directly publishes it to the global message bus (Step 10a). In addition, the finish of the grain instance of Grain_2 causes the host agent to update the condition flag of the locally produced event message that triggered Grain_2 with a value 'finished' to indicate that it has been successfully processed (Step 10b). The response is then sent to the user (Step 11).

4.2.1 Handling Host Failures

In the previous description, all hosts are alive during the course of the workflow. Suppose the processing of the event message for Grain_2 (Step 7 in Figure 4) failed due to the failure of Host_x. When the global message bus detects Host_x's failure, it will reassign Host_x's associated partitions (i.e., $\text{GQ}_{1,1}$ and $\text{GQ}_{2,1}$). Suppose there is another host Host_y taking over these two partitions. In our example, only Grain_2's grain instances were triggered via the locally produced event messages, meaning that the condition flags were published to $\text{GQ}_{2,1}$ (i.e., Host_x's partition in Grain_2's global message queue).

When Host_y starts the recovery process, it retrieves all event messages in $\text{GQ}_{2,1}$ (and also $\text{GQ}_{1,1}$). For each message, Host_y's host agent checks its condition flag. If the flag indicates that an event message has been processed successfully (i.e., 'finished'), this message is skipped because Host_x failed after processing this event message. If the flag indicates that the processing of the event message has just started (i.e., 'processing'), Host_y processes this event message following the steps in Figure 4.

It is possible that Host_y fails during the recovery process. To avoid the loss of event messages, Host_y continuously synchronizes its progress on the consumed messages from the reassigned partitions with the global message bus. It does not retrieve any new messages from the partitions until all messages of the failed host have been processed successfully. As a result, each host replacing a failed host deals with smaller reassigned partitions.

4.3 Additional System Components

Here, we briefly describe a few additional system components that complete SAND.

Frontend Server. The *frontend server* is the interface for developers to deploy their applications as well as to manage grains and workflows. It acts as the entry point to any application on SAND. For scalability, multiple frontend servers can run behind a standard load balancer.

Local and Global Data Layers. Grains can share data by passing a reference in an event message instead of passing the data itself. The *local data layer* runs on each host similar to the local message bus, and enables fast access to the data that local grains want to share among themselves via an in-memory key-value store. The *global data layer* is a distributed data storage running across the cloud infrastructure similar to the global message bus. The coordination between the local and global data layers is similar to the coordination between the local and global message buses (§3.2). Each application can only access its own data in either layer.

To ensure the data produced by a grain instance persists, it is backed up to the global data layer during the (backup) publication of the locally produced event message. This backup is facilitated with another flag value (between 'processing' and 'finished' described in §3.2) to indicate the start of the data transfer to the global data layer. This value contains the data's metadata (i.e., name, size, hash), which is checked during the recovery process to decide whether an event message needs to be processed: if the metadata in the flag matches the metadata of the actual data in the global data layer, the event message was successfully processed but the 'finished' flag could not be published by the failed host; otherwise, this event message needs to be processed again.

5 Implementation

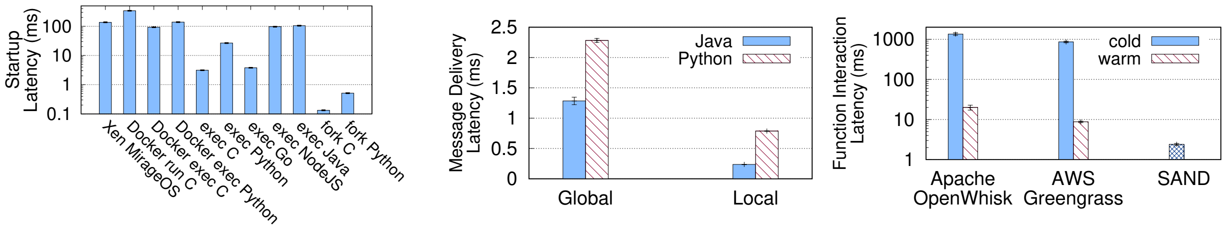
We implemented a complete SAND system with all components described in §4. Our system uses Docker [17] for application sandboxes, Apache Kafka [3] for the global message bus, Apache Cassandra [2] for the global data layer, and nginx [44] as the load balancer for the frontend server instances. We use these components off-the-shelf.

In addition, we implemented the host agent (7,273 lines of Java), the Python grain worker (732 lines of Python) and the frontend server (461 lines of Java). The host agent coordinates the local and global message buses and data layers, as well as manages application sandboxes and grains, by interacting with Kafka, Cassandra and Docker. The grain worker becomes dedicated to a specific grain after loading its code and necessary libraries, interacts with the local message bus, and forks grain instances for each associated event message. We use Apache Thrift [6] to automatically generate the interfaces for our Java implementations of the local message bus and the local data layer. The frontend server accepts connections handed over by the nginx load balancer, interacts with Kafka to deliver user requests into SAND and return application responses back to users. The frontend server embeds Jetty [32] as the HTTP endpoint and employs its thread pool to handle user requests efficiently.

For easy development and testing, we also implemented a SAND emulator (764 lines of Python) that supports SAND's API and logging for debugging. Developers can write their grains and workflows, and test them using the emulator before the actual deployment.

6 Evaluation

We evaluate SAND and compare it to Apache OpenWhisk [5] and AWS Greengrass [7]. We choose these two systems because we can run local installations for a fair comparison. We first report on microbenchmarks of alternative sandboxing mechanisms and SAND's hierarchical message bus. We then evaluate function interaction



(a) Function startup latencies.

(b) Message delivery latencies.

(c) Python function interaction latencies.

Figure 5: Measurements regarding function startup latencies, message delivery latencies and Python function interaction latencies, with error bars showing the 95% confidence interval.

latencies and the memory footprints of function executions, as well as investigate the trade-off between allocated memory and latency. Finally, we revisit the image processing pipeline, which was discussed as a motivational example in §1. We conducted all experiments on machines equipped with Intel Xeon E5520 with 16 cores at 2.27GHz and 48GB RAM, unless otherwise noted.

6.1 Sandboxing and Startup Latency

There are several alternative sandboxing mechanisms to isolate the applications and function executions (see §9). Here, we explore the startup latency of these alternatives.
Methodology. We measured the startup time until a function starts executing, with various sandboxing mechanisms including Docker (CE-17.11 with runc 1.0.0) and unikernel (Xen 4.8.1 with MirageOS 2.9.1), as well as spawning processes in C (gcc 4.8.5), Go (1.8.3), Python (2.7.13), NodeJS (6.12) and Java (1.8.0.151). We used an Intel Xeon E5-2609 host with 4 cores at 2.40GHz and 32GB RAM running CentOS 7.4 (kernel 4.9.63).
Results. Figure 5a shows the mean startup latencies with 95% confidence interval. Starting a process in a running, warm container via the Docker client interface (Docker exec C) is much faster than launching both the container and the process (Docker run C). Nonetheless, Docker adds significant overhead to function starts compared to starts without it (exec C, exec Python). Function starts with a unikernel (Xen MirageOS) are similar to using a container. Not surprisingly, spawning processes with binaries (exec C, exec Go) are faster than interpreted languages (exec Python, exec NodeJS) and Java, and forking processes (fork C, fork Python) is fastest among all.

6.2 Hierarchical Message Bus

Instead of a single unified message bus, SAND utilizes a local message bus on every host for fast function interactions. Here, we show the benefits of this approach.
Methodology. We created two processes on the same host that communicate in a producer-consumer style under load-free conditions. With Python and Java clients, we measured the latency for a message delivered via the global message bus (Kafka 0.10.1.0, 3 hosts, 3 replicas, default settings) and via our local message bus.
Results. Figure 5b shows the mean message delivery latencies with 95% confidence interval. The Python client (used by our grain instances) can deliver an event message to the next grain via the local message bus 2.90× faster than via the global message bus. Similarly, the Java client (used by our host agent) gets a 5.42× speedup.

6.3 Function Interaction Latency

Given two functions in a workflow, the function interaction latency is the time between the first function's finish and the second function's start.
Methodology. We created two Python functions, F_1 and F_2, such that F_1 produces an event message for F_2 to consume. We logged high-resolution timestamps at the end of F_1 and at the start of F_2. We used an Action Sequence in OpenWhisk [48], matching MQTT topic subscriptions in Greengrass [59] and SAND's workflow description. We then triggered F_1 with a request generator.

Recall that SAND uses a single, running container for multiple functions of an application. For a fair comparison, we measure function interaction latencies in OpenWhisk and Greengrass with warm containers. For completeness, we also report their cold call latencies, where a function call causes a new container to be launched.
Results. Figure 5c shows that SAND incurs a significantly shorter (Python) function interaction latency. SAND outperforms OpenWhisk and Greengrass, both with warm containers, by 8.32× and 3.64×, respectively. Furthermore, SAND's speedups are 562× and 358× compared to OpenWhisk and Greengrass with cold containers.

6.4 Memory Footprint

Concurrent calls to a function on today's serverless computing platforms are handled by concurrent execution instances. These instances are served either by launching

Table 1: Workloads and burst parameters.

Load	Rate (calls/min)	Duration (s)	Frequency (s)
A	1,000	8	240
B	250	8	240
C	1,000	30	120
D	1,000	8	120
E	250	30	120

new containers or by assigning them to warm containers if available. Because concurrently-running containers occupy system resources, we examine the memory footprint of such concurrent function executions.

Methodology. We made up to 50 concurrent calls to a single Python function. We ensured that all calls were served in parallel, and measured each platform's memory usage via `docker stats` and `ps` commands.

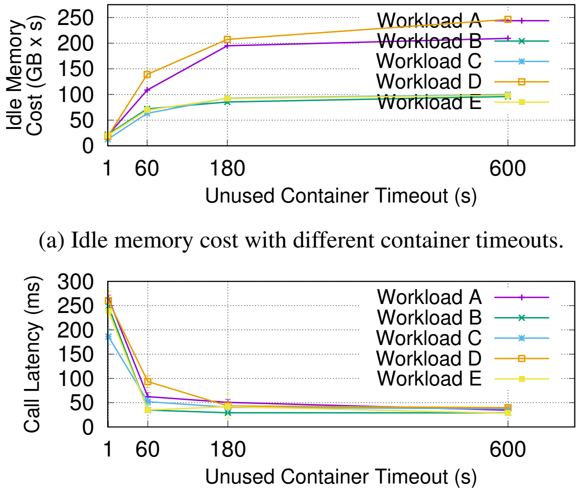
Results. We find that both OpenWhisk and Greengrass show a linear increase in memory footprint with the number of concurrent calls.[4] Each call adds to the memory footprint about 14.61MB and 13.96MB in OpenWhisk and Greengrass, respectively. In SAND, each call only adds 1.1MB on top of the 16.35MB consumed by the grain worker. This difference is because SAND forks a new process inside the same sandbox for each function call, whereas OpenWhisk and Greengrass use separate containers for concurrent calls.

6.5 Idle Memory Cost vs. Latency

Many serverless platforms use warm containers to prevent cold startup penalties for subsequent calls to a function. On the other hand, these platforms launch new containers when there are concurrent calls to a function but no warm containers available (§6.4). These new containers will also be kept warm until a timeout, occupying resources. Here, we investigate the trade-off between occupied memory and function call latency.

Methodology. We created 5 synthetic workloads each with 2,000 function calls. In all workloads, the call arrival time and the function processing time (i.e., busy wait) follow a Poisson distribution with a mean rate of 100 calls per minute and a mean duration of 600ms. To see how the serverless platforms behave under burst, we varied three parameters as shown in Table 1: 1) burst rate, 2) burst duration, and 3) burst frequency.

We explored 4 different unused-container timeouts in OpenWhisk. Unfortunately, this timeout cannot be modified in Greengrass, so we could not use it in this experiment. We computed the idle memory cost by multiplying the allocated but unused memory of the container instances with the duration of their allocations (i.e., total idle memory during the experiment). We reused the memory footprint results from §6.4. In OpenWhisk, the number of container instances depends on the concurrency, whereas SAND uses a single application sandbox.



(a) Idle memory cost with different container timeouts.

(b) Call latency with different container timeouts.

Figure 6: Idle memory cost vs. function call latency.

Results. Figures 6a and 6b show the effects of container timeouts in OpenWhisk on the idle memory cost and the function call latency, respectively. We observe that a long timeout is not suited for bursty traffic, with additional containers created to handle concurrent calls in a burst but are not needed afterwards. Even with a relatively short timeout of 180 seconds, the high idle memory costs suggest that containers occupy system resources without using them during the majority of our experiment. We also observe that a shorter timeout lowers the idle memory cost but leads to much longer function call latencies due to the cold start effect, affecting between 18.15%–33.35% of all calls in all workloads with a 1 second timeout. Interestingly, the frequent cold starts cause OpenWhisk to overestimate the number of required containers, partially offsetting the lowered idle memory cost achieved by shorter timeouts.

In contrast, SAND reduces idle memory cost from 3.32× up to two orders of magnitude with all workloads without sacrificing low latency (15.87–16.29 ms). SAND, by its sandboxing mechanism, handles concurrent calls to a function (or multiple functions) on a single host by forking parallel processes inside a container; therefore, SAND does not suffer from cold startup penalties. With higher load, SAND would amortize the penalty of starting a new sandbox on another host by using it both for multiple executions of a single function and for different functions. Our ongoing work includes intelligent monitoring and scheduling for additional sandboxes.

[4] In Greengrass, this relationship continues until 25 concurrent calls, after which calls get queued as shown in system logs.

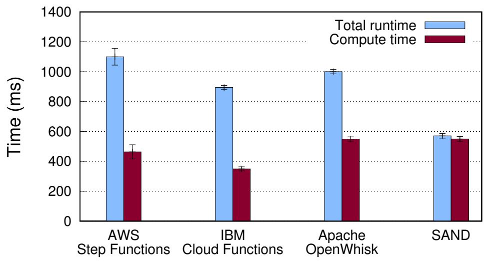


Figure 7: Total runtime and compute time of the image processing pipeline. Results show the mean values with 95% confidence interval over 10 runs, after discarding the initial (cold) execution.

6.6 Image Processing Pipeline

Here, we revisit our motivational example used in §1, i.e., the image processing pipeline. This pipeline consists of four consecutive Python functions, and is similar to the reference architecture used by AWS Lambda [51]. It first extracts the metadata of an image using ImageMagick [30]. A subset of this metadata is then verified and retained by the next function in the pipeline. The third function recognizes objects in the image using the SqueezeNet deep learning model [28] executed on top of the MXNet framework [4, 43]. Names of the recognized objects are appended to the extracted metadata and passed to the final function, which generates a thumbnail of the image and stores the metadata in a separate file.

Methodology. Each function recorded timestamps at the start and end of its execution, which we used to produce the actual compute time. The difference between the total time and the compute time gave each platform's overhead. The image was always read from a temporary local storage associated with each function call. We ran the pipeline on AWS Step Functions, IBM Cloud Functions, Apache OpenWhisk with Action Sequences, and `SAND`.

Results. Figure 7 shows the runtime breakdown of these platforms. Compared to other platforms, we find that `SAND` achieves the lowest overhead for running a series of functions. For example, `SAND` reduces the overhead by 22.0× compared to OpenWhisk, even after removing the time spent on extra functionality not supported in `SAND` yet (e.g., authentication and authorization). We notice that OpenWhisk re-launches the Python interpreter for each function invocation, so that libraries are loaded before a request can be handled. In contrast, `SAND`'s grain worker loads a function's libraries only once, which are then shared across forked grain instances handling the requests. The difference in compute times can be explained by the difference across infrastructures: `SAND` and OpenWhisk ran in our local infrastructure and produced similar values, whereas we had no control over AWS Step Functions and IBM Cloud Functions.

7 Experience with `SAND`

During and after the implementation of `SAND`, we also developed and deployed several applications on it. Here, we briefly describe these applications to show that `SAND` is general and can serve different types of applications.

The first application we developed is a simple web server serving static content (e.g., html, javascript, images) via two grains in a workflow. The first grain parses user requests and triggers another grain according to the requested file type. The second grain retrieves the file and returns it to our frontend server, which forwards it to the user. Our `SAND` web server has been in use since May 2017 to serve our lab's website. The second `SAND` application is the management service of our `SAND` system. The service has 19 grains, connects with the GUI we developed, and enables developers to create grains as well as to deploy and test workflows.

In addition, we made `SAND` available to researchers in our lab. They developed and deployed applications using the GUI and the management service. One group prototyped a simple virus scanner, whereby multiple grains executing in parallel check the presence of viruses in an email. Another group developed a stream analytics application for Twitter feeds, where grains in a workflow identify language, remove links and stop words, and compile a word frequency list to track the latest news trend.

8 Related Work

Despite its recency, serverless computing has already been used in various scenarios including Internet of Things and edge computing [7, 16], parallel data processing [33, 34], data management [14], system security enhancement [13], and low-latency video processing [20]. Villamizar et al. [56] showed that running applications in a serverless architecture is more cost efficient than microservices or monoliths. One can expect that serverless computing is going to attract more attention.

Beside commercial serverless platforms [1, 11, 15, 25, 29, 31], there have also been academic proposals for serverless computing. Hendrickson et al. [24] proposed OpenLambda after identifying problems in AWS Lambda [1], including long function startup latency and little locality consideration. McGrath et al. [42] also investigated latencies in existing serverless frameworks. These problems are important for serverless application development, where function interaction latencies are crucial. In `SAND`, we address these problems via our application sandboxing approach, as well as the hierarchical message queuing and storage mechanisms.

Other approaches also targeted the long startup latency problem. Slacker [23] identifies packages that are critical when launching a container. By prioritizing these packages and lazily loading others, it can reduce the container startup latency. This improvement would benefit serverless computing platforms that launch functions with cold starts. In SAND, an application sandbox is launched once per host for multiple functions of the same application, which amortizes a container's startup latency over time.

Pipsqueak [46] and its follow-up work SOCK [47] create a cache of pre-warmed Python interpreters, so that functions can be launched with an interpreter that has already loaded the necessary libraries. However, many functions may need the same (or a similar) interpreter, requiring mechanisms to pick the most appropriate one and to manage the cache. SAND does not use any sharing nor cache management schemes; a SAND grain worker is a dedicated process for a single function and its libraries.

McGrath et al. [41] proposed a queuing scheme with workers announcing their availability in warm and cold queues, where containers can be reused and new containers can be created, respectively. Unlike SAND, this scheme maps a single container per function execution.

9 Discussion & Limitations

Performance Isolation & Load Balancing. In this paper, we reduce function interaction latencies via our sandboxing mechanism as well as the hierarchical message queuing and storage. SAND executes multiple instances of an application's functions in parallel as separate processes in the same container. This sandboxing mechanism enables a cloud operator to run many functions (and applications) even on a single host, with low idle memory cost and high resource efficiency. However, it is possible that grains in a sandbox compete for the same resources and interfere with each other's performance. A single host may also not have the necessary resources for multiple sandboxes. In addition, SAND's locality-optimized policy with the hierarchical queuing and storage might lead to sub-optimal load balancing.

SAND currently relies on the operating system to ensure that the grains (and sandboxes) running in parallel will receive their fair share of resources. As such, CPU time (or other resource consumption) rather than the wall clock time could be used for billing purposes. Nevertheless, competing grains and sandboxes may increase the latency an application experiences.

Non-fork Runtime Support. SAND makes a trade-off to balance performance and isolation by using process forking for function executions. The downside is that SAND currently does not support language runtimes without native forking (e.g., Java and NodeJS).

Alternative Sandboxing Mechanisms. SAND isolates applications with containers. Virtual machines (VMs), HyperContainers [27], gVisor [21] and CNTR [53] are viable alternatives. VMs provide a stronger isolation than containers, but may increase the maintenance effort for each application's custom VM and have long launch times. Unikernels [38,39] can also be used to isolate applications with custom system software compiled with the desired functionality. However, dynamically adding/removing a function requires a recompilation, affecting the flexibility of function assignment to a host. In contrast, containers provide fast launch times, flexibility to dynamically assign functions, and low maintenance effort because the OS is shared among all application containers on a host. Recently open-sourced gVisor [22] provides a stronger fault isolation than vanilla containers.

For function executions, SAND uses separate processes. Unikernels [35, 38, 39] have also been proposed to isolate individual functions in serverless environments. A bare-bones unikernel-based VM (e.g., LightVM [40]) can launch faster than a container to execute a function; however, its image size depends on the libraries loaded by each function, and thus, may impact startup latency. Other alternatives include light-weight contexts (LWCs) [37] and threads. Particularly, LWCs may provide the best of both worlds by being lighter than processes, but achieving stronger isolation than threads by giving a separate view of resources to each LWC. We plan to extend SAND with these alternative approaches.

10 Conclusion & Future Work

This paper introduced SAND, a novel serverless computing platform. We presented the design and implementation of SAND, as well as our experience in building and deploying serverless applications on it. SAND employs a new sandboxing approach, whereby stronger mechanisms such as containers are used to isolate different applications and lighter OS concepts such as processes are used to isolate functions of the same application. This approach enables SAND to allocate and deallocate resources for function executions much faster and more resource-efficiently than existing serverless platforms. Combined with our hierarchical message bus, where each host runs a local message bus to enable fast triggering of functions running on the same host, SAND reduces function interaction latencies significantly.

For future work, we plan to address the limitations discussed in §9. In particular, we plan to intelligently distribute application functions and sandboxes across many hosts to better balance the system load without sacrificing application latency.

Abstract

Recent deep learning (DL) models are moving more and more to dynamic neural network (NN) architectures, where the NN structure changes for every data sample. However, existing DL programming models are inefficient in handling dynamic network architectures because of: (1) substantial overhead caused by repeating dataflow graph construction and processing every example; (2) difficulties in batched execution of multiple samples; (3) inability to incorporate graph optimization techniques such as those used in static graphs. In this paper, we present "Cavs", a runtime system that overcomes these bottlenecks and achieves efficient training and inference of dynamic NNs. Cavs represents a dynamic NN as a static vertex function $\mathcal{F}$ and a dynamic instance-specific graph $\mathcal{G}$. It avoids the overhead of repeated graph construction by only declaring and constructing $\mathcal{F}$ once, and allows for the use of static graph optimization techniques on pre-defined operations in $\mathcal{F}$. Cavs performs training and inference by scheduling the execution of $\mathcal{F}$ following the dependencies in $\mathcal{G}$, hence naturally exposing batched execution opportunities over different samples. Experiments comparing Cavs to state-of-the-art frameworks for dynamic NNs (TensorFlow Fold, PyTorch and DyNet) demonstrate the efficacy of our approach: Cavs achieves a near one order of magnitude speedup on training of dynamic NN architectures, and ablations verify the effectiveness of our proposed design and optimizations.

1 Introduction

Deep learning (DL), which refers to a class of neural networks (NNs) with deep architectures, is now a workhorse powering state-of-the-art results on a wide spectrum of tasks [53, 54, 30]. One reason for its widespread adoption is the variety and quality of software toolkits, such as Caffe [23], TensorFlow [1], PyTorch [36] and DyNet [33, 34], which ease programming of DL models, and speed computation by harnessing modern computing hardware (e.g. GPUs), software libraries (e.g. CUDA, cuDNN [6]), and compute clusters [56, 57, 7].

One dominant programming paradigm, adopted by DL toolkits such as Caffe and TensorFlow, is to represent a neural network as a static dataflow graph [32, 1], where computation functions in the NN are associated with nodes in the graph, and input and output of the computation map to edges. It requires DL programmers to define the network architecture (i.e. the dataflow graph) using symbolic expressions, once before beginning execution. Then, for a given graph and data samples, the software toolkits can automatically derive the correct algorithm for training or inference, following backpropagation [21] and auto-differentiation rules. With proper optimization, the execution of these static dataflow graphs can be highly efficient; as the dataflow graph is fixed for all data, the evaluation of multiple samples through one graph can be naturally batched, leveraging the improved parallelization capability of modern hardware (e.g. GPUs). Moreover, by separating model declaration and execution, it makes it possible for the graph to be optimized once at declaration time [1], with these optimizations benefiting the efficiency of processing arbitrary input data batches at execution time.

While the dataflow graph has major efficiency advantages, its applicability highly relies on a key assumption – the graph (i.e. NN architecture) is fixed throughout the runtime. This assumption however breaks for *dynamic* NNs, where the network architectures conditionally change with every input sample, such as NNs that compute over sequences of variable lengths [22, 43], trees [45], and graphs [26].

Due to the growing interest in these sorts of dynamic models, recent years have seen an increase in the popularity of frameworks based on *dynamic declaration* [49, 33, 11], which declare a different dataflow graph per sample. While dynamic declaration is convenient to developers as it removes the restriction that computation be completely specified before training begins, it exhibits a few limitations. First, constructing a graph for every sample results in substantial overhead, which grows linearly with the number of input instances. In fact, we find graph construction takes longer time than the computation in some frameworks (see §5.2). It also prevents the application of complex static graph optimization techniques (see §3.4). Moreover, since each sample owns a dataflow graph specifying its unique computational pattern, batching together similarly shaped computations across instances is non-trivial. Without batching, the computation is inefficient due to its lack of ability to exploit modern computational hardware. While some progress has been made in recent research [34, 27], how to automatically batch the computational operations from different graphs remains a difficult problem.

To address these challenges, we present Cavs, an efficient runtime system for dynamic NNs that exploits the recurrent and recursive nature of dynamic NNs. Instead of declaring a dataflow graph per sample, it decomposes a dynamic NN into two components: a static vertex function $\mathcal{F}$ that is only declared (by the user) and optimized once before execution, and an input-specific graph $\mathcal{G}$ obtained via I/O at runtime. Cavs inherits the flexibility of symbolic programming [1, 12, 33] for DL; it requires users to define $\mathcal{F}$ by writing symbolic expressions in the same way as in static declaration. With $\mathcal{F}$ and $\mathcal{G}$, the workflow of training or testing a dynamic NN is cast as scheduling the execution of $\mathcal{F}$ following the structure of the input graph $\mathcal{G}$. Cavs will perform auto-differentiation, schedule the execution following dependencies in $\mathcal{G}$, and guarantee efficiency and correctness.

Cavs' design allows for highly efficient computation in dynamic graphs for a number of reasons. First, it allows the vertex function only to be defined and constructed once for any type of structured data, hence avoiding the overhead of repeated dataflow graph construction. Second, as the dataflow graph encoded by the vertex function is static throughout the runtime, it can benefit from various static graph optimizations [1, 5, 12, 18](§3.4), which is not the case in the scenario of dynamic declaration (§2.2). Moreover, it naturally exposes opportunities for batched computation, i.e. we are able to parallelize the execution of $\mathcal{F}$ over multiple vertices from different input graphs (§3.2) with the support of our proposed memory management strategy (§3.3).

To evaluate Cavs' performance, we compare it to several state-of-the-art systems supporting dynamic NNs. We focus our experiments on GPU training, and verify that both Fold and DyNet suffer from substantial overhead caused by repeated graph preprocessing or construction, which is bypassed by Cavs (§5.2). In a comparison with unbatched dynamic graphs in PyTorch and DyNet, two widely-used dynamic NN libraries, we verify that batching is essential for efficient processing. In a comparison with TensorFlow Fold and DyNet Autobatching, two libraries that allow for the use of dynamic NNs with automatic operation batching, we find that Cavs' has significant performance advantages; on static graphs it performs equivalently or slightly better, and on dynamic NNs with difficult-to-batch workloads (e.g. Tree-LSTM [45] and Tree-FC [27]), Cavs demonstrates near one order of magnitude speedups across multiple dataset and hyper-parameter settings (§5.1). We further investigate the effectiveness of our design choices: Cavs benefits from not only our proposed memory management strategy, but also various optimizations on graph execution, which were originally for static dataflow graphs and not applicable in dynamic declaration.

To summarize, we make three primary contributions in this paper: (1) We propose a novel representation for dynamic NNs, based on which we design four APIs and implement the Cavs runtime system (§3.1); (2) We propose several novel strategies in Cavs for efficient training and inference of dynamic NNs: the batching policy (§3.2), a memory management mechanism to guarantee the memory coalescing (§3.3), and multiple graph execution optimizations (§3.4); (3) We compare Cavs to state-of-the-art systems for dynamic NNs (§5). We reveal the problems of existing systems, and report near 10x speedup for Cavs on various experimental settings. We also verify the effectiveness of our proposed design strategies, and quantize their contributions to the final performance.

2 Background

2.1 Dynamic Neural Networks

Successful NN models generally exhibit suitable architectures that capture the structures of the input data. For example, convolutional neural networks [24, 53], which apply fixed-structured operations to fixed-sized images, are highly effective precisely because they capture the spatial invariance common in computer vision domains [39, 44]. However, apart from images, many forms of data are structurally complex and can not be readily captured by fixed-structured NNs. Appropriately reflecting these structures in the NN design has shown effective in sentiment analysis [45], semantic similarity between sentence pairs [40], and image segmentation [26].

To see this, we will take the constituency parsing problem as an example. Sentences in natural languages are often represented by their constituency parse tree [45, 31], whose structure varies depending on the content of the sentence itself (Fig. 1(a)). Constituency parsing is an important problem in natural language processing that aims to determine the corresponding grammar type of all internal nodes given the parsing tree of a sentence. Fig. 1(b) shows an example of a network that takes into account this syntactic structure, generating representations for the sentence by traversing the parse tree bottom-up and combining the representations for each sub-tree

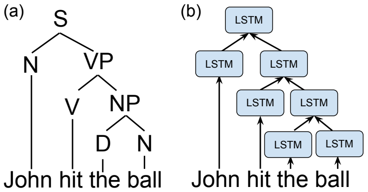

Figure 1: An example of a dynamic NN: (a) a constituency parsing tree, (b) the corresponding Tree-LSTM network. We use the following abbreviations in (a): S for sentence, N for noun, VP for verb phrase, NP for noun phrase, D for determiner, and V for verb.

using a dynamic NN called Tree Structured Long Short-term Memory (Tree-LSTM) [45]. In particular, each node of the tree maps to a LSTM function [22]. The internal computations and parameters of the LSTM function is defined in Fig. 4. At each node, it takes a variable number of inputs and returns to the parent node a vector representing the parsing semantics up to that point, until the root LSTM node returns a vector representing the semantics of the entire sentence.

The important observation is that the NN structure varies with the underlying parsing tree over *each* input sample, but the same LSTM cell is constant in shape and repeated at each internal node. Similar examples can be found for graph input [25, 26] and sequences of variable lengths [43, 2]. We refer to these NNs that exhibit different structures for different input samples as *dynamic neural networks*, in contrast to the static networks that have fixed network architecture for all samples.

2.2 Programming Dynamic NNs

There is a natural connection between NNs and directed graphs: we can map the graph nodes to the computational operations or parameters in NNs, and let the edges indicate the direction of the data being passed between the nodes. In this case, we can represent the process of training NNs as batches of data flowing through computational graphs, i.e. *dataflow graphs* [3, 1, 33].

Static declaration. As mentioned previously, *static declaration* is one dominant programming paradigm for programming NNs [3, 1, 5]. Fig 2(a) summarizes its workflow, which assumes all data samples share a fixed NN structure declared symbolically in a dataflow graph $\mathcal{D}$. Static declaration, using a single dataflow graph $\mathcal{D}$, cannot express dynamic NNs with structures changing with data samples. A primary remedy to this problem is to forgo the efficiency gains of static dataflow graphs and instead use a *dynamic declaration* framework.

Dynamic declaration. Fig 2(b) illustrates the workflow of dynamic declaration. By creating a unique dataflow graph $\mathcal{D}_k^p$ for each sample x_k^p according to its associated structure, dynamic declaration is able to express sample-dependent dataflow graphs. It however causes extra overhead on graph construction and puts constraints on runtime optimization, which usually lead to inefficient execution. Particularly, since a dataflow graph $\mathcal{D}_k^p$ needs to be constructed per sample, the overhead is linearly increasing with the number of samples, and sometimes yields downgraded performance [27] (§5.2), even for frameworks with optimized graph construction implementations [33]. Moreover, we can hardly benefit from any well-established dataflow graph optimization (§3.4). We will have to perform graph processing/optimization for each dataflow graph and every single sample; but incorporating this optimization itself has a non-negligible overhead. More importantly, as we are unable to batch the computation of different structured graphs, we note in Fig 2(b) single-instance computation $\mathcal{D}_k^p(x_k^p)$ would be very inefficient in the absence of batched computation.

Dynamic batching. To address the batching problem, some recent effort, notably TensorFlow Fold [27] and DyNet [34], propose *dynamic batching* that dynamically groups similarly shaped operations from different graphs, and batch their execution whenever possible.

Fold turns dynamic dataflow graphs into a static control flow graph to enable batched execution, but introduces a complicated functional programming-like interface and a large graph preprocessing overhead. As we will show in §5.2, the graph construction sometimes slows down the computation by 4x. DyNet proposes an auto-batching strategy that searches for batching opportunities by profiling every fine-grained operator, while this step itself has non-negligible overhead (§5.2). It is also not open to dataflow graph level optimizations.

In summary, there are three major challenges that prevent the efficient execution of dynamic neural networks: (1) non-negligible graph construction overhead; (2) difficulties in parallel execution; (3) unavailability to graph execution optimization.

2.3 Motivation

Our motivation for Cavs comes from a key property of dynamic NNs: most dynamic NNs are designed to exhibit a recursive structure; Within the recursive structure, a static computational function is being applied following the topological order over instance-specific graphs. For instance, if we denote the constituency parsing tree in §2.1 as a graph $\mathcal{G}$, where each node of the tree maps to a vertex in $\mathcal{G}$, we note the Tree-LSTM can be interpreted as follows: a computational cell function, specified in advance, is applied from leaves to the root, following the dependencies in $\mathcal{G}$. $\mathcal{G}$ might change with input samples, but the cell function itself is always static: It is parametrized by a fixed set of learnable parameters and interacts in the same way with its neighbors when applied at different vertices of $\mathcal{G}$.

These observations motivate us to decompose a dynamic NN into two parts: (1) a static computational *vertex function* $\mathcal{F}$ that needs to be declared by the program-

```
/* (a) static declaration */
// all samples must share one graph
declare a static dataflow graph $\mathcal{D}$.
for $p = 1 \to P$:
  read the $p$th data batch $\{x_k^p\}_{k=1}^K$.
  batched computation: $\mathcal{D}(\{x_k^p\}_{k=1}^K)$.
```

```
/* (b) dynamic declaration */
for $p = 1 \to P$:
  read the $p$th data batch $\{x_k^p\}_{k=1}^K$.
  for $k = 1 \to K$:
    declare a dataflow graph $\mathcal{D}_k^p$ for $x_k^p$.
    single-instance computation: $\mathcal{D}_k^p(x_k^p)$.
```

```
/* (c) our proposed vertex-centric model */
declare a symbolic vertex function $\mathcal{F}$.
for $p = 1 \to P$:
  read the $p$th data batch $\{x_k^p\}_{k=1}^K$.
  read their associated graphs $\{\mathcal{G}_k^p\}_{k=1}^K$.
  compute $\mathcal{F}$ over $\{\mathcal{G}_k^p\}_{k=1}^K$ with inputs $\{x_k^p\}_{k=1}^K$.
```

Figure 2: The workflows of (a) static declaration, (b) dynamic declaration, (c) Cavs. Notations: $\mathcal{D}$ notates both the dataflow graph itself and the computational function implied by it; p is the index of a batch while k is the index of a sample in the batch.

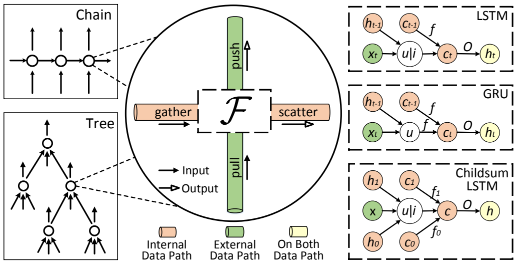

Figure 3: Cavs represents a dynamic structure as a dynamic input graph $\mathcal{G}$ (left) and a static vertex function $\mathcal{F}$ (right).

mer once before runtime; (2) a dynamic *input graph* $\mathcal{G}$ that changes with every input sample[1]. With this representation, the workflow of training a dynamic NN can be cast as scheduling the evaluation of the symbolic construct encoded by $\mathcal{F}$, following the graph dependencies of $\mathcal{G}$, as illustrated in Fig 2(c). This representation exploits the property of dynamic NNs to address the aforementioned issues in the following ways:

Minimize graph construction overhead. Cavs only requires users to declare $\mathcal{F}$ using symbolic expressions, and construct it once before execution. This bypasses repeated construction of multiple dataflow graphs, avoiding overhead. While it is still necessary to create an I/O function to read input graphs $\mathcal{G}$ for each sample, this must be done by any method, and only once before training commences, and it can be shared across samples.

Batched execution. With the proposed representation, Cavs transforms the problem of evaluating data samples $\{x_k^p\}_{k=1}^K$ (at the pth batch) on different dataflow graphs $\{\mathcal{D}_k^p\}_{k=1}$ [27, 34] into a simpler form – scheduling the execution of the vertex function $\mathcal{F}$ following the dependencies in input graphs $\{G_k^p\}_{k=1}$. For the latter problem, we can easily batch the execution of $\mathcal{F}$ on multiple vertices at runtime (§3.2), leveraging the batched computational capability of modern hardware and libraries.

Open to graph optimizations. Since the vertex function $\mathcal{F}$ encodes a dataflow graph which is static throughout runtime, it can benefit from various graph optimizations originally developed for static declaration, such as kernel fusion, streaming, and our proposed lazy batching, which are not effective in dynamic declaration.

Based on this motivation, we next describe the Cavs system. Cavs faces the following challenges in system design: (1) how to design minimal APIs in addition to the symbolic programming interface to minimize user code; (2) how to schedule the execution of $\mathcal{F}$ over multiple input graphs to enable batched computation; (3) how to manage memory to support the dynamic batching; (4) how to incorporate static graph optimization in Cavs's execution engine to exploit more parallelism.

3 Cavs Design and Optimization

3.1 Programming Interface

Conventional dataflow graph-based programming models usually entangle the computational workflow in $\mathcal{F}$ with the structure in $\mathcal{G}$, and require users to express them as a whole in a single dataflow graph. Instead, Cavs separates the static vertex function $\mathcal{F}$ from the input graph $\mathcal{G}$ (see Fig 3). While users use the same set of symbolic operators [1, 11] to assemble the computational workflow in $\mathcal{F}$, Cavs proposes four additional APIs, `gather`, `scatter`, `pull`, `push`, to specify how the messages shall be passed between connected vertices in $\mathcal{G}$:

- `gather(child_idx)`: `gather` accepts an index of a child vertex, gets its output, and returns a list of symbols that represent the output of the child.
- `scatter(op)`: `scatter` reverses `gather`. It sets the output of the current vertex as `op`. If this vertex is `gather`ed, the content of `op` will be returned.

`gather` and `scatter` are motivated by the GAS model in graph computing [14] – both are vertex-centric APIs that help users express the overall computational patterns by thinking locally like a vertex: `gather` receives messages from dependent vertices, while `scatter` updates information to parent vertices (see discussion in §6).

However, in dynamic NNs, the vertex function $\mathcal{F}$ usually takes input from not only the internal vertices of $\mathcal{G}$ (internal data path in Fig 3), but also the external environment, e.g. an RNN can take inputs from a CNN feature extractor or some external I/O (external data path in Fig 3). Cavs therefore provides another two APIs to express such semantics:

- `pull()`: `pull` grabs inputs from the external of the current dynamic structure, e.g. another NN, or I/O.
- `push(op)`: `push` reverses `pull`. It sets the output of the current vertex as `op`. If this vertex is `pull`ed by others, the content of `op` will be returned.

[1] In the following text, we will distinguish the term *vertex* from *node*. We use *vertex* to denote a vertex in the input graph while *node* to denote an operator/variable in a dataflow graph. Hence, a vertex function can have many nodes as itself represents a dataflow graph.

```
def ℱ():
  for k in range(N):
    S = gather(k) # gather states of child vertices
    c_k, h_k = split(S, 2) # get hidden states c and h
  x = pull() # pull the first external input x

  # specify the computation
  h = ∑_{k=0}^{N−1} h_k
  i = sigmoid(W^(i)× x + U^(i)× h + b^(i))
  for k in range(N):
    f_k = sigmoid(W^(f)× x + U^(f)× h_k + b^(f))
  o = sigmoid(W^(o)× x + U^(o)× h + b^(o))
  u = tanh(W^(u)× x + U^(u)× h + b^(u))
  c = i ⊗ u + ∑_{k=0}^{N−1} f_k ⊗ c_k
  h = o ⊗ tanh(c)

  scatter(concat([c, h], 1)) # scatter c, h to parents
  push(h)                    # push to external connectors
```

Figure 4: The vertex function of an N-ary child-sum TreeLSTM [45] in Cavs. Within $\mathcal{F}$, users declare a computational dataflow graph using symbolic operators. The defined $\mathcal{F}$ will be evaluated on each vertex of $\mathcal{G}$ following graph dependencies.

Once $\mathcal{F}$ declared, together with an input graph $\mathcal{G}$, they encode a recursive dataflow graph structure, which maps to a subgraph of the implicit full dataflow graph of the model that may needs to be explicitly declared in traditional programming models. Via push and pull, Cavs allows users to connect any external static dataflow graph to a dynamic structure encoded by $(\mathcal{F}, \mathcal{G})$, to express more complex model architectures, such as the LRCN [9] (i.e. connecting a CNN to an RNN), or an encoder-decoder LSTM network [43] (i.e. connecting two different recursive structures). With these four APIs, we present in Fig 4 an example user program how the N-ary child-sum Tree-LSTM [45] can be simply expressed by using them and other mathematical operators.

Auto-differentiation. Given a vertex function $\mathcal{F}$ Cavs derives $\partial\mathcal{F}$ following the auto-differentiation rules: for each math expression such as $s_l = \mathrm{op}(s_r)$ in $\mathcal{F}$, Cavs generates a corresponded backward expression $\nabla s_r = \texttt{grad\_op}(\nabla s_l, s_l, s_r)$ in $\partial\mathcal{F}$. For the four proposed operators, we note scatter is the gradient operator of gather in the sense that if gather collects inputs from child vertex written by scatter at the forward pass, a scatter needs to be performed to write the gradients for its dependent vertices to gather at the backward pass. Hence, for an expression like $s_l = \texttt{gather}(\texttt{child\_idx})$ in $\mathcal{F}$, Cavs will generate a backward expression $\texttt{scatter}(\nabla s_l)$ in $\partial\mathcal{F}$. Similarly, the gradient operator of scatter is gather. The same rules apply for push and pull.

Expressiveness. With these four APIs, Cavs can be seen as a middle ground between static and dynamic declaration. In the best case that the NN is fully recursive (e.g. most recurrent or recursive NNs), it can be represented by a single vertex function and an input graph. While in the worst case, that every sample has a unique input graph while every vertex in the graph has a unique way to interact with its neighboring vertices (i.e. the NN is dynamic but non-recursive), Cavs reduces to dynamic declaration that one has to define a vertex function for each vertex of each input graph. Fortunately, dynamic NNs in this scenario are usually avoided because of the difficulties in design, programming and learning.

3.2 Scheduling

Once $\mathcal{F}$ is defined and $\mathcal{G}$ is obtained from I/O, Cavs will perform computation by scheduling the evaluation of $\mathcal{F}$ over data samples $\{x_i\}_{i=1}^N$ and their input graphs $\{\mathcal{G}_i\}_{i=1}^N$.

Forward pass. For a sample x_i with its input graph $\mathcal{G}_i$, the scheduler starts the forward pass from the input vertices of $\mathcal{G}_i$, and proceeds following the direction indicated by the edges in $\mathcal{G}_i$: at each sub-step, the scheduler figures out the next activated vertex in $\mathcal{G}_i$, and evaluates all expressions in $\mathcal{F}$ at this vertex. It then marks this vertex as *evaluated*, and proceeds with the next activated vertex until reaching a terminal vertex (e.g. the loss function). A vertex of $\mathcal{G}$ is activated if and only if all its dependent vertices have been evaluated.

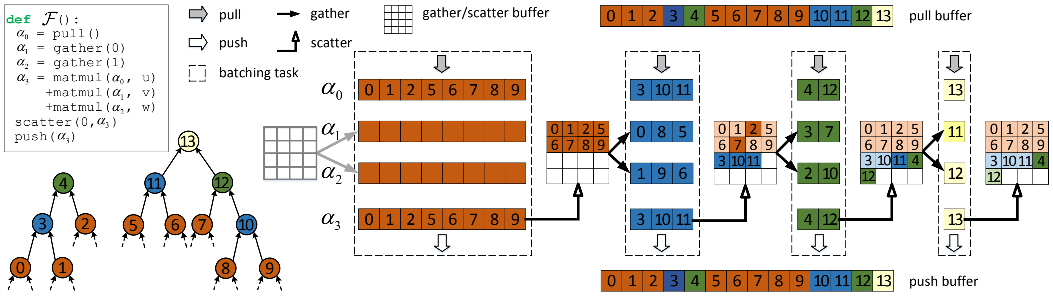
Backward pass. The backward pass is continued right after the forward. The scheduler first resets the status of all vertices as *not evaluated*, then scans the graph in a reverse direction, starting from the ending point of the forward pass. It evaluates $\partial\mathcal{F}$ at each vertex until all vertices have been evaluated in the backward pass.

To train a NN to convergence, the above process has to be iterated on all samples $\{x_i\}_{i=1}^N$ and their input graphs $\{\mathcal{G}_i\}_{i=1}^N$, for many epochs. We next describe our batched execution policy to speed the computation.

Batching policy. Given a data batch $\{x_k\}_{k=1}^K \subseteq \{x_i\}_{i=1}^N$ and associated graphs $\{\mathcal{G}_k\}_{k=1}^K$, this policy groups multiple vertices and performs batched evaluation of $\mathcal{F}$ in order to reduce kernel launches and exploit parallelism. Specifically, a forward pass over a batch $\{x_k\}_{k=1}^K$ are performed in multiple steps. At each step t, Cavs analyzes $\{\mathcal{G}_k\}_{k=1}^K$ at runtime and determines a set V_t that contains all activated vertices in graphs $\{\mathcal{G}_k\}_{k=1}^K$. It then evaluates $\mathcal{F}$ over these vertices by creating a *batched execution task*, with the task ID set to t[2]. The task is executed by the Cavs execution engine (§3.4). Meanwhile, the scheduler records this task by pushing V_t into a stack $\mathcal{S}$. To perform backward pass, the scheduler pops out an element V_t from $\mathcal{S}$ at each step – the execution engine will evaluate the derivative function $\partial\mathcal{F}$ over vertices in V_t, until all vertices of $\{\mathcal{G}_k\}_{k=1}^K$ are evaluated.

We note the batching policy is similar to the *dynamic batching* in Fold [27] and DyNet [33]. However, Cavs determines how to batch fully dynamically during runtime using simple breadth-first search with negligible cost (instead of analyzing full dataflow graphs before every iteration of the execution). Since batched computation requires the inputs to an expression over multiple

[2] Whenever the context is clear, we use V_t to denote both the set of vertices to be batched together, and the batched execution task itself.



```
def 𝓕():
  α₀ = pull()
  α₁ = gather(0)
  α₂ = gather(1)
  α₃ = matmul(α₀, u)
      +matmul(α₁, v)
      +matmul(α₂, w)
  scatter(0,α₃)
  push(α₃)
```

Figure 5: The memory management at the forward pass of $\mathcal{F}$ (top-left) over two input trees (bottom-left). Cavs first analyzes $\mathcal{F}$ and inputs – it creates four dynamic tensors $\{\alpha_n\}_{n=0}^{3}$, and figures out there will be four batch tasks (dash-lined boxes). Starting from the first task (orange vertices $\{0,1,2,5,6,7,8,9\}$), Cavs performs batched evaluation of each expression in $\mathcal{F}$. For example, for the pull expression $\alpha_0 = \texttt{pull}()$, it indexes the content of α_0 on all vertices from the *pull buffer* using their IDs, and copies them to α_0 continuously; for scatter and push expressions, it scatters a copy of the output (α_3) to the *gather buffer*, and pushes them to the push buffer, respectively. Cavs then proceeds to the next batching task (blue vertices). At this task, Cavs evaluates each expression of $\mathcal{F}$ once again for vertices $\{3,10,11\}$. (e.g. for a pull expression $\alpha_0 = \texttt{pull}()$, it pulls the content of α_0 from pull buffer again; for a gather expression $\alpha_2 = \texttt{gather}(1)$ at vertex 3, it gathers the output of the second child of 3, which is 1); it writes results continuously at the end of each dynamic tensor. It proceeds until all batching tasks are finished.

vertices to be placed on a continuous memory buffer, we develop a new memory management support for it.

3.3 Memory Management

In static declaration [1, 33], a symbol in the user program usually corresponds to a fixed-sized *tensor* object with a batch size dimension. While in Cavs, each batching task V_t is determined at runtime. For the batched computation to be efficient, Cavs must guarantee for each batching task, the inputs to each expression of $\mathcal{F}$ over a group of runtime-determined vertices coalescing in memory.

```
struct DynamicTensor {
  vector<int> shape;
  int bs;
  int offset;
  void* p; };
```

Figure 6: Dynamic tensor.

Cavs proposes a novel data structure *dynamic tensor* to address this challenge (Fig 6). A dynamic tensor is a wrapper of a multi-dimensional array [1, 52]. It contains four attributes: `shape`, `bs`, a pointer `p` to a chunk of memory, and `offset`. `shape` is an array of integers representing the specific shape of the tensor excluding the batch dimension. It can be inferred from the user program and set before execution. The batch size `bs` is dynamically set by the scheduler at runtime at the beginning of a batching task. To access a dynamic tensor, one moves `p` forward with the value of `offset`, and reads/writes number of elements equal to $\texttt{bs} \cdot \prod_i \texttt{shape}[i]$. Therefore, `bs` together with `offset` provide a view of the tensor, and the state of the tensor will vary based on their values. Given a vertex function $\mathcal{F}$, Cavs creates dynamic tensors $\{\alpha_n\}_{n=1}^{N}$ for each non-parameter symbol $s_n (n = 1, \ldots, N)$ in $\mathcal{F}$, and also $\{\nabla\alpha_n\}_{n=1}^{N}$ as their gradients, while it creates static tensors for model parameters.

Fig 5 illustrates how the memory is assigned during the forward pass by manipulating dynamic tensors. In particular, in a training iteration, for a batching task V_t, the scheduler sets `bs` of all $\{\alpha_n\}_{n=1}^{N}$ to $M_t = |V_t|$ (the number of vertices in V_t). The execution engine then performs batched evaluation of each expression in $\mathcal{F}$. For an expression $s_l = \texttt{op}(s_r)$[3], Cavs first accesses α_r (the dynamic tensor of the RHS symbol s_r) – it offsets $\alpha_r.\texttt{p}$ by $\alpha_r.\texttt{offset}$, and reads a block of $M_t \prod_i \alpha_r.\texttt{shape}[i]$ elements, and presents it as a tensor with batch size M_t and other dimensions as $\alpha_r.\texttt{shape}$. It then applies batched computational kernels of the operator `op` over this memory block, and writes the results to α_l (the dynamic tensor of the LHS symbol s_l) on the continuous block in between $[\alpha_l.\texttt{p} + \alpha_l.\texttt{offset}, \alpha_l.\texttt{p} + \alpha_l.\texttt{offset} + M_t \prod_i \alpha_l.\texttt{shape}[i]]$. Upon the completion of V_t, the scheduler increases `offset` of all $\{\alpha_n\}_{n=1}^{N}$ by $M_t \prod_i \alpha_n.\texttt{shape}[i]$, respectively. It then starts the next task V_{t+1}. Hence, intermediate results generated in each batching task at forward pass are stored continuously in the dynamic tensors, and their offsets are recorded.

At the entrance of $\mathcal{F}$, the vertices $\{v_m\}_{m=1}^{M_t}$ in V_t need to interact with its dependent vertices in previous V_{t-1} to `gather` their outputs as inputs (L3 of Figure 4), or `pull` inputs from the external (L5 of Figure 4). Cavs maintains memory buffers to enable this (Figure 5). It records the offsets of the dynamic tensors for each $v_m \in V_t$, and therefore during the execution of `gather` operator, the memory slices of specific children can be indexed. As shown in Figure 5, `gather` and `scatter` share the same temporary buffer for memory re-organization, but `push` and `pull` operate on external memory buffers.

Algorithm 1 summarizes the memory management during forward pass. The backward execution follows an exactly reverse order of the forward pass (§3.2), which we skip in the text. With this strategy, Cavs guarantees memory continuity for any batched computation of $\mathcal{F}$ and $\partial\mathcal{F}$. Compared to dynamic batching in DyNet, Cavs performs memory movement only at the entrance

[3] Note that the user-defined expressions can be arbitrary, e.g. with more than one argument or return values

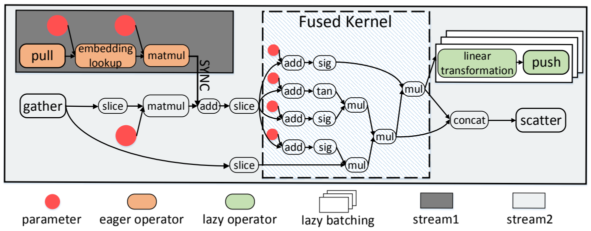


Figure 7: The dataflow graph encoded by $\mathcal{F}$ of Tree-LSTM.

and exit of $\mathcal{F}$, instead of for each expression (operator). We empirically find this significantly reduces overhead of memory operations (§5.3).

Algorithm 1 Memory management at forward pass.

```
function FORWARD($\{V_t\}_{t=1}^{T}, \{\alpha_n\}_{n=1}^{N}, \mathcal{F}$)
  for $t = 1 \to T$ do
    for $n = 1 \to N$ do $\alpha_n$.bs $\leftarrow M_t$ end for
    for each expression like $s_l = \texttt{op}(s_r)$ in $\mathcal{F}$ do
      if op $\in \{\texttt{gather}, \texttt{pull}\}$ then
        $C \leftarrow \prod_i \alpha_l.\texttt{shape}[i], q \leftarrow \alpha_l.\texttt{p} + \alpha_l.\texttt{offset}$.
        for $v_m \in V_t (m = 1 \to M_t)$ do
          $\texttt{src} \leftarrow \texttt{IndexBuffer}(\texttt{op}, m), \texttt{dest} \leftarrow q + (m-1)C$.
          $\texttt{memcpy}(\texttt{dest}, \texttt{src}, C)$.
        end for
      else if op $\in \{\texttt{scatter}, \texttt{push}\}$ then
        $C \leftarrow \prod_i \alpha_r.\texttt{shape}[i], q \leftarrow \alpha_r.\texttt{p} + \alpha_r.\texttt{offset}$.
        for $v_m \in V_t (m = 1 \to M_t)$ do
          $\texttt{dest} \leftarrow \texttt{IndexBuffer}(\texttt{op}, m), \texttt{src} \leftarrow q + (m-1)C$.
          $\texttt{memcpy}(\texttt{dest}, \texttt{src}, C)$.
        end for
      else
        perform batched computation: $\alpha_l = \texttt{op\_kernel}(\alpha_r)$.
      end if
    end for
    for $n = 1 \to N$ do $\alpha_n.\texttt{offset} += M_t \prod_i \alpha_n.\texttt{shape}[i]$ end for
  end for
end function
```

3.4 Optimizing Execution Engine

Since Cavs separates out a static dataflow graph encoded by $\mathcal{F}$, we can replace the original $\mathcal{F}$ with an optimized one that runs more efficiently, as long as maintaining correctness. We next described our optimization strategies.

Lazy batching and streaming[4]**.** In addition to batched execution of $\mathcal{F}$, the lazy batching and streaming explore potential parallelism for a certain group of finer-grained operators in $\mathcal{F}$ or $\partial\mathcal{F}$ called lazy and eager operators.

Definition. An operator in $\mathcal{F}$ ($\partial\mathcal{F}$) is a *lazy operator* if at the forward (backward) pass, for $\forall v \in \mathcal{G}, \forall \mathcal{G} \in \{\mathcal{G}_k\}_{k=1}^{K}$, the evaluation of $\mathcal{F}$ ($\partial\mathcal{F}$) at any parent (dependent) vertex of v does not rely on the evaluation of $\mathcal{F}$ at v. It is an *eager operator* if the evaluation at v does not rely on the evaluation of $\mathcal{F}$ ($\partial\mathcal{F}$) at any dependents (parents) of v.

Proposition. Denote $\mathcal{D}_{\mathcal{F}}$ ($\mathcal{D}_{\partial\mathcal{F}}$) as the dataflow graph encoded by $\mathcal{F}$ ($\partial\mathcal{F}$), and $g, s \in \mathcal{D}_{\mathcal{F}}$ ($\mathcal{D}_{\partial\mathcal{F}}$) as nodes of `gather` and `scatter` operator, respectively. A node that has g as its dependent and is not on any path from g to s is a lazy operator. A node that has s as its ancestor and is not on any path from g to s is an eager operator.

Fig 7 illustrates a forward dataflow graph of the vertex function of Tree-LSTM, with eager and lazy operators colored. A property of them is that their evaluation is not fully subject to the dependency reflected by the input graph $\mathcal{G}$. For instance, the `pull` operator in Fig 7 is eager and can be executed in prior – even before $\mathcal{F}$ has been evaluated at the vertices that `gather` tries to interact with; the `push` operator is lazy, so we can defer its execution without impacting the evaluation of $\mathcal{F}$ at parent vertices. Similarly, in $\partial\mathcal{F}$, the gradient derivation for model parameters are mostly lazy – their execution can be deferred as long as the gradients of hidden states are derived and propagated in time. Cavs leverages this property and proposes the lazy batching strategy. It defers the execution of all lazy operators in $\mathcal{F}$ and $\partial\mathcal{F}$ until all batching tasks $\{V_t\}_{t=1}^{T}$ has finished. It then performs a batched execution of these lazy operators over all vertices of $\{\mathcal{G}_k\}_{k=1}^{K}$. These operators includes, but is not limited to, the `push` operator that is doing memory copy, and operators for computing gradients of model parameters. Lazy batching helps exploit more parallelism and significantly reduces kernel launches. Empirically lazy batching brings 20% overall improvement (§5.3).

To leverage the exhibited parallelization opportunity between eager operators and the operators on the path from `gather` to `scatter` (Figure 7), Cavs proposes a streaming strategy that pipelines the execution of these two groups of operators. It allocates two streams, and puts the eager operators on one stream, and the rest (excluding lazy operators) on the other. Hence, independent operators in two streams run in parallel, while for those operators that depend on an eager operator, this dependency is respected by synchronization barriers (Fig 7).

Automatic kernel fusion. Given $\mathcal{F}$, before execution, Cavs will run a *fusion detector* [20] to scan its corresponded dataflow graph and report all *fuse-able* subgraphs therein, i.e. all nodes in a fuse-able subgraph can be fused as a single operator that behaves equivalently but takes less execution time (e.g. with fewer kernel launches and I/O, or faster computation). Currently, we only detect groups of directly linked elementwise operators, such as $+$, `sigmoid`, as shown in Fig 7, and we use a simple union-find algorithm to detect the largest possible fuse-able subgraphs. Given a fuse-able subgraph, Cavs adopts de facto automatic code generation techniques [37, 8, 38, 35] to generate lower-level kernel implementations. Replacing the original fuse-able subgraphs with fused operators during execution is beneficial in many aspects: (1) it reduces the number of kernel launches; (2) on some devices such as GPUs, kernel fu-

[4] Streaming is a borrowed terminology from CUDA programming which means executing different commands concurrently with respect to each other on different GPU streams. As Cavs' optimizations are agnostic to the low-level hardware, we use streaming interchangeably with multi-threading if the underlying computing hardware is CPU.

sion transform device memory access into faster device registers access. We empirically report another 20% improvement with automatic kernel fusion (§5.3).

4 Implementation

Cavs is implemented as a C++ library and integrable with existing DL frameworks to enhance their support for dynamic NNs. It is composed of three major layers (which is the case for most popular frameworks [3, 1, 33]): (1) a frontend that provides device-agnostic symbolic programming interface; (2) an intermediate layer that implements the core execution logic; (3) a backend with device-specific kernels for all symbolic operators.

Frontend. In addition to the four APIs, Cavs provides a macro operator `VertexFunction`. Users instantiate it by writing symbolic expressions and specifying methods to read input graphs. It encapsulates scatter/gather semantics, so users can continue using higher level APIs. To construct more complex NN architectures (e.g. encoder-decoder LSTM [43], LRCN [9])), users employ `push` and `pull` to connect multiple vertex functions, or to external structures.

Intermediate Layer. Cavs has its core runtime logic at this layer, i.e. the batching scheduler, the memory management, and the execution engine, etc.

Backend. Following practice [1, 33, 12], we implement device-specific operator kernels at this layer. Cavs has optimized implementations for the four proposed operators (`gather`, `scatter`, `pull`, `push`). Specifically, `gather` and `pull` index different slices of a tensor and puts them together continuously on memory; `scatter` and `push` by contrast splits a tensor along its batch dimension, and copy different slices to different places. Cavs implements customized memcpy kernels for there four operators, so that copying multiple slices from (or to) different places is performed within one kernel.

Distributed Execution. While Cavs's implementations are focused on improving the efficiency on a single node, they are compatible with most data-parallel distributed systems for deep learning [56, 7, 1], and can also benefit distributed execution on multiple nodes.

5 Evaluation

In this section, we evaluate Cavs on multiple NNs and datasets, obtaining the following major findings: (1) Cavs has little overhead: on static NNs, Cavs demonstrates equal performance on training and inference with other systems; On several NNs with notably difficult-to-batch structures, Cavs outperforms all existing frameworks by a large margin. (2) We confirm the graph construction overhead is substantial in both Fold [27] and dynamic declaration [33], while Cavs bypasses it by loading input graphs through I/O. (3) We verify the effectiveness of our proposed design and optimization via ablation studies, and discuss Cavs' advantages over other DL systems for dynamic dataflow graphs.

Environment. We perform all experiments in this paper on a single machine with an NVIDIA Titan X (GM200) GPU, a 16-core CPU, and CUDA v8.0 and cuDNN v6 installed. As modern DL models are mostly trained using GPUs, we focus our evaluation on GPUs, but note Cavs' design and implementation do not rely on a specific type of device. We mainly compare Cavs to TensorFlow v1.2 [1] with XLA [18] and its variant Fold [27], PyTorch v0.3.0 [11], and DyNet v2.0 [33] with autobatching [34], as they have reported better performance than other frameworks [5, 50] on dynamic NNs. We focus on metrics for system performance, e.g. time to scan one epoch of data. Cavs produces exactly the same numerical results with other frameworks, hence the same per-epoch convergence

Models and dataset. We experiment on the following models with increasing difficulty to batch: (a) `Fixed-LSTM` language model (LM): a static sequence LSTM with fixed steps for language modeling [42, 43, 55]. We train it using the PTB dataset [48] that contains over 10K different words. We set the number of steps as 64, i.e. at each iteration of training, the model takes a 64-word sentence from the training corpus, and predicts the next word of each word therein. Obviously, the computation can be by nature batched easily, as each sentence has exactly the same size. (b) `Var-LSTM` LM: that accepts variable-length inputs. At each iteration the model takes a batch of natural sentences with different length from PTB, and predicts the next words; (c) `Tree-FC`: the benchmarking model used in [27] with a single fully-connected layer as its cell function. Following the same setting in [27], we train it over synthetic samples generated by their code [47] – each sample is associated with a complete binary tree with 256 leaves (therefore 511 vertices per graph); (d) `Tree-LSTM`: a family of dynamic NNs widely adopted for text analysis [26, 51]. We implement the binary child-sum Tree-LSTM in [45], and train it as a sentiment classifier using Stanford sentiment treebank (SST) dataset [40]. The dataset contains 8544 training sentences, each associated with a human annotated grammar tree, and the longest one has 54 words.

5.1 Overall Performance

We first verify the viability of our design on the easiest-to-batch case: `Fixed-LSTM` language model. We compare Cavs to the following three strong baselines: (1) `CuDNN` [6]: a CuDNN-based fixed-step sequence LSTM, which is highly optimized by NVIDIA using handcrafted kernels and stands as the best performed implementation on NVIDIA GPUs; (2) `TF`: the official implementation of `Fixed-LSTM` LM in TensorFlow repository [46] based on static declaration; (3) `DyNet`: we implement a 64-step

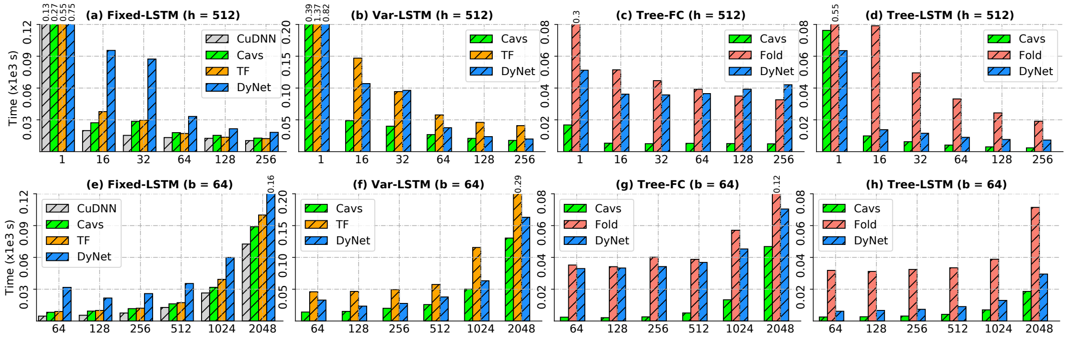

Figure 8: Comparing five systems on the averaged time to finish one epoch of training on four models: `Fixed-LSTM`, `Var-LSTM`, `Tree-FC` and `Tree-LSTM`. In (a)-(d) we fix the hidden size *h* and vary the batch size *bs*, while in (e)-(h) we fix *bs* and vary *h*.

LSTM in DyNet based on dynamic declaration – we declare a dataflow graph per sample, and train with the autobatching [34] enabled; (4) `Cavs` with batching policy, and all input samples have a same input graph – a 64-node chain. We train the model to converge, and report the average time per epoch in Fig 8(a)(e), where in (a) we fix the hidden size *h* of the LSTM unit as 512 and vary the batch size *bs*, and in (e) we fix $bs = 64$ and vary *h*. Empirically, CuDNN performs best in all cases, but note it is highly inflexible. Cavs performs slightly better than `TF` in various settings, verifying that our system has little overhead handling fully static graphs, though it is specialized for dynamic ones. We also conclude from Fig 8 that batching is essential for GPU-based DL: $bs = 128$ is nearly one order of magnitude faster than $bs = 1$ regardless of used frameworks. For Cavs, the batching policy is 1.7x, 3.8x, 7.0x, 12x, 15x, 25x, 36x faster than non-batched at $bs = 2, 4, 8, 16, 32, 64, 128$, respectively.

Next, we experiment with `Var-LSTM`, the most commonly used RNN for variable-length sequences. We compare the following three implementations (CuDNN-based LSTM cannot handle variable-length inputs): (1) `TF`: an official TensorFlow implementation based on the dynamic unroll approach described in §6; (2) `DyNet`: an official implementation from DyNet benchmark repository based on dynamic declaration [10]; (3) `Cavs`: where each input sentence is associated with a chain graph that has number of vertices equal to the number of words. We vary *h* and *bs*, and report the results in Figure 8(b)(f), respectively. Although all three systems perform batched computation in different ways, `Cavs` is consistently 2-3 times faster than `TF`, and outperforms `DyNet` by a large margin. Compared to `TF`, `Cavs` saves computational resources. `TF` dynamically unrolls the LSTM unit according to the longest sentence in the current batch, but it cannot prevent unnecessary computation for those sentences that are shorter than the longest one.

We then turn to `Tree-FC`, a dynamic model for benchmarking. Since vanilla TensorFlow is unable to batch its computation, we compare `Cavs` to (1) `DyNet` and (2) `Fold`, a specialized library built upon TensorFlow for dynamic NNs, with a depth-based dynamic batching strategy. To enable the batching, it however needs to preprocess the input graphs, translate them into intermediate representations and pass them to lower-level TensorFlow control flow engine for execution. We report the results in Figure 8(c)(g) with varying *bs* and *h*, respectively. For all systems, we allocate a single CPU thread for graph preprocessing or construction. `Cavs` shows at least an order of magnitude speedups than `Fold` and `DyNet` at $h \leq 512$. Because the size of the synthetic trees is large, one major advantage of `Cavs` over them is the alleviation of graph preprocessing/construction overhead. With a single CPU thread, `Fold` takes even more time on graph preprocessing than computation (§5.3).

Finally, we compare three frameworks on `Tree-LSTM` in Figure 8(d)(h): `Cavs` is 8-10x faster than `Fold`, and consistently outperforms `DyNet`. One difference in this experiment is that we allocate as many CPU threads as possible (32 on our machine) to accelerate graph preprocessing for `Fold`, otherwise it will take much longer time. Further, we note `DyNet` performs much better here than on `Tree-FC`, as the size of the input graphs in SST (maximally 54 leaves) is much smaller than the synthetic ones (256 leaves each) in `Tree-FC` experiments. We observe `DyNet` needs more time on graph construction for large input graphs, and `DyNet`'s dynamic batching is less effective on larger input graphs, as it has to perform frequent memory checks to support its dynamic batching, which we will discuss in §5.3. We also compare Cavs with PyTorch – its per-epoch time on Tree-LSTM is 542s, 290x slower than Cavs when the batch size is 256. Compared to other systems, PyTorch cannot batch the execution of dynamic NNs.

5.2 Graph Construction and Computation

In this section, we investigate the graph construction overhead in Fold and DyNet. To batch computation of different graphs, Fold analyzes the input graphs to recognize batch-able dynamic operations, then translates them into intermediate instructions, with which, TensorFlow generates appropriate control flow graphs for evaluation – we will treat the overhead caused in both steps as

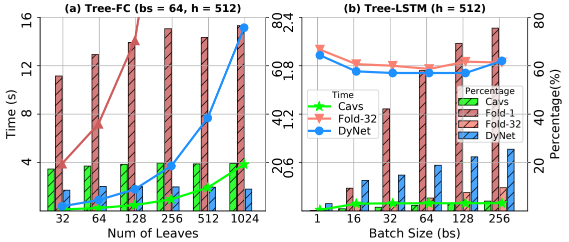

Figure 9: The averaged graph construction overhead per epoch when training (a) Tree-FC with different size of input graphs (b) Tree-LSTM with different batch size. The curves show absolute time in second (left y-axis), and the bar graphs show its percentage of the overall time (right y-axis).

Fold's graph construction overhead. DyNet, as a typical dynamic declaration framework, has to construct as many dataflow graphs as the number of samples. Though DyNet has optimized its graph construction to make it lightweight, the overhead still grows with the training set and the size of input graphs. By contrast, Cavs takes constant time to construct a small dataflow graph encoded by $\mathcal{F}$, then reads input graphs through I/O. To quantify the overhead, we separate the graph construction from computation, and visualize in Figure 9(a) how it changes with the average number of leaves (graph size) of input graphs on training Tree-FC, with fixed $bs = 64, h = 512$. We compare (1) Cavs (2) Fold-1 which is Fold with one graph processing thread and (3) DyNet. We plot for one epoch, both the (averaged) absolute time for graph construction and it percentage of the overall time. Clearly we find that all three systems take increasingly more time when the size of the input graphs grows, but Cavs, which loads graphs through I/O, causes the least overhead at all settings. In terms of the relative time, Fold unfortunately wastes 50% at 32 leaves, and 80% when the tree has 1024 leaves, while DyNet and Cavs take only 10% and 20%, respectively.

We also wonder how the overhead is related with batch size when there is fixed computational workload. We report in Figure 9(b) the same metrics when training Tree-LSTM with varying bs. We add another baseline Fold-32 with 32 threads for Fold's graph preprocessing. As Fold-1 takes much longer time than others, we report its time at $bs = 1, 16, 32, 64, 128, 256$ here (instead of showing in Figure 9): 1.1, 7.14, 31.35, 40.1, 46.13, 48.77. Except $bs = 1$, all three systems (except Fold-1) take almost constant time for graph construction in one epoch, regardless of bs, while Fold-32 and DyNet take similar time, but Cavs takes 20x less. Nevertheless, at the percentage scale, increasing bs makes this overhead more prominent, because larger batch size yields improved computational efficiency, therefore less time to finish one epoch. This, from one perspective, reflects that the graph construction is a main obstacle that grows with the number of training samples and prevents the efficient training of dynamic NNs in existing frameworks, while Cavs successfully overcomes this barrier.

# leaves	time (s)	Speedup	bs	time (s)	Speedup
32	**0.6** / 3.1 / 4.1	**5.4** / 7.1	1	76 / 550 / **62**	**7.2** / 0.8
64	**1.1** / 3.9 / 8.0	3.7 / 7.5	16	**9.8** / 69 / 12	7.0 / 1.2
128	**2** / 6.2 / 16	3.0 / 7.9	32	**6.2** / 43 / 9.9	7.0 / 1.6
256	**4** / 10.6 / 33.7	2.7 / 8.7	64	**4.1** / 29 / 7.4	**7.2** / 1.8
512	**8** / 18.5 / 70.6	2.3 / 8.9	128	**2.9** / 20.5 / 5.9	7.1 / 2.0
1024	**16** / 32 / 153	2.1 / **9.7**	256	**2.3** / 15.8 / 5.4	7.0 / **2.4**

Table 1: The averaged computation time (Cavs/Fold/DyNet) and the speedup (Cavs vs Fold/DyNet) for training one epoch on Tree-FC with varying size of the input trees (left part), and on Tree-LSTM with varying batch size (right part).

Apart from the graph construction we report in Table 1 the computation-only time. Cavs shows maximally 5.4x/9.7x and 7.2x/2.4x speedups over Fold/DyNet on Tree-FC and Tree-LSTM, respectively. The advantages stem from two main sources: an optimized graph execution engine, and a better-suited memory management strategy, which we investigate next.

5.3 Optimizations

Graph Execution Engine. To reveal how much each optimization in §3.4 contributes to the final performance, we disable lazy batching, fusion and streaming in Cavs and set this configuration as a baseline (speedup = 1). We then turn on one optimization at a time and record how much speedup it brings. We train Fixed-LSTM and Tree-LSTM, and report the averaged speedups one computation-only time in one epoch over the baseline configuration in Fig 10, with $bs = 64$ but varying h. Lazy batching and fusion consistently deliver nontrivial improvement – lazy batching is more beneficial with a larger h while fusion is more effective at smaller h, which are expected: lazy batching mainly parallelizes matrix-wise operations (e.g. matmul) commonly with $O(h^2)$ or higher complexity, while fusion mostly works on elementwise operations with $O(h)$ complexity [19].

Streaming, compared to the other strategies, is less effective on Tree-LSTM than on Fixed-LSTM, as we have found the depth of the input trees in SST exhibit high variance, i.e. some trees are much deeper than others. In this case, many batching tasks only have one vertex to be evaluated. The computation is highly fragmented and the efficiency is bounded by kernel launching latency. Lazy batching and fusion still help as they both reduce kernel launches (§3.4). Streaming, which tries to pipeline multiple kernels, can hardly yield obvious improvement.

Memory Management. Cavs' performance advantage also credits to its memory management that reduces memory movements while guarantees continuity. Quantitatively, it is difficult to compare Cavs to Fold, as Fold relies on TensorFlow where memory management is highly coupled with other system aspects. Qualitatively, we find Cavs requires less memory movement (e.g. memcpy) during dynamic batching. Built upon the tf_while operator, whenever Fold performs depth-

Programming Model	**Frameworks**	**Expressiveness**	**Batching**	**Graph Construction Overhead**	**Graph Optimization**
static declaration	Caffe, TensorFlow	×	√	low	beneficial
dynamic declaration (eager evaluation)	PyTorch, Chainer	√	×	N/A	unavailable
dynamic declaration (lazy evaluation)	DyNet	√	√	high	limited benefits
Fold	TensorFlow-Fold	√	√	high	unknown
Vertex-centric	Cavs	√	√	low	beneficial

Table 2: A side-by-side comparison of existing programming models for dynamic NNs, and their advantages and disadvantages.

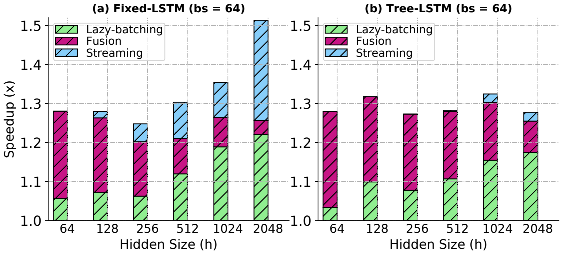

Figure 10: Improvement of each optimization strategy on execution engine over a baseline configuration (speedup = 1).

bs	Memory operations (s) (*Cavs / DyNet*)		Computation (s) (*Cavs / DyNet*)	
	Train	Inference	Train	Inference
16	**1.14** / 1.33	**0.6** / 1.33	**9.8** / 12	**2.9** / 8.53
32	**0.67** / 0.87	**0.35** / 0.87	**6.1** / 9.8	**1.9** / 5.35
64	**0.39** / 0.6	**0.21** / 0.6	**4.0** / 7.4	**1.3** / 3.48
128	**0.25** / 0.44	**0.13** / 0.44	**2.9** / 5.9	**0.97** / 2.52
256	**0.17** / 0.44	**0.09** / 0.44	**2.3** / 5.4	**0.77** / 2.58

Table 3: Breakdowns of average time per epoch on memory-related operations and computation, comparing Cavs to DyNet on training and inference of `Tree-LSTM` with varying *bs*.

based batching at depth d, it has to move all the contents of nodes in the dataflow graphs at depth $d-1$ to a desired location, as the control flow does not support cross-depth memory indexing. This results in redundant memcpy, especially when the graphs are highly skewed. By contrast, Cavs only copies contents that are necessary to the batching task. DyNet has a specialized memory management strategy for dynamic NNs. Compared to Cavs, it however suffers substantial overhead caused by repeated checks of the memory continuity – whenever DyNet wants to batch operators with same signatures, it checks whether their inputs are continuous on memory [34]. The checking overhead increases with *bs* and is more prominent on GPUs. Thanks to the simplicity of both systems, we are able to profile the memory-related overhead during both training and inference, and separate it from computation. We compare them on `TreeLSTM`, and report the breakdown time per epoch in Table 3 under different *bs*. We observe the improvement is significant (2x - 3x) at larger *bs*, especially during inference where DyNet has its continuity checks concentrated.

6 Related Work

DL programming models. In addition to §2.2, we summarize in Table 2 the major programming models and frameworks for dynamic NNs, and their pros and cons, in contrast to Cavs. Within static frameworks, there are also efforts on adapting static declaration to support sequence RNNs, such as *static unrolling* [17], *bucketing* [15] and *dynamic unrolling* [16]. The ideas are to pad zero at the end of samples so that they have the same structure (i.e. same length) for batched computation. However, they all result in unnecessary computation and can not express more complex structures than sequences. Asynchronous model-parallelism [13] enables the concurrent execution of different graphs similar to batched execution in Cavs, it however may suffer from insufficient cache re-usage and overhead by multiple kernel launches (on GPUs).

Execution optimization. A variety of developed techniques from other areas (e.g. kernel fusion, constant folding) have been adapted to speed the computation of DL dataflow graphs [1, 5, 12, 18]. Cavs separates the static vertex function from the dynamic-varying input graph, so it benefits from most of the aforementioned optimizations. We learn from these strategies and reflect them in Cavs' execution engine. We further propose lazy batching and concurrent execution to exploit more parallelism exposed by our APIs.

Graph-based systems. The vertex-centric programming model has been extensively developed in graph computing [29, 14, 4, 41]. Cavs draws insights from the GAS model [14], but is fundamentally different: `gather` and `scatter` in Cavs are fully symbolic – they allow backpropagation through them; graph computing systems compute on large natural graphs, while Cavs addresses problems that each sample has a unique graph and the training is iterative on batches of samples. In terms of system design, Cavs also faces different challenges, such as scheduling for batched execution of different graphs, guaranteeing the memory continuity. There are also some graph-based ML systems, such as GraphLab [28], but they do not handle instance-based graphs, and do not offer batching advantages for dynamic DL workloads.

7 Conclusion

We present Cavs, an efficient system for dynamic neural networks. With a novel representation, designed scheduling policy, memory management strategy, and graph execution optimizations, Cavs avoids substantial graph construction overhead, allows for batched computation over different structured graphs, and can benefit from well-established graph optimization techniques. We compare Cavs to state-of-the-art systems for dynamic NNs and report a near one order of magnitude speedup across various dynamic NN architectures and settings.

Abstract

Recurrent neural networks (RNNs) are an important class of deep learning (DL) models. Existing DL frameworks have unsatisfying performance for online serving: many RNN models suffer from long serving latency and high cost, preventing their deployment in production.

This work characterizes RNN performance and identifies low data reuse as a root cause. We develop novel techniques and an efficient search strategy to squeeze more data reuse out of this intrinsically challenging workload. We build DeepCPU, a fast serving library on CPUs, to integrate these optimizations for efficient RNN computation. Our evaluation on various RNN models shows that DeepCPU improves latency and efficiency by an order of magnitude on CPUs compared with existing DL frameworks such as TensorFlow. It also empowers CPUs to beat GPUs on RNN serving. In production services of Microsoft, DeepCPU transforms many models from non-shippable (due to latency SLA violation) to shippable (well-fitting latency requirements) and saves millions of dollars of infrastructure costs.

1. Introduction

Deep learning (DL) is a fast-growing field pervasively influencing many applications on image, speech, and text processing. Traditional feed forward neural networks assume that all inputs (and outputs) are independent of each other. This could be a bad idea for many tasks. For example, to predict the next word in a sentence, we had better know which words come before that. To classify what kind of event is happening to the next point of a movie, we had better reason from the previous events. Recurrent neural networks (RNNs) are an important and popular class of DL models that address this issue by making use of sequential information [22,35,51]. RNNs perform the same task for every element in the sequence, with the output being dependent on the previous computation. This is somewhat similar to the human learning, e.g., to understand a document, we read word by word, sentence by sentence, and carry the information along in our memory while reading. RNNs have shown great promise in many natural language processing tasks, e.g., language model [16,44], machine translation [15,21,58], machine reading comprehension [18,25,39,53], speech recognition [31,34,66], and conversational bots [62].

Like other DL models, using RNNs requires two steps: (1) learning model weights through training, and (2) applying the model to predict the results of new requests, which is referred to as *serving*, or equivalently, inferencing or scoring. Training is a throughput-oriented task: existing systems batch the computation of multiple training inputs to obtain massive parallelism, leveraging GPUs to obtain high throughput. Users can often tolerate fairly long training time of hours and days because it is offline. Serving, on the other hand, makes online prediction of incoming requests, imposing different goals and unique challenges, which is the focus of this paper.

Latency and efficiency are the two most important metrics for serving. Interactive services often require responses to be returned within *a few or tens of milliseconds* because delayed responses could degrade user satisfaction and affect revenue [27]. Moreover, large-scale services handle massive request volumes and could require thousands of machines to serve a single model. Many RNN models from production services such as web search, advertisement, and conversational bots require intensive computation and could not be shipped because of serving latency violation and cost constraints.

Detailed investigation shows that popular DL frameworks, e.g., TensorFlow and CNTK, exhibit poor performance when serving RNNs. Consider the performance metric of floating point operations per second (flops), which is a standard measure for computations like DL that are dominated by floating-point calculations. Our test results show that on a modern Intel CPU with peak performance of 1.69Tflops, using TensorFlow/CNTK for RNN serving only gets less than 2% of hardware peak. This naturally raises many questions: Why is there such a big performance gap between hardware peak and the existing implementations? Are we dealing with an intrinsically challenging workload or less optimized systems? Would different hardware, such as GPU, help?

We carefully characterize RNN performance and answer the above questions.

First, RNN serving is an intrinsically challenging workload. Due to stringent latency SLA, online serving systems often process each request upon its arrival, or at best, batch a few requests whenever possible. With a batch size of 1 (or a few), the computation is dominated

*Both authors contributed equally. Order of appearance is random.

by several vector-matrix multiplications (or matrix multiplications), that have poor *data reuse* and thus are bottlenecked on cache/memory bandwidth. Since the speed of data transfer is far slower than the computational speed of CPUs, this leaves cores waiting for data instead of conducting useful computation, leading to poor performance and latency.

Second, existing DL frameworks rely on parallel-GEMM (GEneral Matrix to Matrix Multiplication), implementations which are not targeted to optimize the type of matrix multiplications (MMs) in RNN computations. parallel-GEMM is designed to optimize large MMs with high data reuse by hiding the data movement cost with ample computation [29]. MMs in RNNs are usually much smaller, fitting entirely in shared $L3$ cache, but with minimal data reuse: data movement from shared $L3$ cache to private $L2$ cache is the main bottleneck. Due to limited data reuse, parallel-GEMM can no longer hide the data movement, requiring different considerations and new techniques. Furthermore, as weights are repeatedly used at MMs of each step along the sequence, it presents a potential reuse opportunity from RNN domain knowledge, which parallel-GEMM does not exploit.

Lastly, would GPU help? RNN serving is computationally intensive but with limited parallelism. In particular, the amount of computation grows linearly with the sequence length: the longer the sequence, the more steps the computation carries. However, the sequential dependencies make it hard to parallelize across steps. As the batch size is also small in serving scenario, there is rather limited parallelism for RNN serving. As GPUs use a large number of relatively slow cores, they are not good candidates because most of the cores would be idle under limited parallelism; CPUs are a better fit with a smaller number but faster cores.

With the challenges and opportunities in mind, we develop novel techniques to optimize data reuse. We build DeepCPU, an efficient RNN serving library on CPUs, incorporating the optimization techniques. Our key techniques include (1) private-cache-aware partitioning, that provides a principled method to optimize the data movement between the shared $L3$ cache to private $L2$ cache with formal analysis; (2) weight-centric streamlining, that moves computation to where weights are stored to maximize data reuse across multiple steps of RNN execution. Both help overcome the limitation of directly applying parallel-GEMM and optimize data reuse on multi-core systems. We also leverage existing techniques, such as MM fusion and reuse-aware parallelism decision, in the new context of RNN optimization.

Effectively integrating these techniques together is non-trivial, requiring to search a large space to find optimized schedules. We model RNN computation using a Directed Acyclic Graph of Matrix Multiplication nodes (MM-DAG), supporting a rich set of optimization knobs such as partitioning (splitting a node) and fusion (merging nodes). It is well known that the traditional DAG scheduling problem of minimizing execution time by deciding the execution order of the nodes is NP-hard even in the absence of additional knobs [28]. The optimization knobs further enlarge the search space exponentially, and it is infeasible to exhaustively enumerate all schedules. We develop an efficient search strategy that requires far fewer calibration runs.

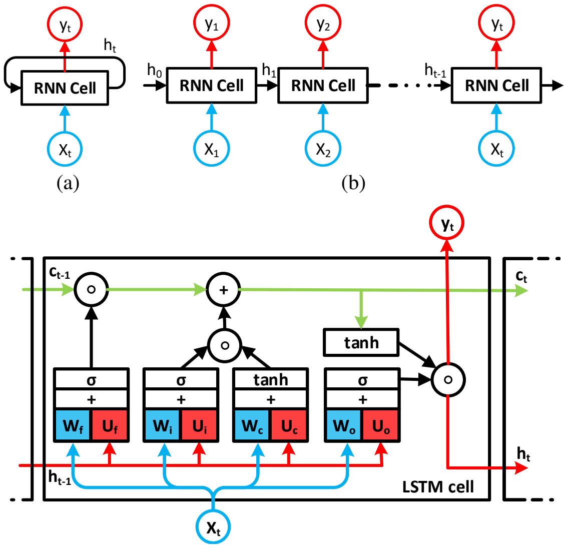
We compare DeepCPU with popular state-of-the-art DL frameworks, including TensorFlow and CNTK, for a wide range of RNN models and settings. The results show DeepCPU consistently outperforms them on CPUs, improving latency by an order of magnitude. DeepCPU also empowers CPUs to beat highly optimized implementations on GPUs. We further demonstrate its impact on three real-world applications. DeepCPU reduces their latency by 10–20 times in comparison to TensorFlow. To meet latency SLA, DeepCPU improves the throughput of the text similarity model by more than 60 times, serving the same load using less than 2% of machines needed by the existing frameworks.

The key contributions of the work include: 1) Characterizing performance limitations of the existing methods (Section 3). 2) Developing novel techniques and a search strategy to optimize data reuse (Section 4 and 5). 3) Building DeepCPU, a fast and efficient serving library on CPUs (Section 4 and 5). 4) Evaluating DeepCPU and showing order of magnitude latency and efficiency improvement against the existing systems (Section 6).

DeepCPU has been extensively used in the production of Microsoft to reduce serving latency and cost. It transforms the status of many DL models from impossible to ship due to violation of latency SLA to well-fitting SLA requirements. It empowers bigger and more advanced models, improving accuracy and relevance of applications. DeepCPU also greatly improves serving efficiency, saving thousands of machines and millions of dollars per year for our large-scale model deployments.

2. Background

An RNN models the relationships along a sequence by tracking states between its steps. At each step t (Fig. 1a), it takes one unit of input x_t (e.g., a token in a text, or a phoneme in a speech stream) and makes a prediction y_t based on both the current input x_t and the previous hidden (or cell) state h_{t-1}. The hidden states $\{h_t\}$ form a loop, allowing information to be passed from one step to the next. The block of computation per step is called an RNN cell, and the same cell computation is used for all inputs of the sequence. An RNN (sequence) computation can be viewed as an unrolled chain of cells (Fig. 1b).



(a) (b)

(c)

Figure 1: a) RNN with a recurrent structure. b) Unrolled RNN. c) LSTM structure.

LSTM/GRU. There are many variations of RNNs, inheriting the recurrent structure as above but using different cell computations. The two most popular ones are Long Short Term Memory (LSTM) and Gated Recurrent Unit (GRU) network, best known for effectively catching long-term dependencies along sequences. We use LSTM as an example and illustrate its cell computation:

$$\begin{aligned}
i_t &= \sigma(\mathbf{W}_i \cdot x_t + \mathbf{U}_i \cdot h_{t-1} + b_i) \\
f_t &= \sigma(\mathbf{W}_f \cdot x_t + \mathbf{U}_f \cdot h_{t-1} + b_f) \\
o_t &= \sigma(\mathbf{W}_o \cdot x_t + \mathbf{U}_o \cdot h_{t-1} + b_o) \\
c_t &= f_t \circ c_{t-1} + i_t \circ \tanh(\mathbf{W}_c \cdot x_t + \mathbf{U}_c \cdot h_{t-1} + b_c) \\
h_t &= o_t \circ \tanh(c_t) \ .
\end{aligned}$$

Here $\sigma(\cdot)$ denotes the sigmoid function. Online tutorials [7, 12] describe good insights of the formulation on how it facilitates learning. Here we focus on describing the main computations. We denote E as the input dimension of the input vector x_t, and H as the hidden dimension of the hidden vector h_t. LSTM includes 4 input MMs, which multiply input vector x_t with four input weight matrices $\mathbf{W}_{\{i,f,o,c\}}$ of size $E \times H$ each (marked as blue in Fig. 1c). It has 4 hidden MMs, which multiply hidden vector h_{t-1} with four hidden weight matrices $\mathbf{U}_{\{i,f,o,c\}}$ of size $H \times H$ each (red in Fig. 1c). Within each cell, there is no dependency among the 8 MMs, and across cells, the hidden state of step t depends on step $t-1$ (as shown by Fig. 1c). LSTM also consists of a few element-wise additions ($+$) and products ($\circ$), as well as activation functions such as σ and tanh.

Similar to the LSTM cell, GRU cell has 6 instead of 8 MMs but with additional dependencies within them [22].

Single vs. batch mode. To make real-time predictions, online requests are often processed one by one as they arrive, or occasionally, under a small batch. Given a batch size of B, the batched input x_t can be represented as a matrix of size $B \times E$, which transforms the underlying computation from a vector-matrix to a matrix-matrix multiplication, exposing more opportunities for data reuse. However, because of tight latency requirements and spontaneous request arrivals, the batch size at serving is usually much smaller (e.g., 1 to 10) than the large mini-batch size (often hundreds) during training.

3. Performance Characterization

Existing DL frameworks such as TensorFlow/CNTK implement RNNs as a loop of cell computation: as shown in Lis. 1, 8 MMs in the LSTM cell are fused into a single MM, executed using parallel BLAS libraries such as Intel-MKL [3], OpenBLAS [6] or Eigen [1]. We measure their performance in serving scenarios with small batch size from 1 to 10. On a dual-socket Xeon E5-2650 CPU machine, we often observe performance of < 30Gflops: less than 2% of the machine peak of 1.69Tflops. What is the cause of such a big gap?

Listing 1: LSTM Implementation in TensorFlow/CNTK

```
for t in input_sequence:
    $[f'_t \;\; i'_t \;\; o'_t \;\; c'_t] = [x_t \;\; h_{t-1}] \begin{bmatrix} \mathbf{W}_f & \mathbf{W}_i & \mathbf{W}_o & \mathbf{W}_c \\ \mathbf{U}_f & \mathbf{U}_i & \mathbf{U}_o & \mathbf{U}_c \end{bmatrix}$
    $c_t = \sigma(f'_t) \circ c_{t-1} + \sigma(i'_t) \circ \tanh(c'_t)$
    $h_t = \sigma(o'_t) \circ \tanh(c_t)$
```

The first step of performance analysis is to identify the dominating computation. In RNNs, the total amount of computation is dominated by MMs. The total ops in MMs per RNN cell are $\mathcal{O}(B \times (E+H) \times H)$, and the total ops in element-wise operations and activations functions are $\mathcal{O}(B \times H)$. Typically the total number of ops in MMs is two to three orders of magnitude larger than the rest combined. As such, RNN performance primarily depends on the MMs, which is the focus of this study.

We analyzed MMs in the RNNs, and identified three key factors causing poor performance.

i) Poor data reuse. Data reuse at a particular level of memory hierarchy is a measure of the number of computational ops that can be executed per data load/store at that level of memory hierarchy. Assuming a complete overlap between computation and data movement (best case scenario), the execution time of a computation can be estimated as a function of the data reuse using the roofline model [65] as

$$\begin{aligned}
Time &\geq Max(DataMoveTime, CompTime) \quad (1) \\
&= Max(\frac{DataMoved}{DataBandwidth}, \frac{TotalComp}{Peak}) \\
&= Max(\frac{TotalComp/Reuse}{DataBandwidth}, \frac{TotalComp}{Peak})
\end{aligned}$$

Based on this execution time, note that poor data reuse results in poor performance because on modern architectures, the computational throughput is significantly higher than the data movement throughput. Let us look at an example of $L3$ to $L2$ bandwidth since all RNN models we have seen fit in $L3$ cache of modern CPUs: the *peak* computational performance of a Xeon E5-2650 machine is 1.69Tflops while the observable *DataBandwidth* between $L3$ and $L2$ cache on it is 62.5 GigaFloats/s (250 GB/s), measured using the stream benchmark [8]. If the reuse is low, the total execution time is dominated by the data movement, resulting in poor performance.

This is indeed the case for RNN in serving scenario where the batch size tends to be very small. To see this, consider an MM:$\mathbf{C}[i,j] = \sum_k \mathbf{A}[i,k] \times \mathbf{B}[k,j]$. If we assume that both the inputs and the outputs reside in $L3$ cache at the beginning of the computation, then both the inputs and the outputs must be read from $L3$ cache to $L2$ cache at least once, and the outputs must be stored from $L2$ cache to $L3$ cache at least once during the MM. Therefore, the maximum possible data reuse during this MM from $L2$ cache is given by $\frac{2 \times I \times J \times K}{|\mathbf{A}|+|\mathbf{B}|+2|\mathbf{C}|}$, where I, J and K are the size of indices i, j and k. Similarly, the fused MM of LSTM has the shape $[B, E+H] \times [E+H, 4H]$, and its data reuse is:

$$MaxDataReuse = \frac{8 \times B \times H \times (E+H)}{|Input|+|Weights|+2|Output|} \quad (2)$$

$$= \frac{8 \times B \times H \times (E+H)}{B \times (E+H) + 4 \times (E+H) \times H + 8 \times B \times H} \quad (3)$$

When batch size $B \ll \min(H,E)$, the maximum data reuse in Eqn. 2 reduces to $2B$. Take $B = 1$ as an example: the best achievable performance of LSTM on the Xeon E5-2650 machine is at most 125Gflops based on the measured $L3$ bandwidth of 250 GB/s. This is less than 8% percent of the machine's peak of 1.69Tflops.

ii) Sub-optimal MM partitioning. Parallel-GEMM libraries are designed to optimize performance of large MMs that have significant data reuse ($>$ 1000). They exploit this reuse from $L2$ cache level using loop-tiling to hide the data movement cost from both memory and $L3$ cache [29]. In contrast, the amount of reuse in RNNs is in the order of B, which is often a small value between 1 and 10 for most serving cases. This is not enough to hide the data movement cost even though MMs in RNN are small enough to fit in $L3$ cache. In the absence of large reuse, the performance of parallel-GEMM is limited by the data movement cost between shared $L3$ cache and private $L2$ caches. Parallel-GEMM is sub-optimal at minimizing this data movement.

More specifically, $L3$ cache on a modern CPU feeds to *multiple* $L2$ caches that are private to each core. During RNN computations, some data might be required by multiple cores, causing multiple transfers of the same piece of data from $L3$ cache. Thus, the total data movement between $L3$ and $L2$ caches depends on the partitioning of the MM computation space and its mapping to the cores. For example, if we split an MM computation among two cores, such that the first core computes the upper half of the output matrix **C**, while the second core computes the lower half, then input matrix **B** must be replicated on $L2$ cache of both cores, as the entire matrix **B** is required to compute both halves of matrix **C**. Alternatively, if the computation is split horizontally, then the input matrix A must be replicated on $L2$ cache of both cores. Different partitionings clearly result in different amount of data reuse. Parallel-GEMM does not always produce a partitioning that maximizes this data reuse. Libraries specialized for small matrices are not sufficient either, as some focus only on sequential execution [56] while others focus on MM small enough to fit in $L1$ cache [43].

iii) No data reuse across the sequence. During serving, weight matrices of RNNs remain the same across the sequence, but existing solutions do not take advantage of that to optimize data reuse. More precisely, parallel-GEMM used to execute the MMs is not aware of this reuse across the sequence. During each step of the sequence, the weight matrix could be loaded from $L3$ cache to $L2$ cache. However, it is possible to improve performance of RNNs by exploiting this data reuse.

Beyond MM: Beyond limited data reuse at MMs, existing RNN implementations in DL frameworks such as TensorFlow have other performance limiting factors, e.g., data transfer overheads among operators, buffer management overheads, unoptimized activation functions, which we address in DeepCPU. For example, we develop efficient SIMD implementations of *tanh* and *sigmoid* activation functions using continued fraction expansion, supporting any desired degree of precision by adjusting the number of terms to terminate the expansion [60]. Since these improvements mostly require good engineering practice than novel methods, we did not discuss them in detail for the interest of space.

4. Challenges and Strategies

Challenges. Finding an optimized implementation for RNN execution that maximizes data reuse while also efficiently using low-level hardware resources (such as SIMD hardware) is challenging due to the explosive space of optimization knobs and execution schedules. Practically infinite number of valid choices can be obtained through loop permutations, loop fusions, loop unrolling, unroll factor selection, loop tiling, tile-size selection, MM reordering, vectorization, register tiling, register tile size selection, parallel loop selection, parallelization granularity selection, thread-to-core mapping etc., and their combinations. Furthermore, enabling those optimization knobs and creating a schedule generator for all choices is a non-trivial engineering task. Additionally, the optimal choice is dependent on both hardware architecture and RNN parameters: a single solution will not work for all cases and an optimized schedule needs to be tuned case by case in an efficient manner. All of the above make the problem challenging in practice.

Figure 2: DeepCPU optimization overview.

Strategies: DeepCPU overview. To overcome these challenges, we judiciously define the search space and identify the most important techniques to boost data locality. This empowers efficient search within a selective set of optimization knobs and schedules for obtaining the best RNN performance. We build the entire optimization pipeline into a library, which we call DeepCPU. Fig. 2 highlights its key features and workflow.

An important start of the optimization is to define a concise search space, which we develop upon two insights. (1) We identify the most performance critical operators, MMs, and model the computation graph connecting them to capture the first-order impact. We can do this by constructing a Matrix Multiplication Directed Acyclic Graph (MM-DAG) to represent the RNN computation, where each node represents an MM and edges represent dependencies among them. This model allows us to build schedules using MMs as the basic building blocks, capturing key computations while abstracting away other low-level details. (2) Instead of examining all valid schedules for the MM-DAG, which is not trackable, we can leverage the iterative nature and other properties of RNNs, prune search space to deduplicate the performance-equivalent schedules, and remove those that cannot be optimal. These two insights are implemented as $\boxed{1}$ and $\boxed{2}$ in Fig. 2.

We then identify and develop four techniques to effectively boost data locality for RNNs, applying them on each schedule (shown as $\boxed{3}$,$\boxed{4}$,$\boxed{5}$,$\boxed{6}$ in Fig. 2):

- **MM-fusion:** fuses smaller MMs into larger ones, improving data reuse;
- **Reuse-aware parallelism generator:** identifies best parallelism degree within and across MMs through auto-tuning, jointly considering locality;
- **Private-cache-aware-partitioning (PCP):** optimizes data movement between shared $L3$ cache and private $L2$ cache with a novel and principled partitioning method;
- **Weight centric streamlining (WCS):** maps the partitions produced by PCP to cores in a way that enables reuse of weights across the sequence.

The parallelism generator $\boxed{4}$ iterates over different choices on parallelism degrees. For a parallelism choice, we use PCP $\boxed{5}$ to obtain locality optimized parallel partitions. The partitions are then mapped to cores using WCS $\boxed{6}$. Individual partitions are implemented using highly optimized single-threaded BLAS library which optimizes for low-level hardware resources such as $L1$ cache and SIMD instruction set. DeepCPU applies this schedule to obtain the execution time, and loop over to find the best parallelism choice. Once this process is completed for all schedules generated by $\boxed{2}$, DeepCPU simply chooses the schedule that is the fastest. This calibration process is often called once during model construction, and then the optimized schedule is repeatedly used for serving user requests of the model.

In the design of DeepCPU, we deliberately combine analytical performance analysis (at search space pruning and PCP) with empirical calibration (to measure the combined impact of locality and parallelism). The former effectively reduces the search space, saving tuning time to run many suboptimal/redundant schedules. The latter reliably measures the actual execution time to capture complex software and hardware interaction, which can hardly be accurately estimated. This combination empowers both effectiveness and efficiency.

5. DeepCPU Optimizations

This section dives into DeepCPU optimizations from refining search space to locality optimizations. We conclude it by demonstrating the performance breakdown and impact of these optimizations.

5.1. MM-DAG Scheduling

DeepCPU models RNN computations as MM-DAGs and optimizes the schedules to execute them. Given an MM-DAG, a valid schedule determines an execution ordering of its nodes that satisfies all the dependencies. We consider only those valid schedules that are composed of phases: A *phased schedule* executes an MM-DAG in a sequence of phases $S_1, S_2, S_3, ..., S_i, ...$, where each phase S_i represents a non-overlapping subset of nodes and $S = \sum_i S_i$ consists of all nodes. There is a total ordering between phases such that if $i < j$, then all nodes in S_i must be executed before S_j. However, nodes within a phase can be executed in parallel. Lst. 2 shows two examples of valid phased schedules for LSTM. In Schedule 1, all MMs at a timestep t are in Phase t.

The phases can be divided into two categories: i) If a phase consists of an MM that has dependency across the timesteps, we call it a *time-dependent phase*, e.g., those MMs taking hidden state h_t as inputs, ii) Otherwise, if a phase does not contain any MM that has dependency across the sequence, we call it a *time-independent phase*. For example, in Schedule 2 of Lst. 2, Phase 1 is time-independent, and consists of all the MMs computing input transformation (with weights $\mathbf{W_i}, \mathbf{W_f}, \mathbf{W_c}$ and $\mathbf{W_o}$) across all timesteps; all other phases are time-dependent, requiring the value of h_{t-1} to compute h_t.

Listing 2: Phased LSTM Schedule-1 and 2

```
//Phased LSTM Schedule 1
for t:
  Phase t:   //time-dependent
    $\mathbf{W}_i \cdot x_t, \mathbf{W}_f \cdot x_t, \mathbf{W}_c \cdot x_t, \mathbf{W}_o \cdot x_t$
    $\mathbf{U}_i \cdot h_{t-1}, \mathbf{U}_f \cdot h_{t-1}, \mathbf{U}_c \cdot h_{t-1}, \mathbf{U}_o \cdot h_{t-1}$

//Phased LSTM Schedule 2
Phase 1:   //time-independent
   $\mathbf{W}_i \cdot x_0, .., \mathbf{W}_i \cdot x_t, \mathbf{W}_f \cdot x_0, .., \mathbf{W}_f \cdot x_t,$
   $\mathbf{W}_c \cdot x_0, .., \mathbf{W}_c \cdot x_t, \mathbf{W}_o \cdot x_0, .., \mathbf{W}_o \cdot x_t$
for t:
  Phase (t+1):   //time-dependent
     $\mathbf{U}_i \cdot h_{t-1}, \mathbf{U}_f \cdot h_{t-1}, \mathbf{U}_c \cdot h_{t-1}, \mathbf{U}_o \cdot h_{t-1}$
```

Reducing search space. We propose three rules to prune the search space, removing sub-optimal and redundant schedules: i) Time-dependent phases must have symmetry across timesteps. As RNN computation is identical across timesteps, the fastest schedule for executing each timestep should also be identical. ii) If two consecutive phases are of the same type, then there must be a dependency between the two phases. If no dependency exists then this schedule is equivalent to another schedule where a single phase consists all MMs in both phases. iii) We compute time-independent phases before all dependent ones, as shown in Schedule 2 of Lst. 2. Having phases of the same type in consecutive order increases reuse of weights.

5.2. Data Locality Optimizations

DeepCPU improves data reuse within each phase and across phases through four techniques.

5.2.1 Fusion of MMs

DeepCPU fuses all possible MMs within each phase — *Two MMs can be fused into a single MM if they share a common input matrix.*

How to fuse? Consider two MMs, $MM1 : \mathbf{C1}[i1, j1] = \sum_{k1} \mathbf{A1}[i1,k1] \times \mathbf{B1}[k1, j1]$ and $MM2 : \mathbf{C2}[i2, j2] = \sum_{k2} \mathbf{A2}[i2,k2] \times \mathbf{B2}[k2, j2]$. W.l.o.g., assume $\mathbf{A1}[i1,k1] = \mathbf{A2}[i1,k1]$, as shared input matrix. The two MMs can be fused into a single one $MM12$ by concatenating $\mathbf{B1}$ and $\mathbf{B2}$, and $\mathbf{C1}$ and $\mathbf{C2}$ along the column, i.e., $\mathbf{C12}[i1, j12] = \sum_{k1} \mathbf{A1}[i1,k1] \times \mathbf{B12}[k1, j12]$ where $\mathbf{B12}[k1, j1] = \mathbf{B1}[k1, j1]$, $\mathbf{B12}[k2, J1 + j2] = \mathbf{B2}[k2, j2]$, and $\mathbf{C12}[i1, j1] = \mathbf{C1}[i1, j1]$, $\mathbf{C12}[i2, J1 + j2] = \mathbf{C2}[i2, j2]$ ($J1$ is the size of index $j1$).

Why fuse? Fusion improves data reuse. Consider using any GEMM implementation to execute $MM1$ and $MM2$ without fusion. While both $MM1$ and $MM2$ share a common input, GEMM is not aware of this reuse and could not take advantage of it. However, if we fuse them, this reuse is explicit in the MM and GEMM can exploit it to improve both performance and scalability.

5.2.2 Reuse-aware Parallelism Generator

Parallelism boosts compute capacity but may also increase data movement. This part discusses the relation of locality and parallelism, and our parallelism strategy.

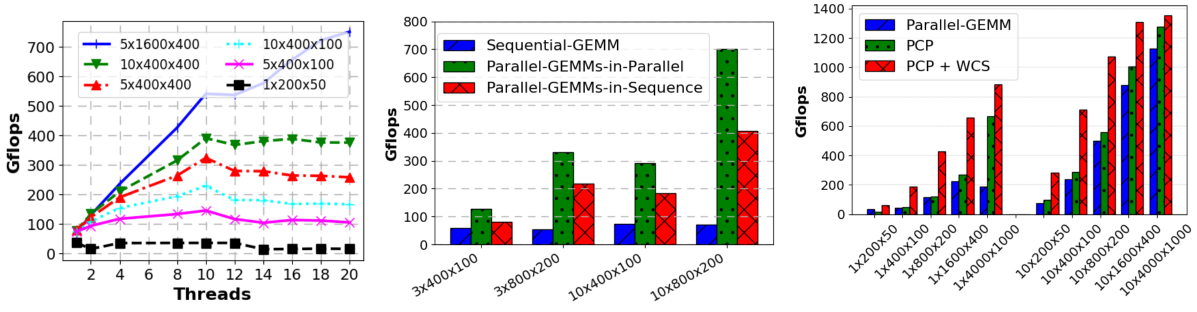
How to parallelize a single MM? Executing an MM with the maximum available parallelism is not always the best option for performance. As the parallelism increases, either the input or output must be replicated across multiple $L2$ private caches, thus increasing the total data movement. Once the level of parallelism reaches a certain threshold, the performance is limited by the data movement instead of the computational throughput. As shown in Fig. 3a, the MM performance degrades after certain parallelism. It is crucial to find the optimal level of parallelism instead of applying the common wisdom of using all available cores.

How to parallelize concurrent MMs? Multiple MMs within a phase do not have any dependencies. DeepCPU executes them as *Parallel-GEMMs-in-Parallel*, where multiple MMs are executed concurrently with each MM executing in parallel. For example, to compute two independent MMs, $M1$ and $M2$, on P cores, we run $M1$ and $M2$ in parallel, each using $P/2$ cores. This is in contrast with Parallel-GEMMs-in-Sequence, where we run $M1$ first using P cores followed by $M2$. Parallelizing an MM across multiple cores increases the data movement from $L3$ to $L2$ cache. In contrast, executing multiple MMs in parallel across multiple divided groups of cores allows each group to work on a unique MM without requiring data replication across them, improving data reuse while maintaining the same parallelism level. Fig. 3b shows empirical results. We run two independent and identical MMs with increased parallelism and report the best performance achieved. Parallel-GEMMs-in-Parallel significantly outperforms Parallel-GEMMs-in-Sequence.

How to optimize parallelism degree? Finding the optimal parallelism degree analytically is non-trivial as it depends on many architectural parameters. However, it is also not necessary in practice. DeepCPU applies Parallel-GEMMs-in-Parallel if a phase has multiple fused MMs. It then uses auto-tuning to identify the optimal parallelism for the phase quickly, as the number of cores on a modern multi-core CPU is less than two orders of magnitude and well-known RNN operators such as LSTMs/GRUs have at most two fused MMs per phase.

5.2.3 Private-Cache-Aware Partitioning (PCP)

We develop PCP, a novel private-cache-aware partitioning strategy for executing MMs across multicores to optimize $L2$ reuse within and across phases. PCP provides a principled method to optimize data movement with for-



(a) (b) (c)

Figure 3: For MMs of different sizes, (a) shows performance results by increasing the parallelism degree. (b) ompares Parallel-GEMMs-in-Parallel vs Parallel-GEMMs-in-Sequence, plus Sequential-GEMM as baseline. C) compares parallel-GEMM, PCP with and without weight-centric streamlining for running MMs.

mal analysis: For a given MM with parallelism degree P, we show PCP produces a P-partitioning of the computation space such that the total data movement between $L3$ and $L2$ cache is minimized. DeepCPU employs PCP to generate a locality-optimized schedule for each parallelism configuration without requiring to empirically calibrate different partitions and measure their performance.

Reuse within phases. Suppose an MM $\mathbf{C}[i,j] = \sum_k \mathbf{A}[i,k] \times \mathbf{B}[k,j]$ has P partitions, where X_i, X_j and X_k are the number of partitions along each of the i, j, k dimensions and $X_i \times X_j \times X_k = P$. We first derive the total data movement between $L3$ and $L2$ cache as a function of the partitions. This data movement depends on the relation between the size of the input and output matrices of the MM and the sizes of the $L3$ and $L2$ caches. For all RNNs of interest in serving scenario, we observe that the input matrix is much smaller than $L2$ cache, and the sum of all matrices fit in $L3$ cache. Under such conditions, we prove in Lemma 5.1 and Theorem 5.2 that the total data movement between $L3$ and $L2$ cache is equal to $X_j|\mathbf{A}| + X_i|\mathbf{B}| + 2X_k|\mathbf{C}|$. By choosing X_i, X_j, and X_k that minimizes this quantity, PCP obtains a parallel partitioning that maximizes data reuse from $L2$ cache.

Lemma 5.1. *The tight bound on data movement between a slow memory and a fast memory of size S for an MM* $\mathbf{C}[i,j] += \sum_k \mathbf{A}[i,k] \times \mathbf{B}[k,j]$ *is given by* $|\mathbf{A}| + |\mathbf{B}| + 2|\mathbf{C}|$, *when* $S \geq min(|\mathbf{A}|, |\mathbf{B}|, |\mathbf{C}|) + H + 1$. *Here we assume that the inputs and output matrices initially reside in the slow memory, and the final output must also reside in the slow memory. H is a constant not greater than* $\max(I,J,K)$, *where I, J and K are the sizes of indices i, j and k respectively.*

Proof. Lower bound: As both inputs and outputs originally reside in slow memory they must be read to fast memory at least once to compute the MM. After computation, the output must be written to slow memory at least once. That gives $|\mathbf{A}| + |\mathbf{B}| + 2|\mathbf{C}|$ as a lower bound.

Upper bound: W.l.o.g., assume $\mathbf{A}$ fits in S. Lst. 3 shows a schedule where the total data movement between slow and fast memory is given by $|\mathbf{A}| + |\mathbf{B}| + 2|\mathbf{C}|$, when $S \geq |\mathbf{A}| + K + 1$. Note H (=K) is a (small) buffer space to hold a single column of $\mathbf{B}$ during the computation. □

Listing 3: MM Schedule that achieves data movement of $|\mathbf{A}| + |\mathbf{B}| + 2|\mathbf{C}|$ when $S \geq |\mathbf{A}| + K + 1$

```
//C[i,j] = Σk A[i,k] × B[k,j]
Load A[*,*] in A_buf //MemReq = |A|
for j
  Load B[*,j] in B_buf //MemReq = K
  for i
    Load C[i,j] in c //MemReq  = 1
    for k
      c += A_buf[i,k] × B_buf[k]
    Store c in C[i,j]
```

Theorem 5.2. *Consider P cores on a CPU, and an MM* $\mathbf{C}[i,j] += \sum_k \mathbf{A}[i,k] \times \mathbf{B}[k,j]$, *where* $|\mathbf{A}| + |\mathbf{B}| + |\mathbf{C}| \leq |L3Cache|$ *and* $min(|\mathbf{A}|, |\mathbf{B}|, |\mathbf{C}|) + H + 1 \leq |L2Cache|$. *H is a constant not greater than* $max(I,J,K)$, *where I, J and K are the sizes of indices i, j and k. For a P-way partitioning* $\langle X_i, X_j, X_k \rangle$ *where* $X_i \times X_j \times X_k = P$, *a tight bound on the data movement between L3 and L2 cache is given by* $X_j|\mathbf{A}| + X_i|\mathbf{B}| + 2X_k|\mathbf{C}|$.

Proof. Each of the partitions given by $\langle X_i, X_j, X_k \rangle$ is an MM of size $\frac{I}{X_i} \times \frac{J}{X_j} \times \frac{K}{X_k}$. From Lemma. 5.1 we see that a tight bound on the data movement between $L3$ cache and $L2$ cache for each of these sub-MMs is given by $\frac{I \times K}{X_i \times X_k} + \frac{K \times J}{X_k \times X_j} + 2\frac{I \times J}{X_i \times X_j}$. Thus the total data movement for all partitions is given by $X_i \times X_j \times X_k \times (\frac{I \times K}{X_i \times X_k} + \frac{K \times J}{X_k \times X_j} + 2\frac{I \times J}{X_i \times X_j}) = X_j|\mathbf{A}| + X_i|\mathbf{B}| + 2X_k|\mathbf{C}|$. □

Reuse across phases. PCP so far maximizes the data reuse by considering each phase independently. However, identical time-dependent phases (TDPs) across a sequence have data reuse between them. For each MM in these phases, weight matrices stay the same. We extend PCP to exploit the reuse in weights across phases.

For a given P-partitioning strategy $\langle X_i, X_j, X_k \rangle$, the weight matrix $\mathbf{B}$ is divided into blocks of size $\frac{|\mathbf{B}|}{X_j \times X_k}$. If this block fits in $L2$ cache of an individual core, then it will not be evicted from $L2$ cache for the entire computation sequence as long as the mapping between the MM partitions and the compute cores does not change. In such cases, denoting the sequence length of RNN as *seq_len*, the total data movement is given by

$$seq\_len \times (X_j|\mathbf{A}| + 2X_k|\mathbf{C}|) + X_i|\mathbf{B}|$$

as the weight matrix **B** needs to be read only once from $L3$ cache at the first time step. In general, total data-movement between $L3$ and $L2$ caches is calculated as

$$\begin{cases} seq\_len \times (X_j|\mathbf{A}| + 2X_k|\mathbf{C}|) + X_i|\mathbf{B}| & \text{if } \frac{|\mathbf{B}|}{X_j * X_k} \leq |L2| \\ seq\_len \times (X_j|\mathbf{A}| + X_i|\mathbf{B}| + 2X_k|\mathbf{C}|) & \text{if } \frac{|\mathbf{B}|}{X_j * X_k} > |L2| \end{cases}$$

By minimizing this piecewise function, we maximize the data reuse across a sequence. In practice, it is not necessary for a block of the weight matrices to fit entirely in $L2$ cache. As long as the block is not much larger than $L2$ cache, we can still get partial reuse.

5.2.4 Weight-Centric Streamlining (WCS)

WCS is our implementation to enable full-fledged PCP, supporting reuse of weight matrices across TDPs. For a given parallelism degree, PCP produces a partitioning such that the weights required to compute the partition fit in $L2$ cache of a single core (when possible), allowing the weights to be reused from $L2$ cache across TDPs, without being evicted. However, to ensure this reuse, the computation must be conducted at where the weights are, i.e., the mapping between parallel partitions and the cores that execute them must not change across TDPs.

To this end, we use OpenMP [24] to create a parallel region that spans the entire RNN sequence of computation. The parallelism degree is equal to the max parallelism degree among all phases in the schedule. Each thread in the parallel region is responsible for executing at most a single parallel partition during each phase. Some threads may remain idle during phases where the parallelism degree is less than the number of threads. Each thread ID is mapped to a unique partition ID, and this mapping is identical across TDPs. In essence, we alternate the order of the sequence loop and the parallel region such that the sequence loop is inside the parallel region, shown as ParallelOuterRNN in Lst. 4.

Listing 4: Parallel Outer vs Parallel Inner RNN

```
ParallelOuterRNN(intput_sequence, output)
  #pragma omp parallel
    int id = omp_get_thread_num()
    for t in intput_sequence:
      ComputeRNNOuterParallel(id, t, output)

ParallelInnerRNN(intput_sequence,output)
  for t in intput_sequence:
    #pragma omp parallel
      int id = omp_get_thread_num()
      ComputeRNNInnerParallel(id, t, output)
```

This has two major advantages over creating parallel regions inside the sequence loop as ParallelInnerRNN, i) it allows easy pinning of each MM parititon to a particular core across RNN steps. In OpenMP, threads in each parallel region have their local thread IDs starting from 0. A unique mapping between this local thread ID and the global thread ID is not guaranteed across multiple parallel regions separated in time. Thread affinity settings allow binding global thread IDs to cores or hyperthreads, but not local thread IDs. By creating a single parallel region, we create a unique mapping between a local thread ID and the global thread ID throughout the computation, which ensures that an MM partition is always executed on the same core across the entire sequence. ii) It reduces the overhead of creating parallel regions. Instead of opening and closing parallel regions during each step of the RNN sequence, we only create a parallel region once for the entire computation.

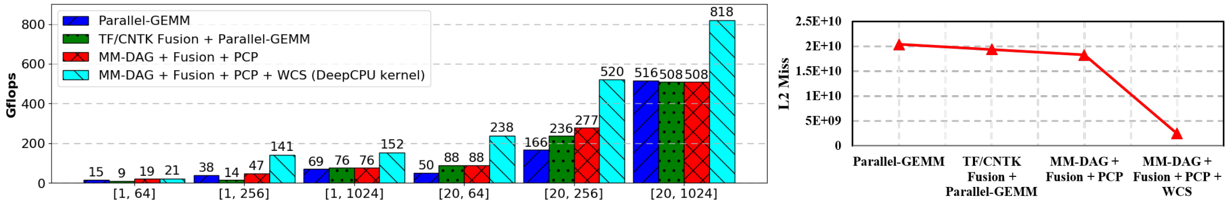
Fig. 3c compares performance of running a sequence of parallel-GEMM and PCP with/without WCS for varied sizes of MMs. The latter two consistently outperform the former, but the full benefit of PCP (across phases) is realized only when used together with WCS.

5.3. Performance Impact of Optimization Techniques

We compare four implementations using different LSTM configurations: i) Parallel-GEMM(baseline): Runs each step of LSTM as 8 MMs in sequence, and each MM is executed with Intel-MKL parallel-GEMM. ii) TensorFlow/CNTK Fusion: the fused MM (as Lst. 1) is executed using Intel-MKL parallel-GEMM. iii) MM-DAG+Fusion+PCP: All optimizations in DeepCPU except WCS. iv) DeepCPU Kernel: All aforementioned optimizations.

Results. TensorFlow/CNTK Fusion has roughly the same performance as baseline. MM-DAG+Fusion+PCP is as good as or better than both of them. It searches for the fused phased schedules including TensorFlow/C-NTK fusion, as well as those that increase reuse by fusing across time steps. It also applies PCP for better partitioning. However, it does not ensure that MMs sharing same weights are mapped to the same core. In contrast, DeepCPU kernel is often much faster, particularly for small batch sizes where the reuse is small within a single phase and reuse across TDPs must be exploited for better performance. Even for larger batch size with the input/hidden dimension 256 and 1024, where the total size of the weight matrices is larger than the $L2$ cache but individual weight blocks fit in $L2$ cache, DeepCPU kernel offers good speedup by enabling reuse of weights across TDPs.

Performance counters. We measure the amount of data movement from $L2$ to $L3$ through $L2$ cache misses using *L2_RQSTS.ALL_DEMAND_MISS* counter in Intel® VTune™ Amplifier [2]. Fig.4b shows DeepCPU significantly reduces $L2$ cache misses (by 8 times), verifying its effectiveness on locality optimization.



(a) (b)

Figure 4: (a) Performance of LSTMs (in the form of [batch size, input/hidden dimension]) with different optimization techniques. (b) $L2$ cache misses for config [20, 256]. Measured at $sequence\_length = 100$ with 2000 iterations.

Search space size. DeepCPU finds the optimal execution schedule with just a few hundred calibration runs. In the example of LSTM, we search approximately $P \times Q$ configurations by generating $P = \#cores$ parallelism choices, and Q phased schedules that satisfies all three pruning criteria described in Sec. 5.1. For LSTMs, $Q < 20$, which can be verified by enumerating all such valid schedules. Per parallelism choice, PCP identifies optimized partitioning analytically (e.g., integer programming) without requiring additional empirical exploration, greatly saving search space. This search/calibration process is often called once during model construction, and then the optimized schedule is repeatedly used for serving upcoming user requests.

6. Evaluation

We compare DeepCPU with RNN implementations from state-of-the-art DL frameworks: DeepCPU is an order of magnitude faster than TensorFlow and CNTK for a wide range of RNN models and configurations on CPUs. DeepCPU also outperforms GPU implementations significantly for most of the cases. Furthermore, we test DeepCPU on real-world applications used in production: it transforms these models from impossible to ship due to latency violation to well-fitting SLA while also saving millions of dollars in infrastructure cost.

Hardware. Our evaluation is conducted on a server with two 2.20 GHz Intel Xeon E5-2650 V4 processors, each of which has 12-core (24 cores in total) with 128GB RAM, running 64-bit Linux Ubuntu 16.04. The peak Gflops of the CPU is around 1.69Tflops. The server has one Nvidia GeForce GTX TITAN X which is used for measuring RNN performance on GPU.

6.1. RNN Performance Comparison

Workload. We evaluate LSTM/GRU by varying input dimension, hidden dimension, batch size, and input sequence length to cover a wide range of configurations.

Comparison frameworks. There are many DL frameworks such as TensorFlow [13], CNTK [52], Caffe2 [37], Torch [41], Theano [17], and MXNet [19] that support RNNs on CPUs and GPUs. We compare DeepCPU with TensorFlow and CNTK. We choose TensorFlow because it is adopted widely. We use TensorFlow version 1.1.0 with Accelerated Linear Algebra (XLA) compiler, optimizing pointwise kernels, and with Intel Math Kernel Library (MKL) for efficient matrix operations. We let TensorFlow pick appropriate degrees for inter-op and intra-op parallelism. We choose CNTK since a recent study showed that it achieves good performance on RNNs [55]. CNTK also uses MKL and sets the number of threads equal to the number of cores for MMs by default. On GPUs, we evaluate TensorFlow, CNTK and a highly optimized cuDNN implementation [14, 20].

Speedup on CPUs. Table 1 presents the execution time and speedup results of DeepCPU, in comparison to TensoFlow and CNTK on CPUs, covering a wide range of RNN model sizes. The first four columns describe the specification of RNNs: input dimension, hidden dimension, batch size, and sequence length. Both absolute execution time and speedup are reported. Speedup is measured as the ratio between the execution times of TensorFlow (or CNTK) versus DeepCPU, e.g., a value of 2 indicates that DeepCPU is 2 times faster. To make reliable measurement, we run each config 2000 times and report the average. The results show that *DeepCPU significantly and consistently outperforms TensorFlow and CNTK, with speedup in the range of 3.7 to 93 times, and average speedup of 18X among all tested configurations.*

Next, we conduct an in-depth performance comparison, showing how model parameters affect the results, on both CPU and GPU, across 6 implementations.

Varying input/hidden dimension. Fig. 5a reports the execution time and Gflops of LSTMs with varying input/hidden dimension from 32 to 1024. This is the range of dimension size commonly observed from RNN models in practice. Here we choose batch size of 1 to represent a common case in serving. As expected, the execution time for all implementations increases with the increase in dimension size. However, compared to all implementations, DeepCPU always has the shortest execution time and the highest Gflops on both CPUs and GPUs for all sizes. Note that the y-axis of the execution time is in log-scale, so the actual gap is larger than it appears. DeepCPU is more than an order of magnitude faster than both TensorFlow and CNTK on CPUs. On GPUs, DeepCPU has significantly higher performance when the dimension size is small or medium (e.g., less than 256). As the dimension size gets larger, this perfor-

Model parameters				LSTM exec. time (ms)			GRU exec. time (ms)			LSTM speedup		GRU speedup

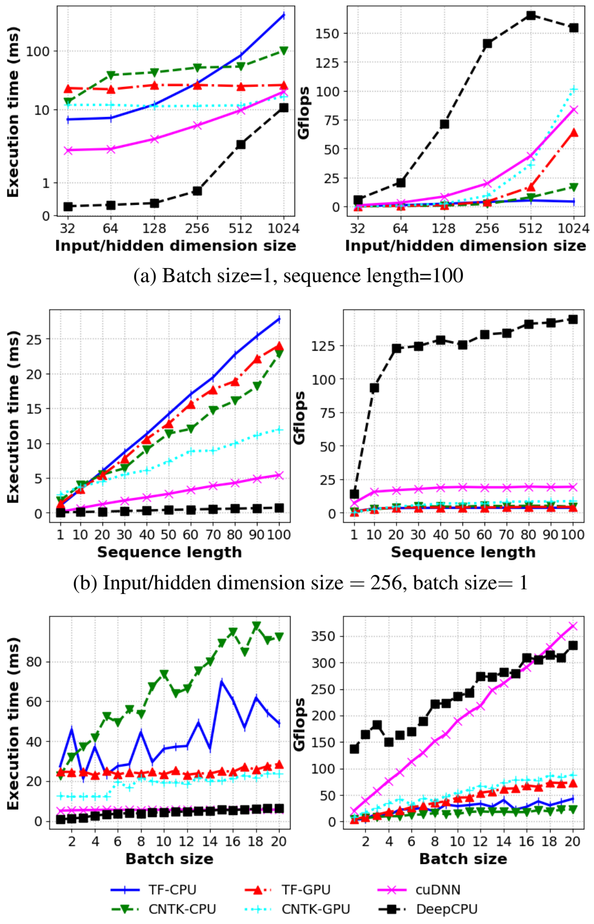
Table 1: Execution times and speedups of LSTMs and GRUs, comparing DeepCPU, TensorFlow and CNTK on CPU.

mance gap decreases due to increase in parallelism that allows for an increasing number of GPU cores to kick in. On the other hand, the CPU Gflops plateaus after dimension size of 512.

Varying sequence length. Fig. 5b shows the performance impact of varying input sequence lengths from 1 to 100. As the sequence length increases, the execution time of all implementations except DeepCPU increases almost linearly, or equivalently, their Gflops stays constant. DeepCPU, however, has a sharp jump in performance when sequence length increases from 1 to 10. It demonstrates that DeepCPU exploits data reuse across steps: when sequence length > 1, later steps reuse the weights from the first step, increasing Gflops. Once the sequence length becomes larger than 10, the increase in reuse per flop is marginal. Thus, the Gflops curve is relatively flat when sequence length grows from 20 to 100.

Varying batch size. As shown in Fig. 5c, among all CPU implementations, DeepCPU performs and scales the best with increasing batch size. Among GPU implementations, cuDNN performs significantly better than TensorFlow and CNTK. Comparing DeepCPU with cuDNN, the best CPU versus GPU implementation, DeepCPU is better with small and moderate batch size (< 15) and cuDNN is better with large batch sizes. This crossover is expected. However, as discussed earlier, batch size is often rather small for serving scenarios due to the stringent latency SLA.



(a) Batch size=1, sequence length=100

(b) Input/hidden dimension size = 256, batch size= 1

(c) Input/hidden dimension size = 256, sequence length= 100

Figure 5: LSTM execution time and Gflops with varying input/hidden dimension, sequence length and batch size.

The GPU implementation in existing framework such as TF-GPU has worse performance than cuDNN. This is because TF-GPU and cuDNN do not use the same underlying implementation. In the case of LSTMs, TensorFlow constructs the LSTM operator as a composition of matrix multiplications and activation functions. A single LSTM operator produces hundreds of nodes in the TensorFlow computation graph. While some of these nodes are computed on the GPUs (for example matrix multiplication using cuBLAS), transferring tensors among nodes incurs quite significant overhead. In contrast, cuDNN implementation is a single highly optimized kernel invocation for the entire sequence of the LSTM computation.

6.2. Serving Real-World RNN-Based Models

We evaluate DeepCPU on serving three real-world models. Table 2 provides their RNN specifications.

What's inside DeepCPU? DeepCPU focuses on RNN families and supports LSTM/GRU cell, LSTM/GRU sequence, bidirectional RNN, and stacked RNN networks. It includes fundamental building blocks such as efficient matrix multiplication kernels, activation functions, as well as common deep learning layers such as highway network [57], max-pooling layer [40], multilayer perceptron [50], variety of attention layers [39, 53], and sequence-to-sequence decoding with beam search [59].

Converting trained models into DeepCPU. DeepCPU focuses on serving, and we take a two-step approach to convert trained models (e.g., from TensorFlow/CNTK) to use it. 1) Replace the RNN part(s) of the original model using DeepCPU APIs. In this paper, we implement all three models using DeepCPU C++ APIs. The engineering work is manageable as our library contains many reusable and common components for building neural networks. A more automated way is to integrate our library with an existing framework, which we consider as future work. 2) Port the weights of the trained model to initialize the DeepCPU model instances.

Text similarity (TS). TS measures semantic similarity between texts [45]. It is widely used for grading machine translation results, detecting paraphrase, and ranking query document relevance. It uses bidirectional GRUs to encode text inputs (e.g., sentences) into semantic vectors and measures their relevance with cosine similarity. The GRU computation dominates the performance of the model. The first row in Fig. 6 shows that with DeepCPU, TS runs 12X faster than TensorFlow on CPUs and 15X faster than TensorFlow on GPUs.

Attention sum reader (ASR). ASR extracts single token answer from a given context and can be used for online question and answering [39]. The model uses bidirectional GRU to encode both query and context into semantic vectors and performs reasoning steps to figure out which token in the context is the answer. Fig. 6 shows that DeepCPU reduces ASR serving latency from more than 100ms to less than 10ms, a more than 10X speedup over TensorFlow on CPUs and GPUs.

Bidirectional attention flow model (BiDAF). BiDAF is a high-ranked model on SQuAD reading comprehension competition list [11] for question and answering [53]. It has a hierarchical structure composed of five neural network layers. Among them, three are LSTM-based (Table 3). Fig. 6 shows that DeepCPU reduces the execution time of BiDAF from more than 100ms to less than 5ms, achieving more than 20x speedup against TensorFlow. Table 3 lists the execution time breakdown across layers after the optimization: DeepCPU significantly decreases the execution time of LSTM-based layers.[1]

Correctness. We use TensorFlow for correctness verification: DeepCPU always produces prediction results matching those generated by TensorFlow.

Hardware choice. While not reported in the paper, we have tried DeepCPU on a few different SKUs and processor generations. We have found significant performance improvements even on Haswell and Ivy Bridge generations. The techniques are effective as long as the model is not significantly larger than $L3$ cache of the hardware. DeepCPU also provides additional performance boost from weight-centric streamlining when the weight matrices fit in $L2$ caches of multiple cores.

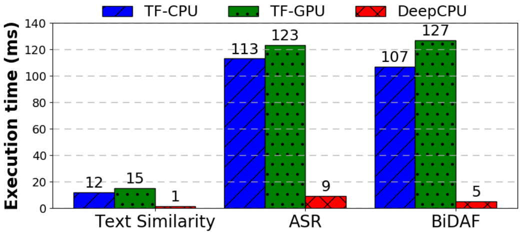


Figure 6: Execution time of TS, ASR, and BiDAF.

Meeting latency SLA with significant cost savings. Besides greatly reducing latency to meet SLA, DeepCPU significantly improves efficiency and reduces serving cost. Take TS model as an example, which is used for ranking query and document pair at our search services. The latency SLA is 6ms and 33 selected documents are ranked for each query. The original TensorFlow model takes 12ms to serve a single ⟨query, document⟩ pair on one CPU machine, violating latency SLA and unable to ship. DeepCPU not only reduces the latency to meet SLA, but more importantly, as shown in Table 4, it only takes 5.6ms to serve a query and *all of its 33 document* on the same machine. *DeepCPU achieves more than 60x throughput gain (i.e.,* $12 \times 33/5.6$*).* Our large-scale search service answers tens of thousands of requests per second, and would originally require more than 10K machines for hosting this model. DeepCPU reduces it to a couple hundred, saving millions of dollars of infrastructure cost just for this model alone.

7. Related Work

DL acceleration library. The closest work to DeepCPU are cuDNN [14, 20] and MKL-DNN [4], which are libraries for accelerating DL frameworks. CuDNN is a GPU library mainly designed for maximizing training throughput, and its performance can be limited by insufficient parallelism when the model size and batch size are small. Other work on optimizing RNNs also target

[1] We also optimized embedding and attention layer to improve end-to-end latency, where the details are beyond the scope of the paper.

Table 2: The description of model parameters of RNNs used in real-world models. Sequence lengths refer to maximum sequence length, and both TensorFlow and DeepCPU support variable sequence lengths.

	TF on CPUs	DeepCPU
Embedding + highway	0.69	0.84
Phrase embedding (LSTMs)	13	0.23
Attention layer	13	1.30
Modeling layer (LSTMs)	31	0.90
Output layer (LSTMs)	49	1.50
Total	107	4.77

Table 3: BiDAF execution time (millisecond) per layer.

	T@10	T@15	T@20	T@33
Embedding	0.28	0.24	0.24	0.36
RNN	2.20	2.60	3.40	5.20
Cosine similarity	0.04	0.04	0.04	0.04
Total	2.50	2.90	3.60	5.60

Table 4: Text similarity model execution time where T@K reports execution time of ⟨query, K documents⟩.

GPUs [26, 30, 64]. On CPUs, MKL-DNN is a C/C++ library from Intel to boost DL model performance on Intel architecture, but it only supports convolutional neural networks and has no support for RNNs yet. Other work on multi-core CPUs is similar, targeted more towards CNNs, fully connected neural networks, etc [43, 49, 61]. Some DeepCPU optimizations (e.g., parallelization, fusion) can be generalized to these other networks, whereas optimizations like WCS are more specialized to RNNs.

Compiler and runtime optimizations. There has been work on optimizing DL model performance through compile-time and runtime strategies. Many of them use static analysis to find pipelined operations that can be fused together for improved performance, such as XLA [10], Weld [47], and TensorRT [5]. The compile-time and runtime strategies of these systems are not designed for global optimization of complex structures like RNN sequences. Halide is a domain specific language and compiler to optimize image processing pipeline [48], conveniently separating algorithms with schedules. It is not specially designed for RNN type of recurrent computation, and optimizations such as the weight-centric streamlining cannot be supported easily. It is also hard for its autotuner to search the space efficiently without domain-specific pruning and partitioning methods.

Model deployment. TensorFlow Serving [9] and Clipper [23] are two serving platforms for deploying and serving machine learning models on production systems. Both support caching inference results and batching individual inference requests for better performance. Clipper selects from multiple models to balance latency with accuracy. Our work and these model deployment platforms complement each other: while they focus on the deployment process for serving requests, our library focus on optimizing the inference time of a model itself.

Hardware accelerators. Apart from CPU and GPU, researchers and practitioners are also looking into specialized hardware such as FPGA [42, 46, 54] and ASIC [32, 38], which often require expert hardware designers and long development cycles to obtain high performance. They are not yet widely available commercially.

Model simplification and compression. Existing work shows many model simplification techniques [33, 36, 63] such as sparsifying and quantization that could reduce computation time and space with a small accuracy tradeoff. Co-designing these model optimizations together with system optimizations like those in DeepCPU could present new opportunities to boost performance further.

8. Conclusion

The paper unravels the mystery of poor RNN performance on existing DL frameworks — low data reuse — and develops optimization schemes to reduce latency and improve efficiency of RNN serving. Powered by the new techniques and search strategy, DeepCPU, our serving library on CPUs, improves performance by an order of magnitude, compared with existing work. It transforms many RNN models from non-shippable to shippable with great latency and cost improvement in production.

9. Acknowledgments

We thank great collaborators for their support of DeepCPU, including Junhua Wang, Rangan Majumder, Saurabh Tiwary, Yuesheng Liu, Qifa Ke, Bruce Zhang, Chandu Thekkath, Yantao Li, Jason Li, Fang Liu, and their team. We thank Bin Hu, Elton Zheng, Aniket Chakrabarti, Ke Deng, Doran Chakraborty, Guenther Schmuelling, Stuart Schaefer, Michael Carbin, Olatunji Ruwase, and Sameh Elnikety. The usability and functionality of DeepCPU has been greatly expanded by incorporating their feedback. We thank Kathryn McKinley for reading a previous version of this paper and providing feedback. We thank our shepherd, Deniz Altinbuken, for helping improving the presentation quality of the work.

Closing the Performance Gap Between Volatile and Persistent Key-Value Stores Using Cross-Referencing Logs

Yihe Huang[‡] *Matej Pavlovic*[†*] *Virendra J. Marathe*[◇] *Margo Seltzer*[◇‡]

Harvard University[‡] *EPFL*[†] *Oracle Labs*[◇]

Abstract

Key-Value (K-V) stores are an integral building block of modern datacenter applications. With byte-addressable persistent memory (PM) technologies, such as Intel/Micron's 3D XPoint, on the horizon, there has been an influx of new high performance K-V stores that leverage PM for performance. However, there remains a significant performance gap between PM optimized K-V stores and DRAM resident ones, largely reflecting the gap between projected PM latency relative to that of DRAM. We address that performance gap with Bullet, a K-V store that leverages both the byte-addressability of PM and the lower latency of DRAM, using a technique called *cross-referencing logs (CRLs)* to keep most PM updates off the critical path. Bullet delivers performance approaching that of DRAM resident K-V stores by maintaining two hash tables, one in the slower (backend) PM and the other in the faster (frontend) DRAM. CRLs are a scalable persistent logging mechanism that keeps the two copies mutually consistent. Bullet also incorporates several critical optimizations, such as dynamic load balancing between frontend and backend threads, support for nonblocking Gets, and opportunistic omission of stale updates in the backend. This combination of implementation techniques delivers performance within 5% of that of DRAM-only key-value stores for realistic (read-heavy) workloads. Our general approach, based on CRLs, is "universal" in that it can be used to turn any volatile K-V store into a persistent one (or vice-versa, provide a fast cache for a persistent K-V store).

1 Introduction

Key-value (K-V) stores with simple Get/Put based interfaces have become an integral part of modern data center infrastructures. The list of successfully deployed K-V stores is long – Cassandra [28], Dynamo [13], LevelDB [30], Memcached [36], Redis [44], Swift [48] – to name just a few. The research community continues to publish K-V store improvements along a variety of dimensions including network stack optimizations, cache management, improved parallelism, hardware extensions, etc. [5, 14, 15, 20, 27, 31, 33, 32, 34, 37, 40, 51, 53, 56]. However, many of these works assume that the K-V store is a volatile cache for a backend database. Most of the persistent K-V stores [7, 13, 18, 28, 30, 34, 51, 44, 48] assume a slow, block-based storage medium, and therefore, marshal updates into blocks written to the file system.

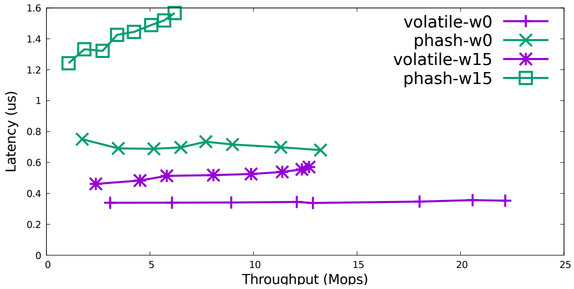

Figure 1: Throughput vs. Latency results of hash table based K-V stores: (i) phash, hosted entirely in emulated PM (Intel's Software Emulation Platform [43, 57]), and (ii) an almost identical K-V store hosted entirely in DRAM (volatile). The emulated PM has 300 nanosecond load latency and bandwidth identical to that of DRAM; DRAM latency is approximately 150 nanoseconds. 0 and 15 represent the percent of K-V accesses that are Puts; keys are selected according to a zipfian distribution. The points on the curves represent the number of threads used in the tests, ranging from 2 to 16 in increments of 2.

At the same time, byte-addressable persistent memory technologies are emerging, e.g., *spin-transfer torque MRAM (STT-MRAM)* [21, 23], *memristors* [46]), and most notably, the Intel/Micron 3D XPoint persistent memory [1]. These technologies provide the persistence of traditional storage media (SSDs, HDDs) with the byte addressability and performance approaching that of DRAM (100-1000x faster than state-of-the-art NAND flash). Byte addressability allows load/store access to persistence (as opposed to the traditional file system interface). As a result, these technologies can profoundly change how we manage persistent data.

The research community has recognized this potential, producing an endless stream of new, PM-optimized K-V stores that leverage PM's byte addressability and low latency, yielding systems that greatly outperform traditional block-based approaches [3, 8, 9, 12, 22, 39, 41, 54, 55, 58]. While this body of work has grown rapidly, most of it ignores the fact that for the forseeable future, PM will be much slower than DRAM [47], making PM resident K-V stores significantly slower than their DRAM counterparts. Figure 1 illustrates the performance gap between K-V stores hosted in DRAM and *emulated* PM. Their implementations differ only in their failure semantics (section 3) and pointer representation (section 6). The 0% writes curves in the graph mirror the $2X$ latency gap between DRAM and emulated PM. This $2X$ gap grows to $3-4.5X$ in the 15%-write case, since writes use expensive persist barriers and transactions for failure atomic updates to the persistent data structures.

Recent PM-based K-V store proposals [41, 54, 55] address this problem by partitioning their data structures between faster DRAM and slower PM, with the DRAM resident structures reconstructed during recovery/warmup. However, these optimizations focus exclusively on B-Tree based indexing structures, not on hash table based structures, which are predominantly used in workloads with `Get`/`Put` point queries. Since these hash tables are central to many popular K-V stores [30, 36, 44], leveraging both DRAM and PM in their implementations is critical to their performance.

We present Bullet, a new K-V store designed for multi-/many-core systems equipped with persistent memory. Bullet explicitly leverages the combination of fast DRAM and slower, byte-addressable PM, to deliver performance comparable to that of a DRAM resident K-V store in realistic workloads. Bullet's architecture is designed to handle most, if not all, client requests in the faster DRAM, minimizing the number of PM accesses on the critical path. This naturally leads to an architecture with a DRAM resident cache, similar to the approach taken by traditional databases and K-V stores. However, Bullet deviates from traditional approaches in that the cached *frontend* hash table and the persistent *backend* hash table representations are virtually identical – differing only in their pointer representations (section 6) and failure handling semantics. This facilitates efficient access to backend data whenever there is a miss in the frontend – PM's byte addressability plays a critical role in making this possible.

We keep the frontend and backend mutually consistent by employing a novel, efficient, and highly concurrent logging scheme, called *cross-referencing logs (CRLs)*. In an architecture using per-thread persistent logs, CRLs track ordering dependencies between log records using simple cross-log links instead of synchronizing the threads' log access [29, 52]. Bullet processes `Get` requests exclusively in the frontend, without log access. On their critical path, `Put` requests access the frontend as well, while also writing log records to CRLs. This results in a single thread-local log append per update.

Backend threads, called *log gleaners*, apply persisted log records to the backend hash table. We use an *epoch* based scheme to apply log records to the backend in batches. The epoch based scheme's primary purpose is to enable correct log space reclamation. The backend's hash table updates must be applied in a crash consistent manner. We address this problem using a backend runtime system [35] that supports *failure atomic transactions* similar to several other persistent memory transaction runtimes [16, 50]. The resulting code path is complex, but *not on the critical path* of client requests.

We apply four key optimizations in Bullet: 1) fully decoupling frontend execution from PM performance on `Put` operations, 2) nonblocking `Gets`, 3) dynamic thread switching between the frontend and backend, based on the write-load in the system, and 4) opportunistic `Put` collapsing. Our base design, coupled with these optimizations, make Bullet's performance close to that of a DRAM resident K-V store: For realistic, read-heavy workloads, Bullet either matches or comes close to the performance of a DRAM-resident volatile K-V store, delivering throughput and latency $2X$ better than that of a state-of-the-art hash table based K-V store, HiKV [54], on a system with emulated PM whose access latency is $2X$ of DRAM access latency. For pathological write-heavy workloads, Bullet's throughput is comparable to or better than that of HiKV and its operations' latency is approximately $25-50\%$ lower. Relative to a volatile K-V store, Bullet's latency and throughput degrade by approximately 50% under write-heavy workloads.

2 Bullet's Architecture

2.1 Overview

Figure 2 depicts the high level architecture of Bullet, separated into the frontend and backend components, each of which contains almost identical hash tables. The frontend resides in the *volatile domain* (DRAM). It contains a configurable number of threads that process incoming requests, applying them to its hash table. Each frontend thread additionally "passes on" update requests to the backend, by appending update requests to a *thread-local* persistent log. An update completes when it has been safely written to the log. The backend resides in the *persistent domain* (PM). The backend's *log gleaner* threads periodically read requests from their corresponding persistent logs and apply them to the persistent hash table, in a failure-atomic and correctly ordered manner. In this "base" configuration, each persistent log maps both to a *log writer* thread in the frontend and a log gleaner thread in the backend.

While processing client requests, a frontend thread first looks up the target key in the frontend K-V store. If the lookup succeeds, the frontend applies the operation. If it is an update (`Put` or `Remove`), the thread also appends the `<opcode,payload>` tuple to its persistent log. If the lookup in the frontend fails, the thread issues a lookup to the backend. A successful lookup creates a copy of the key-value pair in the frontend, at which point the operation proceeds as if the original frontend lookup succeeded. If the lookup fails: (i) a `Get` returns a failure

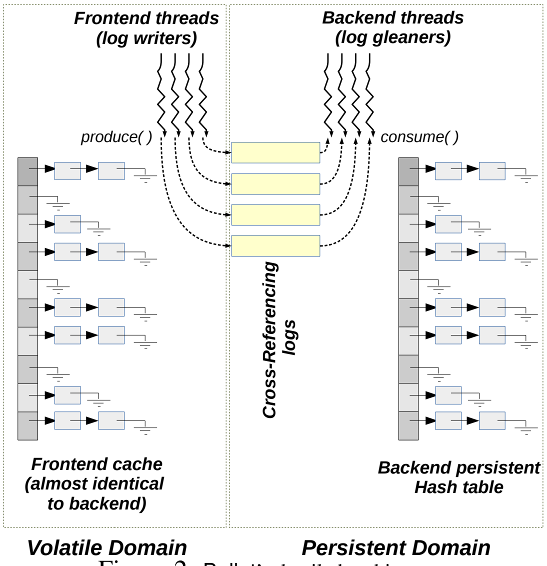

Figure 2: Bullet's detailed architecture.

code to the client, (ii) a `Put` inserts the pair into the frontend, including the log write, and (iii) a `Remove` returns with a failure code.

The rest of this section details our solutions to a number of technical challenges: persistent and volatile hash table implementation (subsection 2.2), the parallel logging scheme (subsection 2.3), correct coordination between frontend and backend threads (subsection 2.4), and failure atomic updates (section 3).

2.2 Hash Tables

As shown in Figure 2, Bullet's frontend hash table is in DRAM and therefore volatile. It supports the standard K-V operations: `Get`, `Put`, and `Remove`. The hash table is similar in structure to other key-value stores [36]: It is closed addressed, with chaining to handle hash conflicts. It grows via a background thread responsible for doubling the number of hash table buckets when occupancy crosses a threshold size (twice the number of buckets). Regular operations can occur concurrently with growing the table. Each hash table bucket has its own reader-writer spinlock for thread synchronization – lookups acquire the spinlocks for reading (shared), and updates acquire the spinlocks for writing (exclusive).

The backend hash table is structurally identical to the frontend one, with its own per-bucket chains and spinlocks. However, unlike the frontend (volatile) hash table, the backend hash table resides in persistent memory and must survive failures. Bullet uses failure atomic transactions for `Put` and `Remove` operations to provide this guarantee (section 3). `Gets` execute identically to those in the frontend (except a failure to find a key is always a failure in the backend, while the frontend has to check the backend before failing).

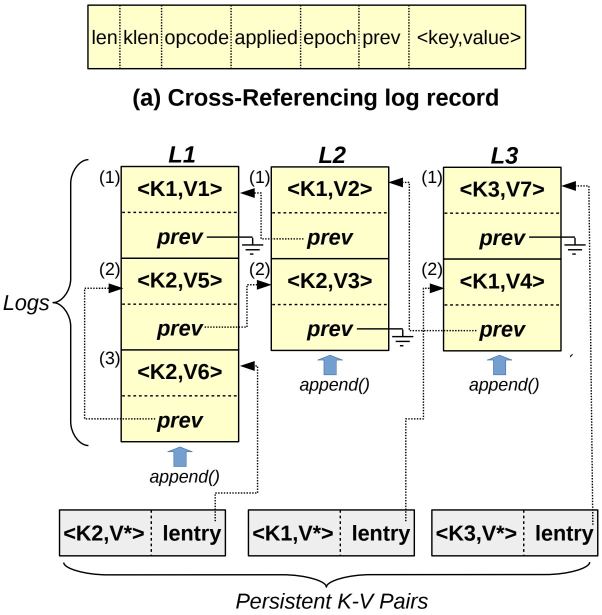
The per-bucket spinlocks in the persistent hash table are used only for synchronization between concurrent backend threads and are semantically volatile. We found placing the spinlocks in the bucket extremely convenient, with the added benefit of improved cache locality compared to an alternative where the spinlocks are mapped elsewhere in DRAM. Since a bucket's spinlock resides in persistent memory, its state can persist at arbitrary times (e.g., due to cache line evictions). A failure could leave a spinlock in the *locked* state. We leverage a generation number technique [10] to reinitialize such locks after a restart – Bullet increments a global persistent generation number during every warm-up and compares that generation number to a generation number contained in every lock. If the generation numbers do not match, Bullet treats the lock as available and reinitializes it.

2.3 Cross-Referencing Logs

The frontend communicates updates to the backend via a log. In a conventional, centralized log design [25, 26, 38], the log becomes a bottleneck, because concurrent updates must all append records to the log. Thread-local logs neatly address this contention problem, but introduce a new challenge: records from a multitude of logs must be applied to the backend in the correct order – the order in which the corresponding operations were applied in the frontend. While prior systems partition the key space so that all updates to a particular K-V pair appear in the same log file (e.g., [34]), Bullet does not partition the data and K-V pair updates can happen in any thread. This way Bullet is not susceptible to load balancing issues encountered in partitioned K-V stores [34]. We address the ordering problem in a different way: We introduce *cross-referencing logs (CRLs)*, to provide highly scalable, concurrent logging on PM, without relying on centralized clocks [29, 52] to enforce a total order of update operations.

Figure 3 illustrates CRLs. Each frontend log writer thread maintains its own persistent log. Logically, each log record is a `<opcode,payload>` tuple. Opcode allows the application to define high-level operations expressed by each log record. For example, when Bullet manages a hash table of lists, each list append can be expressed by a single log record, where the opcode refers to the list append operation, and the payload contains the record identifier (a reference to the list in question) plus the value to be appended. The order in which non-commutative operations like this are applied is important, hence the necessity of the CRL scheme. The logs require no synchronization on appends, because there is only one writer per log. The backend maintains corresponding log gleaner threads that consume log records and apply them to the backend persistent hash table in a failure-atomic manner.

The logs are structured so that log gleaners can easily



(a) Cross-Referencing log record

(b) Cross-Referencing log structure

Figure 3: Cross-Referencing Log (CRL) architecture.

determine the correct order in which to apply log records. Figure 3a shows the log record layout. The `len, klen, opcode, <key,value>` fields contain the information implied by their names. The `applied` field contains a flag indicating whether the backend K-V store accurately reflects the log record. The `prev` field contains a persistent pointer to the prior log record, if one exists, for the given key. We defer discussion of `epoch` until subsection 2.4.

Appending Log Records: Figure 3b depicts three logs $L1$, $L2$, and $L3$ containing log records for keys $K1$, $K2$, and $K3$. The `lentry` field of the persistent key-value pairs (shown at the bottom) contains a persistent pointer to the most recent log record for the key-value pair. Thus, the list formed by the `lentry` and `prev` pointers represents the evolution of a key-value pair in reverse chronological order, where the log record containing a NULL `prev` pointer indicates the first update to the pair present in any of the logs. The list for a specific key can *criss-cross* among multiple logs, hence the name *cross-referencing logs*. For instance, log records for key $K1$ appear in all three logs, whereas log records for key $K2$ appear only in logs $L1$ and $L2$.

Before a log writer appends a log record, it acquires the key's hash bucket lock, to ensure that it is the only writer for the target key-value pair. Then, the writer (i) populates the log record at the tail end of the log, setting the log record's `prev` field to the value stored in the K-V pair's `lentry`, (ii) persists the log record, (iii) updates and persists the log's tail index, and finally (iv) updates and persists the key-value pair's `lentry` pointer, thus completing the linked list insertion. In all, an append requires 3 persist barriers.

Applying Log Records: Gleaner threads periodically scan logs and apply log records to the backend hash table in a failure-atomic manner. A log gleaner starts processing from the beginning of the log (the head). For each log record encountered, the gleaner looks up the corresponding key-value pair in the backend persistent hash table; a new key-value pair is created if necessary.

The gleaner retrieves the key-value pair's `lentry` to process all existing log records for that key-value pair. At this point, we need to ensure that at most one gleaner is processing log records for a given key-value pair. To that end, we add another spinlock that enables only one gleaner to apply all the log records for a key-value pair. This spinlock is placed in the key-value pair itself. A gleaner must acquire this spinlock before processing the log records for the key-value pair. The gleaner then traverses to the end of the list, checking the `applied` flag of each log record to determine the point from which the gleaner needs to apply log records. Upon finding the last (chronologically the first) unapplied log record, the gleaner applies the log records in the chronological order determined by the linked list (i.e., in the reverse order of the list). The gleaner sets the `applied` field after applying the log record to the persistent hash table. We discuss the transaction mechanism that ensures recoverability of these updates in section 3.

After applying all the log records for a key-value pair, the gleaner can reset `lentry` to `NULL`. This however races with a frontend log writer's append for the same key-value pair, which requires an update to the key-value pair's `lentry`. Fortunately the data race can be avoided using a `compare-and-swap` instruction, by both the appender and the gleaner, to atomically change `lentry`.

Consider the example in Figure 3. A gleaner for log $L1$ will first encounter log record labeled (1). It uses the log record's key, $K1$, to retrieve the corresponding persistent key-value pair (at the bottom of Figure 3b). From that key-value pair object, the gleaner begins at the end of the log record list at $L3(2)$, then continues to $L2(1)$ and finally $L1(1)$. It then applies each of those log records in reverse traversal order.

Handling Removes: Removes are unique, in that they logically require removing a record at the front end, but the same record at the persistent back end may not be removed at the same time due to log delays. If a deletion is followed by a re-insertion of the same key, the front end and back end can grow inconsistent, due to the fact that CRL relies on the back end record to generate cross-references. To address this problem, we keep the front end record alive as long as we need to by using a special "tombstone" marker. Appending a delete log record only sets the tombstone marker at the front end, but does not remove the record. Future look-ups on the front end regarding this record now return “not found”, until a reinsertion clears this tombstone marker. The front end records marked with tombstones are only physically removed when the corresponding records in the back end are removed during the log gleaning phase.

Rationale: While cross-referencing logs are interesting, one could argue that the criss-crossing could lead to bad cache locality for log gleaner threads. However, it is a trade-off – a thread may suffer poorer locality in its log traversal, but it enjoys superior cache locality, by repeatedly acting upon the same key-value pair. This cache benefit is further enhanced, because log records are concise representations of operations, but the operations themselves tend to lead to “write amplification”, accessing and updating many more memory locations than a single log entry. By continuing to operate on the same key-value pair, we observe that those accesses are far more likely to produce cache hits. Additionally, gleaners never block behind other gleaners. If a gleaner detects that the key-value pair it needs to process is already locked by another gleaner, it can safely assume that the spinlock owner will apply the log record. As a result, the gleaner simply skips that log record. This approach works for the *fail-stop* failure model we assume – a failure terminates the entire key-value store process.

2.4 Log Space Reclamation

The cross-referencing logs that act as bridges between Bullet’s frontend and backend do not grow indefinitely. In fact, they are circular logs and contain persistent `head` and `tail` indexes. To keep the system running without interrupt, Bullet must recycle log space.

The log gleaners work in phases or *epochs*. Between epochs, the gleaners wait for a signal from the *epoch advancer* thread, which periodically tells the gleaners to start applying logs records. Each gleaner reads the log, beginning at the head, and applies the log records as described above. However, it does not advance its log’s head index. Instead, the epoch advancer periodically terminates the current epoch by telling the gleaners to stop processing the log. At this point, the epoch advancer updates each gleaners’ head index. If a log writer fills the log more quickly than the corresponding log gleaner applies the log, the log can fill. If this happens, the writer blocks until the gleaner frees space in the log.

3 Failure Atomic Transactions

To ensure a consistent state after system failure, the backend’s hash table updates must be failure atomic. We use failure atomic persistent memory transactions. Similar to prior work [6, 10, 16, 50], we developed a persistent memory *access library* [35], which contains support for low level programming abstractions that greatly simplify application development for persistent memory. Our access library supports transactions that provide failure atomicity guarantees for updates to persistent memory.

```
pm_txn_t *txn_begin();
txn_state_t txn_commit(txn);
void txn_read(txn, src, len, dst);
void txn_write(txn, dst, len, src);
... // other accessor functions
pm_region_t *pm_region_open(path);
void pm_region_close(region;
void *pm_get_region_root(region);
void pm_set_region_root(region,addr);
... // other region management functions
void *pm_alloc(txn, len);
void pm_free(txn, addr);
```

Figure 4: Base persistent transactions API.

Figure 4 presents our transaction runtime’s API. The interface provides `txn_begin` and `txn_commit` functions to delineate transaction boundaries and various `txn_read` and `txn_write` accessor functions for transactional reads and writes of persistent data. The interface also provides transactional variants of general purpose `libc` functionality, such as `memcpy`, `memset`, `memcmp`, etc. We provide “flat nesting” semantics [19]. The transaction mechanism provides *only* failure atomicity semantics; it does not transparently manage concurrency control, as do some software transactional memory runtimes [10, 50]. Bullet itself performs the necessary synchronization to avoid data races and deadlocks.

The access library also provides a *persistent region* abstraction [6, 10, 50]. The persistent region builds over the `mmap` interface, mapping a persistent memory file into the application’s address space [49]. The persistent region contains a persistent heap, modeled after the Hoard allocator [4, 50]. Application data hosted in a persistent region can be made reachable via a special, per region, *root* pointer. Bullet uses the region’s root pointer to reach its persistent hash table and cross-referencing logs. Finally, the access library uses redo logging [16, 35, 50] to implement failure atomic writes.

4 Optimizations

4.1 Tightening the Update Critical Path

Bullet is designed to streamline critical paths of update operations. To that end, Bullet moves the persistent hash table’s failure-atomic updates off the critical path. However, the design presented thus far does not entirely remove transactions from the update critical path. On a `Put` operation, if the key does not exist in either the frontend or backend hash tables, Bullet allocates a new *persistent* K-V pair object, storing a reference to it in the log record. Furthermore, when the persistent log append completes, we must also update the the key-value pair’s `lentry` to reference that newly created log record. Accessing the persistent K-V pair itself requires a lookup in the backend hash table, which is costly due to the relatively slower persistent memory. All these accesses and updates contribute significant latency to the frontend update operations.

We address this problem by completely decoupling backend data accesses from the frontend update operations, by moving the `lentry` pointer to the frontend hash table's K-V pair. This gets rid of the requirement to locate, and possibly allocate, the backend's K-V pair for a new key. It also eliminates the expensive persist barrier required to persist the `lentry`, since it is no longer persistent; it's part of the volatile copy of the K-V pair. This also eliminates the need for transactions in the frontend, thereby considerably shortening the frontend's update critical path.

4.2 Nonblocking `Gets`

Bullet's "base" version, as described in section 2, uses reader-writer locks to synchronize access to the frontend and backend buckets. While these work well with few frontend and backend threads, they do lead to increased cache contention between concurrent readers on the lock's readers counter – the lock implementation uses a signed integer, where a value greater than 0 indicates one or more readers, and a -1 indicates a writer. The resulting cache contention can restrict scalability. This can be especially pronounced in workloads where accesses follow a power-law distribution and are skewed to a small set of K-V pairs, as is experienced by real world K-V stores [15, 40].

As in prior work [15], we support nonblocking `Get` operations. The principal hurdle for nonblocking `Gets` is memory reclamation – a `Put` or `Remove` can deallocate an object being read by a concurrent `Get`. We need support to *lazily* reclaim the removed objects. Bullet's epochs neatly enable this lazy memory reclamation. The epoch advancer thread periodically increments Bullet's global epoch number. Each frontend thread maintains a local epoch equal to the global epoch number at the beginning of an operation.

When freeing an object, the frontend thread enqueues the object on its local free queue. The enqueued node contains a pointer to the object and the thread's epoch number. On each enqueue, the frontend thread frees the head node of the queue if its epoch is older than the smallest epoch of all the frontend workers. The smallest epoch is a conservative approximation of workers' epochs – it is computed periodically by the epoch advancer thread at the end of each epoch.

Additionally, we structure the frontend hash table's overflow list similar to prior nonblocking concurrent lists [17] so that a reader does not get stuck in a cycle if the node it is accessing is removed from the list by a concurrent writer. While reads are nonblocking, concurrent writers do synchronize with each other on the bucket's spinlock.

4.3 Managing Writer and Gleaner Counts

In the base design, Bullet contains a static mapping between frontend writers, logs, and backend gleaners. Although this approach avoids synchronization among writers and gleaners, it wastes CPU cycles if there is a mismatch in the rates of log record production and consumption. We need to decouple these three parts of Bullet to let threads dynamically perform the roles of frontend and backend based on the write load.

4.3.1 Decoupling Writers from Gleaners

Maximizing Bullet's throughput requires that we keep all threads busy. In practice, this requires that we relax the 1:1 mapping between writers and gleaners. We permit each writer/gleaner to append/consume entries to/from any log. This way we achieve optimal throughput by setting the writer/gleaner ratio according to the ratio of the respective rates of production/consumption of log entries.

Although this requires synchronization among both writers and gleaners, we make the overhead negligible, by coarsening switching intervals between writers and gleaners. Writers lock their log and keep the lock as long as the log is not full. When a log fills, the writer unlocks it and switches to the next free log not currently in use. The same thing happens for gleaners; they switch logs when they have no work to do. For log sizes on the order of megabytes, these switching events are rare enough not to impact performance in an observable way.

4.3.2 Dynamic Adjustment of Writer/Gleaner Ratio

One drawback of the preceding approach is that, selecting the correct writer and gleaner counts, requires knowing the rates of producing and consuming log entries. However, these rates depend heavily on the workload (read/write ratio, key distribution), and the relative performance of DRAM and persistent memory. For example, a write-heavy workload on a machine with a slow persistent memory generally requires more gleaners than a read-heavy workload.

To achieve high throughput in as many scenarios as possible, threads dynamically change their roles, writing or gleaning depending on what is currently needed. The advantage of this approach is twofold. First, it makes Bullet suitable for a wide range of workloads, without prior profiling and configuration. Second, the system adapts to dynamically changing workload, maintaining near optimal throughput throughout.

The key for achieving optimal throughput is preventing the logs from becoming full (writers stalling) or empty (gleaners stalling). To this end, we periodically check (once per epoch) the occupancy of the logs. If the log occupancy passes a pre-defined threshold of 60%, we switch one thread from writing to gleaning. If, upon the next check, the occupancy is still increasing, we add yet another gleaner. We repeat this until the log occupancy starts decreasing. The inverse happens when the log occupancy drops below 30%, in which case we start moving gleaners back to writing.

Making threads switch between worker and gleaner roles is an interesting control theory problem by itself. Our algorithm evolved over several attempts at simpler approaches, which failed to achieve both stability (i.e., avoid frequent role switching) and responsiveness.

4.4 Collapsing `Put` Operations

Recall that multiple updates to the same key result in a linked list of log records. Gleaners traverse the chain and apply all the log records from oldest to newest (see subsection 2.3).

However, it is not necessary to apply every `Put` operation, since the most recent `Put` overwrites the effects of all older `Puts` and `Removes`; same is the case with `Removes`. Thus, a gleaner applies only the newest operation in a chain of log records, without following back pointers at all. To prevent a newer value being overwritten by an older one, a gleaner applies a log record only if it contains the globally newest update for the corresponding key. To determine whether a log entry is the newest for its key, the gleaner checks the corresponding K-V pair's `lentry` pointer, as this always points to the key's newest log record.

Collapsing updates appears to make the criss-cross log record links unnecessary. However, this is the case only for *idempotent* updates, e.g. `Put` and `Remove`. We however plan to extend Bullet to support non-idempotent updates similar to recent data structure stores like Redis [44], where the criss-cross links will be required for correctness.

5 Recovery and Warmup

Recovery is simple for Bullet. Since updates must complete in the frontend before we apply them to the backend and the frontend disappears on failure, Bullet never has anything to undo. In theory, recovery entails two parts: 1) reinitializing the frontend DRAM resident state and 2) applying log records in the CRLs to the backend. Bullet's architecture however permits us to eliminate all of step 2 from recovery, and reduce step 1 drastically: During recovery, the CRLs' log records can be applied to the frontend hash table, instead of applying them to the backend. This has the nice side effect that there is no special recovery code for the backend. We assume that recovery for the backend's persistent transactions happens before Bullet's recovery is triggered. Application of CRLs to the backend is relegated to the normal gleaning process.

Note that recovery itself "warms up" the frontend hash table with key-value pairs found in the CRLs. Thereafter, misses in the frontend populate the corresponding key-value pairs from the backend as described in subsection 2.3. Thus warmup time and recovery time are one and the same and are proportional to the time taken to apply the CRLs.

6 Implementation Notes

We implemented Bullet in C++ and used our PM access library (section 3) developed in C. We used `pthreads` to implement both the frontend and backend threads. The frontend K-V store uses the `jemalloc` library to handle memory allocations. For the backend, we rely on the access library's heap manager, which is based on the scalable Hoard allocator [4, 50].

The PM access library presents to Bullet a persistent memory hosted `mmap()`ped file as a persistent region. Bullet's persistent domain is precisely that region. The `mmap` dependency means that the address of the persistent domain is unpredictable. Therefore, we must represent persistent pointers in a manner amenable to relocation, so we represent persistent pointers as offsets from the region's base address.

Bullet's backend contains a *root structure* that hosts persistent pointers to the persistent hash table and the cross-referencing logs. Wherever we do not use persistent transactions, we carefully order stores and persists to persistent data structures (e.g. CRL appends, initializing a newly allocated key-value pair) for crash consistency.

All update operations in Bullet's backend threads use transactions to apply CRL log records to the backend hash table. In contrast, Bullet's frontend updates need not be transactional; they need only append records to the the CRLs. This indicates two different implementations for all update operations (e.g., frontend and backend implementations of `Put`, `Remove`, etc. operations). This doubles the coding effort for these operations.

The access library's transactional runtime uses Intel's persistence enforcement instructions [24] – cache-line writeback (`clwb`) and persist barrier (`sfence`) instructions to correctly order transactional writes to PM. CRL appends also use these instructions: first, we write back the cache lines of the updated log record using `clwb` and then persist them using `sfence`. Next, we update and persist the log's tail index using the same instructions.

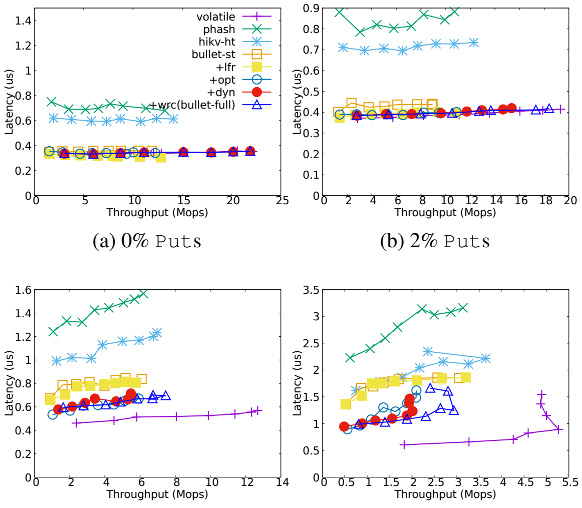
7 Evaluation

We evaluated Bullet's performance on Intel's Software Emulation Platform [43, 57]. This emulator hosts a dual socket 16-core processor, with 512GB of DRAM, of which 384GB is configured as "persistent memory". Persistent memory is accessible to applications via `mmap`ped files hosted in the emulator's PMFS instance [43].

The aforementioned persistence instructions, `clwb` and `sfence`, are not supported by the emulator. We simulated `clwb` with a `nop` and the `sfence` with an idle spin loop of 100 nanoseconds. We expect these to be reasonable approximations since `clwb` is an asynchronous cache line writeback, and an `sfence` ensures that prior writebacks make it to the memory controller buffers, which we assume to be a part of the memory hierarchy's "persistence domain" [45] – 100 nanoseconds is the approximate latency to the memory controller buffers on the emulator. The emulator does support configurable `load` latency to persistent memory; we set it to 300 nanoseconds, twice the load latency of the DRAM on the machine [57]. We configured the PM to have the same bandwidth as that of the emulator's DRAM. We experimented with a lower bandwidth option (1/4 of DRAM bandwidth, which was the only other available option on the emulator), but obtained identical results, suggesting that our experiments did not saturate the memory bandwidth available on the emulator (36 GB/s).

We conducted an 8-way evaluation to see how effectively Bullet eliminates the gap between DRAM and PM performance. The eight systems were as follows. 1) A DRAM-only version that uses just the frontend hash table (volatile), which places an upper bound on performance. 2) A PM-only version that uses Bullet's backend hash table (phash), providing a lower bound on performance. 3) hikv-ht, our implementation of the hash table component of HiKV – a state-of-the-art K-V store, whose hash table resides in PM [54]. HiKV gets a somewhat unfair advantage in our experiments, because it does not ensure that the state of the persistent memory allocator persists. However, the allocator's state can be rebuilt after a restart from HiKV's hash table, although we have not implemented this. 4) bullet-st, the base version of Bullet, which assigns frontend and backend threads statically and uses transactions in the critical path of update operations. 5) +lfr, the base version of Bullet with optimized, lock-free `Get`s. 6) +opt, the version of Bullet that additionally eliminates failure atomic transactions from the critical path of update requests. 7) +dyn, the Bullet version that, along with above optimizations, supports dynamic thread switching between the frontend and backend. 8) bullet-full (also appears as +wrc(bullet-full) in the graphs), the full Bullet version that additionally contains the write collapsing optimization. Although the frontend of Bullet can be a subset of the backend, in our experiments the frontend is a full copy of the backend.

We evaluate various aspects of Bullet comprising scalability and latency, dynamic behavior of worker threads, and log size sensitivity in a microbenchmark setting. In all our experiments, `Get`/`Put` requests are drawn from a pre-created stream of inputs with a zipfian distribution of skewness 0.99, which is the same as YCSB's input distribution [11]. We average over five test runs for each data point. We also use an evaluation framework that uses independent clients to better understand end-to-end performance of these systems as client load increases. The clients are independent threads residing in the same address space as Bullet and communicate requests and responses through globally shared request/response buffers. We do not use clients communicating with Bullet over TCP connections, since the network stack latency itself tends to significantly mute important performance trade offs between the evaluated K-V stores [14, 54].



(a) 0% `Puts`

(b) 2% `Puts`

(c) 15% `Puts`

(d) 50% `Puts`

Figure 5: Latency (99th percentile) vs. Throughput results. Each point on the curves represents a different number of worker threads ranging from 2 to 16 in increments of 2.

7.1 Latency vs. Throughput

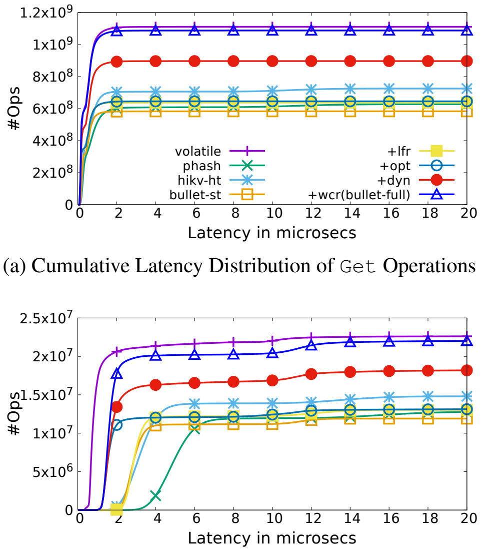
Figure 5 shows performance as a latency/throughput tradeoff under workloads whose write percentage varies from 0% (read-only) to 50% (write-heavy). We begin by creating a 50-million key/value pair store with 16-byte keys and 100-byte data values; these choices are in line with what is observed in real-world settings [2, 54]. Each experiment runs a specified number of of worker threads with the requested read/write ratio, using `Get`/`Put` operations (`Remove` performance is comparable to that of `Put`). Each worker selects key-value pairs from the prepopulated zipfian stream of keys and performs the selected operation. The worker continuously repeats these operations for 1 minute (we experimented with 5 – 10 minute runs, but the results were unchanged).

For the dynamic worker role versions of Bullet (+dyn and bullet-full), some workers switch roles to become backend log gleaners. In such cases, the worker posts its current unapplied operation on a globally visible queue of requests, so that some other frontend worker will process it (to ensure forward progress, we guarantee that at least 1 worker remains in the frontend). We measure latency of only those operations that have a frontend worker assigned to them (the requests posted in the central queue are a rare occurrence and are processed relatively immediately by frontend worker threads).

Notice the clear impact of slower PM on the 0% `Put` case in Figure 5a. The difference between phash's and volatile's latency and throughput mirrors the difference in PM and DRAM latency. hikv-ht performs noticeably better than phash, owing to some of its cache locality oriented optimizations. But these marginal improvements suggest that additional optimizations cannot eliminate the fundamental problem of slower PM. All of Bullet's versions' latencies align almost exactly with volatile. bullet-st shows slight overhead associated with lock-based Gets. All static worker role assignment variants of Bullet (bullet-st, +lfr, +opt) effectively end up using just half of the available workers in the frontend and produce throughput approximating half the throughput of volatile; the backend worker threads effectively waste CPU cycles. Our dynamic worker assignment framework (in +dyn, +wrc(bullet-full)) correctly assigns all workers to the frontend, which performs comparably to volatile.

The 2% Put test is more representative of real-world (read-dominated) workloads [40]. As Figure 5b shows, the relative latency differences remain similar; there is a small increase in the absolute latencies reflecting effects of longer latency Put operations. For the same reason, the absolute throughput numbers are smaller, but the relative difference between volatile, phash, hikv-ht, and the static variants of Bullet remains the same. However, in +dyn and bullet-full we begin to see the impact of logging. The primary source of these overheads is the dynamic switching of 1 or 2 worker threads between the frontend and backend. Note that even with 2% Puts, our CRLs quickly cross the occupancy threshold of 60%, which forces frontend threads to incrementally switch to the backend log gleaner roles if the occupancy keeps growing across epochs. A consistent rate of 2% Put traffic is large enough to force at least one worker to stay a log gleaner through the entire execution. +dyn's performance drops by a significant 25% compared to volatile. However, our write collapsing optimization works exceptionally well to significantly reduce that margin to about 5%: the zipfian distribution of requests allows for substantial write collapsing (30 – 50%), which leads to the log gleaner applying the log more quickly, spending the saved time in frontend request processing.

The 15% workload, shown in Figure 5c, illustrates more clearly the impact of the different optimizations. Compared to volatile, Bullet's bullet-st and +lfr versions show a 40% degradation in latency. The failure atomic transactions used for Put operations of these versions are primarily responsible for this degradation. This degradation is mitigated by half with our critical path optimization present in Bullet's +opt, +dyn, and bullet-full versions. Latency of the PM-only K-V stores, phash and hikv-ht, is approximately 3X and 2.5X higher than that of volatile. Notice the throughput of Bullet's dynamic versions drops significantly. With 15% Puts, we observed a larger fraction (4 – 6) of worker threads getting forced to operate as log gleaners in the backend for the entire duration of the test. That leads to a significant reduction in overall throughput, since threads migrated from the frontend to the backend do not process new requests.



(a) Cumulative Latency Distribution of Get Operations

(b) Cumulative Latency Distribution of Put Operations

Figure 6: Get, Put Cumulative Latency distributions on 16-thread test runs with 2% Puts.X

With the even higher 50% Put rate of Figure 5d, we observe additional interesting behavior. The variants that use transactions in their Put critical paths exhibit significantly increased latency, approaching that of hikv-ht's latency. The rest of Bullet's variants (+opt, +dyn, and bullet-full) exhibit lower latency, which starts to grow only as the set of worker threads grows. We attribute this performance degradation to cache contention between frontend and backend threads. Notice that the working sets of the frontend and backend threads are largely different – a frontend log writer accesses the frontend hash table and a log, whereas the colocated (on the same socket) backend log gleaner accesses the backend hash table and possibly a different log. The more threads there are, the greater the cache contention, and the worse the performance. Overall, the results suggest that workloads with very high write rates are not a good fit for Bullet.

7.2 Latency Distribution of Gets and Puts

Figure 6's segregated cumulative latency distribution graphs for Gets and Puts provide deeper insight into the behaviour of the K-V stores. Figure 6a shows latency of Gets. The phash and hikv-ht latencies average to about 450 and 380 nanoseconds respectively, whereas volatile and all of Bullet's versions average to 220 nanoseconds. Average latencies of Puts are more scattered: volatile is the fastest with 750 nanoseconds, followed by Bullet's versions that do not contain trans-

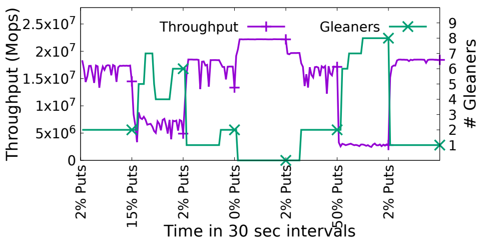


Figure 7: Variation in throughput and log gleaner count as the write load on bullet-full changes. The load, shown on the X-axis labels, switches every 30 seconds. The left Y-axis shows throughput for every second, and the right Y-axis shows the number of log gleaners at the end of each second.

actions in the critical path (at 1 microsecond), followed by Bullet's versions that contain transactions in the critical path (at 2.5 miroseconds). HiKV's latency matches that of Bullet's versions with transactions on the critical path. phash is the slowest with latency averaging to 5 microseconds; this is an $8X$ slowdown compared to volatile. Note that the backend `Put` operations in all of Bullet's versions apply the same `Put` operation used in phash. This largely explains the significantly higher cost associated with applying log records to the backend, and why as little as 2% `Puts` can force worker threads to play the log gleaner role for much longer durations that amplify to a minimum of 10% slowdown in throughput compared to volatile in Figure 5b.

7.3 Dynamic Behavior of Workers

Figure 7 shows bullet-full's dynamic worker role framework in action. It reports the throughput as well as the gleaner count at the end of every second, over a duration of 210 seconds. Every 30 seconds, we change the load of `Puts` on bullet-full. After a warmup phase of 30 seconds of 2% `Put` rate, we vary the `Put` rate between 2-15-2-0-2-50-2%, in that order. As is clear from the graph, our dynamic worker role adaptation strategy works well in adapting to the changing load of `Puts`. At times, as observed in the 15% and 50% `Put` phases, our adaptation algorithm fluctuates around the optimal mix of frontend and backend workers before converging to a stable mix that matches frontend producers of log records with backend gleaners that consume these log records.

Throughout the execution, for 2% `Puts`, the throughput hovers around 16 Mops, and the number of log gleaners ranges from $1-2$. This helps explain the reduction in observed throughput of bullet-full compared to the throughput of volatile in Figure 5b. After a switch to a 15% `Put` rate, the throughput switches immediately, reflecting the corresponding uptick in the gleaner count. For the 0% `Put` case, our algorithm quickly and correctly converges to a gleaner count of 0, thus explaining the throughput reported in Figure 5a that matches the throughput of volatile. For the 15% and 50% `Put` cases, the number of gleaners needed settles down to 6 and 8 respectively. Note that in our 100% `Put` experiments (not reported here in detail), we observed the number of gleaners vary between $13-15$.

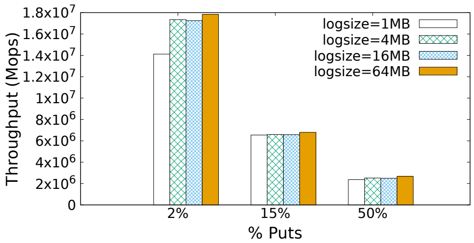

Figure 8: Effect of log size (per thread) on throughput of bullet-full.

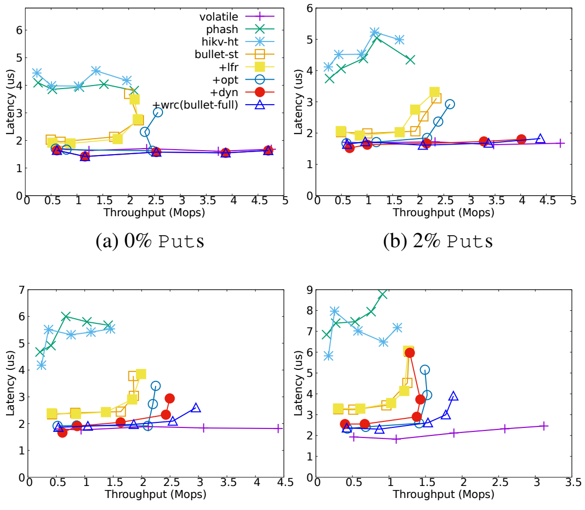
7.4 Log Size Sensitivity

Bullet's CRLs act as speed matching buffers between the frontend and backend worker threads. As long as there is enough available space in CRLs, frontend workers keep appending log records as quickly as they can. When CRL occupancy gets too high, workers are incrementally switched to the backend to match the frontend load of CRL population. If the CRLs are too small in size, Bullet can easily enter a mode where threads bounce between frontend and backend at a high frequency, which in turn could lead to significant disruption in overall performance. The question then to consider is – how big should these logs be to avoid performance degradation due to workers switching frontend and backend roles?

To that end, Figure 8 shows the results of our experiment where we vary the per-thread log size from 64 MBs (the size we used for all experiments described above), down to 1 MB. In addition, the CRL infrastructure maintains 32 logs in-all; when a frontend worker exhausts its log, it can switch to another log that is not in use by another frontend worker. As a result, per-thread log sizes of 1, 4, 16, and 64 MBs result in total CRL footprint of 32, 128, 512, and 2048 MBs respectively. Even the largest 2048 MB CRL footprint may be acceptable in a future PM-equipped system that hosts multi-terabytes of PM.

The overall results were quite surprising to us: We expected log size to have a big impact on performance across the board. However, for write-intensive workloads, the log size does not matter to throughput. The `Put` load is high enough that the system converges to a stable mix of frontend and backend threads. The interesting case is 2% `Puts`. We observe a modest 3% drop in throughput when we transition from 64 MB logs to 4 or 16 MB logs, whereas a further reduction in log size (to 1 MB) results in a significant 20% drop in throughput. The problem with 1 MB logs is that the `Put` load generates enough log traffic to populate CRLs quickly enough that worker threads switch to the backend more aggressively than is necessary. Subsequently, a high number of of backend workers drains the log quickly after which a larger than necessary fraction of backend workers switch



(a) 0% Puts

(b) 2% Puts

(c) 15% Puts

(d) 50% Puts

Figure 9: Latency (99^{th} percentile) vs. Throughput results for test runs with independent client threads (1,2,4,6,8). The number of workers is kept to a constant 8. The graphs show the effect of increasing client load on Bullet.

to the frontend role. This over-aggressive switching of worker roles results in the performance degradation. However, 4 MB log size is big enough to absorb the log population rate more gracefully. Note that the size of each log record (including its header) is 193 bytes.

7.5 End-to-End Performance

To understand the end-to-end performance observed by independent clients, we conducted an experiment where clients generated back-to-back requests based on the zipfian distribution mentioned earlier. The clients were hosted as independent threads in Bullet's address space, eliminating the overheads related to network latencies.

Each client generates a request in its local buffer that is visible to all of Bullet's workers (but not other clients), waits for a response from Bullet, and repeats. The workers synchronize amongst each other, using a per buffer lock, to get and process client requests. We reduce contention on these locks by ensuring that workers serve a multitude of requests (1,000 in our experiments) before releasing an acquired lock and switching over to another buffer. To minimize interference between workers and client threads, we host the workers on one socket of the emulator and the client threads reside on the other socket. We effectively end up getting a maximum of 8 worker threads for each test run in this experiment.

Figure 9 shows performance of the various K-V stores with growing number of client threads. First, notice the $5X$ increase in latency of operations over all the K-V stores compared to earlier experiments (Figure 5). This slowdown was a big surprise. However, additional experimentation revealed cross-socket cache access latencies to be the biggest contributor to the overheads: when we pinned communicating workers and client threads on the same socket the latency increase reduced to approximately 10%. We did not pursue such an intermingled topological layout for clients and workers since workers tend to dynamically switch between clients when some workers are busy performing gleaning operations, which led to unpredictable performance.

Other than the unexpected NUMA effects on performance, the observed relative degradation in latencies of Bullet's flavors bullet-st, +lfr, and +opt appears to be much greater than our prior experiments (Figure 5). This degradation can be squarely attributed to the fact that these flavors of Bullet are effectively left with 4 frontend workers, and a greater number of clients (up to 8) results in overload leading to higher latencies at client counts greater than 4. Similar relative latency degradation can be observed in the 15% and 50% write loads for Bullet flavors +dyn and +wrc(bullet-full) : Some worker threads are forced to play the backend gleaner role, which increases the load on the frontend workers since the number of clients is now greater than the frontend workers.

In general, since writes are expensive, an increasing percentage of writes tends to reduce the performance gains we get from the two-tiered architecture of Bullet. We conclude that Bullet does not really close the performance gap between volatile and persistent K-V stores for write-heavy workloads. However, it significantly closes this performance gap in read-dominated workloads.

8 Conclusion

While emerging byte-addressable persistent memory technologies, such as Intel/Micron's 3D XPoint, will approach the performace of DRAM, we expect to see a non-trivial performance gap (within an order of magnitude) between them. We showed that this performance gap can have significant implications on the performance of persistent memory optimized K-V stores. In particular, we conclude that DRAM does have a critical performance role to play in the new world dominated by persistent memory. We presented our new K-V store, called Bullet, that is architected to exploit this exact observation.

We introduced *cross-referencing logs (CRLs)*, a general purpose scalable logging framework that can be used to build a two-tiered architecture for a persistent K-V store that leverages capabilities of emerging byte-addressable persistent memory technologies, and the much faster DRAM, to deliver performance approaching that of a DRAM-only K-V store for read-dominated workloads. Our performance evaluation shows the effectiveness of Bullet's architectural features that bring its performance close to that of a DRAM-only K-V store for read-heavy workloads. Write-heavy workloads' performance is severely limited by the high latency of *failure-atomic* writes, and further research is warranted to reduce these overheads.

Abstract

Tuning configurations is essential for operating modern cloud systems, but the difficulty arises from the cloud system's diverse workloads, large system scale, and vast parameter space. Building on previous space exploration efforts of searching for the optimal system configuration, we argue that cloud systems introduce challenges to the robustness of auto-tuning. First, performance metrics such as tail latencies can be sensitive to non-trivial noises. Second, while treating target systems as a black box promotes applicability, it complicates the goal of balancing exploitation and exploration. To this end, Metis is an auto-tuning service used by several Microsoft services, and it implements customized Bayesian optimization to robustly improve auto-tuning: (1) diagnostic models to find potential data outliers for re-sampling, and (2) a mixture of acquisition functions to balance exploitation, exploration and re-sampling. This paper uses Bing Ads key-value store clusters as the running example – compared to weeks of manual tuning by human experts, production results show that Metis reduces the overall tuning time by 98.41%, while reducing the 99-percentile latency by another 3.43%.

1 Introduction

For many web-scale cloud systems, main evaluation metric is tail latencies (e.g., 99 and 99.9-percentile latencies) of serving a request [9]. While tail latencies seem rare, the probability of a user request experiencing the tail latency in an end-to-end system can be high, especially that most web-scale applications employ a multi-stage architecture. Imagine a web-scale application with a five-stage processing pipeline, the probability of a request encountering 99-percentile latency at least is $\sim$5%. Furthermore, tail latencies can be more than 10 times higher, as compared to the average latency [9].

Recently, advances in machine learning have spawned strong interests in automating system customizations, where auto-tuning system configuration of parameters is a popular scenario [2, 3, 20]. Notably, cloud systems exhibit two motivating characteristics for auto-tuning. First, the overhead of operating cloud systems is increasingly larger, due to the increasingly more dynamic and variable system workloads, and the scale of modern cloud systems. In many read-intensive web applications such as news sites and advertisement networks, data queries are tied to end-user personal interests and current contexts, which can exhibit temporal dynamics. Furthermore, even within one cloud system, there can be several components that individually impose different data requirement and handle different types of meta data and user data. Second, as cloud systems become more complicated, both design space and parameter space grow significantly. The optimal system configuration is beyond what human operators can efficiently and effectively reason about, and the cost to naïvely benchmark all possible system configurations is exorbitant.

Bayesian optimization (BO) with Gaussian process (GP) has emerged as a powerful black-box optimization framework for system customizations [2, 3, 19]. Mathematically, we model the configuration-vs-performance space by regressing over data points already collected, i.e., system configurations benchmarked. And, this regression model allows us to estimate the global optimum, or the best-performing system configuration. While collecting more data points can improve the regression model, benchmarking one system configuration of parameters can be time-consuming due to system warm-up and stabilization. Fortunately, BO offers a way to iteratively build up the training data by suggesting system configurations to benchmark, with the goal to maximally

Chieh-Jan Mike Liang is the corresponding author. This work was done when Zhao Lucis Li and Wenjia He were interns at Microsoft Research.

improve the regression model accuracy.

1.1 Contributions

In this paper, we report the design, implementation, and deployment of *Metis*, an auto-tuning service used by several Microsoft services for robust system tuning. While Metis is inspired by previous efforts to leverage BO to train the GP regression model, we address the following factors to improve the robustness of optimizing system customizations.

First, since the GP regression model is trained with data points from benchmarking some system configurations, how well these data points capture the configuration-vs-performance space's global optimum determines the auto-tuning effectiveness. At the same time, we should avoid unnecessarily over-sampling the space, as system benchmarking can be resource-intensive and time-consuming. To this end, at each iteration, BO's strategy for picking the next system configuration to benchmark should balance *exploitation* (i.e., regions with high probability of containing optimum) and *exploration* (i.e., regions with high uncertainty of containing optimum). Specifically, inadequate exploration reduces the chance of moving away from a local optimum, and inadequate exploitation impacts the efficiency of identifying the global optimum. In contrast to related efforts that rely on simple-to-implement strategies [2, 3], Metis strongly decouples exploitation and exploration, so that it can independently evaluate each action's expected improvement and anticipated regret.

Second, the theory behind BO and GP mostly assumes the data collection is reasonably noise-free, or susceptible to only the Gaussian noise. Unfortunately, many system performance metrics (e.g., tail latencies) are sensitive to non-Gaussian or unstructured noise sources in the wild, e.g., CPU scheduling and OS updates. In contrast to related efforts [2, 3], not only does Metis consider exploitation and exploration, but it also weighs the benefit of *re-sampling* existing data points. Key enabler is the diagnostic model that Metis creates to identify potential outliers.

To demonstrate the usefulness of Metis for real-world system black-box optimizations, this paper showcases one of our production deployments as the running example – optimizing tail latencies of Microsoft Bing Ads key-value (KV) stores. We present measurements and experiences from two KV clusters that handle $\sim$4.14 billion and $\sim$3.18 billion key-value queries per day, respectively. Compared to weeks of manual tuning by human experts, production results show that Metis reduces the overall tuning time by 98.41%, while reducing the 99-percentile latency by another 3.43%.

2 Background and Motivation

As a black-box optimization service, Metis tunes the configuration of several Microsoft services and networking infrastructure. This section describes one deployment as the running example in this paper – Microsoft Bing Ads key-value (KV) store cluster, *BingKV*. Then, we motivate optimally customizing cloud systems.

2.1 Running Example: *BingKV*

Individual stages of the ads query processing pipeline, e.g., selection and ranking, host separate KV store clusters. Within the cluster, each KV server is responsible for one non-overlapping dataset partition. Therefore, each server can experience different workload, as defined by the frequency distribution and the size distribution of top queried key-value objects. Manually tuning each server is difficult as a cluster can have thousands of servers.

The configuration space consists of parameters of the local caching mechanism, which decides what KV objects should be cached in the in-memory cache or served from the persistent data store. Main evaluation metric is tail latencies of serving key queries after the in-memory cache is full. We describe these parameters and their typical value ranges next.

First, both the recency and frequency distribution are well-known foundation for cache eviction. BingKV supports `NumCacheLevels` (1 - 10) levels of LRU (Least Recently Used) or LFU (Least Frequently Used) based caches – a cached object can move up a level if it has been queried `CachePromotionThreshold` (1 - 1,000) times. Since cached objects at higher levels have been queried more than those at lower levels, locality principle implies that they should not be easily evicted. Therefore, we allow `NumInevictableLevels` (0 - 9) levels to be specified as being inevictable.

Second, many cache designs incorporate a shadow buffer that stores the key only, instead of the entire key-value object. BingKV implements a shadow buffer with a capacity of `ShadowCapacity` (1 - 10) MB, to hold keys with an object size larger than `AdmissionThreshold` (1 - 1,000) bytes. Then, keys in the shadow buffer are moved to the cache only if they have been queried more than `ShadowPromotionFreq` (1 - 1,000) times.

Finally, `CacheCapacity` (1 - 10,000) specifies the cache capacity (excluding the shadow buffer) in MB, and the dataset partition on each server is divided into `NumShards` (1 - 64) shards.

2.2 Impacts of Suboptimal Configurations

To illustrate impacts of suboptimal configurations, we empirically measure BingKV's 99-percentile latency un-

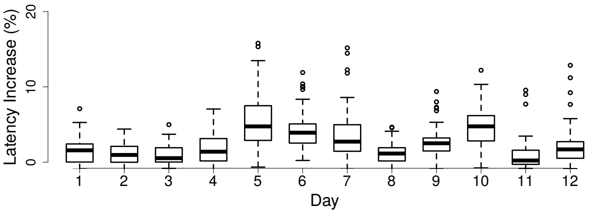

Figure 1: Motivating example – suboptimal configurations can impact the system performance. We use BingKV as the running example, and compare the tail latency increase with respect to the optimal system configuration.

der different parameter configurations, and quantify the tail latency increase with respect to the best-performing system configuration. Experiments use two 12-day pre-recorded production workload traces of BingKV, *Prod_Trace*$_1$ and *Prod_Trace*$_2$, and replay these workload traces to benchmark system configurations.

Suboptimal configurations can happen when system tuning does not consider machine-specific setup. To illustrate, we vary the cache capacity between 32 MB and 512 MB – we find the best-performing configuration (e.g., `AdmissionThreshold` ranging from 1 to 1,000) for each capacity, and then we compare the latency of the best-performing configuration to 100 configurations uniformly sampled from the parameter space. Results show that the average 99-percentile latency increase can range from 15.34% (for 256-MB cache) to 22.74% (for 512-MB cache), with more than 34.14% increase in the worst case. For *Prod_Trace*$_2$, the average 99-percentile latency increase can range from 10.21% (for 32-MB cache) to 13.89% (for 64-MB cache), with more than 13% increase in the worst case.

Suboptimal configurations can also happen when system tuning does not consider temporal dynamics. For each day of *Prod_Trace*$_1$, we compare the best-performing configuration to that of the other 11 days. Figure 1 shows that the average 99-percentile latency increase can be as high as more than 5.58% (day 5).

2.3 Strawman Solutions

Manual tuning. Manual tuning can leverage administrators' knowledge and prior experience about the target system. Unfortunately, as modern systems get larger and more complicated, reasoning the system behavior in a high-dimensional configuration space becomes increasingly difficult. Furthermore, real-world workload can have dynamics across machines and time, and manual tuning does not scale. To illustrate this argument, our experience shows that manually tuning a subset of BingKV can take weeks. And, in some cases, it is not certain whether the manual tuned configuration is indeed the best-performing one.

Figure 2: Architecture of Metis service.

Naïve Bayesian optimization. OtterTune [2] and CherryPick [3] demonstrated the potential of Bayesian optimization in adaptively finding the best-performing configuration for databases and data analytics systems, respectively. Both approaches adopt common BO selection strategies such as Expected-Improvement (EI). While these strategies are easy-to-implement, they do not consider factors impacting the robustness of tuning system customizations: the balance of exploitation and exploration [14], and data outliers.

3 Our Approach

Given a workload of a system, Metis has the objective of predicting the best-performing configuration by selectively exploring the configuration-vs-performance space. Through system benchmarking, Metis can collect data points that describe system inputs (e.g., system workload and parameter values) and outputs (e.g., performance metrics of interests) for training its model. When Metis does not change its prediction of the best-performing configuration with additional data points, we say the model has converged. Maximizing the prediction accuracy and minimizing the model convergence time are two evaluation metrics for Metis. The former relates to the auto-tuning correctness, and the latter relates to the service scalability.

This section first outlines the usage flow of Metis. Then, we formulate auto-tuning as an optimization problem, and highlight practical challenges to motivate customizations proposed in subsequent sections.

3.1 Architectural Overview

Figure 2 shows the architecture of Metis containing components for model training and system tuning.

Model training. The Progressive Sampling Engine solves the optimization problem of robustly constructing the predictive regression model, which models the configuration-vs-performance space. Each model corresponds to one performance metric, and the model dimensionality depends on the number of parameters.

Users start by providing the Progressive Sampling Engine their requirements (e.g., parameters and metric of interest) and workload traces (e.g., production or synthesized traces). The engine bootstraps BO by picking a set of system configurations as bootstrapping trials, for the Trial Manager to benchmark. Benchmarking can happen in simulators or real machines. Then, using performance metrics collected as the training data points, the engine picks subsequent system configuration of parameters to benchmark. Ideally, each iteration should improve the regression model's estimation of the space's global optimum. We formulate this iterative process as an optimization problem in the next subsection (c.f. §3.2).

When a stopping criterion is met, the Progressive Sampling Engine stops collecting more data points, and it outputs the GP regression model trained so far. Stopping criteria can include training time budget and so on. As we show in §6, the system benchmarking time dominates training, rather than the model computation time.

System tuning. The Tuning Manager periodically receives status reports from individual servers of the target system. These status reports contain current workload characterizations and logged performance metrics. If performance degradation is detected (e.g., a significant increase in the tail latency), the Tuning Manager uses the workload characterization to select the nearest regression model. We use DNNs to classify workloads, which minimizes the burden of weighing workload features for classification.

3.2 Optimization Problem Formulation

Formally, for a workload w, we want to find the k-dimensional configuration c^* (representing k system parameters), which has the highest probability of being the best-performing configuration, c_w. The *overall problem objective* is as follows:

$$c^* = \underset{c \,\in\, configs}{\operatorname{argmax}} \; P(c = c_w \mid w)$$

Given the k-dimensional parameter space can be too large for exhaustive searches, Metis opts the regression model to predict with limited amount of data points collected. While more training data will help reducing the regression uncertainty, the *training objective* should also consider the training overhead:

$$\begin{aligned} \text{minimize} \sum_{w \,\in\, workloads} & (confidence\_interval(c_w)) \\ \text{subject to} & \sum T(c) \;\leq\; T_{budget} \end{aligned}$$

$T(c)$ denotes the time necessary to sample a configuration c, and T_{budget} denotes the maximum amount of time cost allocated for model training.

Predictive regression model formulation. Regression allows Metis to model the expected configuration-vs-performance space, with data points already collected from benchmarking some configurations. The regression model captures the conditional distribution of a target performance metric given a system configuration. We pick Gaussian process (GP) [13] as the model, which extends multivariate Gaussian distributions to infinite dimensionality, such that observations for an unsampled data point are assumed to follow a multivariate Gaussian distribution. In other words, assuming a stochastic function f where every input x has an output $f(x)$, each $f(x)$ is defined as a mean μ and a standard deviation σ of a Gaussian distribution.

GP exhibits a number of desirable properties. First, it does not assume a certain mathematical relationship between model inputs and outputs, e.g., the linear relationship. Second, for any x, GP can return the expected value of $f(x)$ and uncertainty (i.e., standard deviation).

Optimization framework. A proven approach to train the GP model is *Bayesian optimization* (BO) [17]. At each iteration, based on the current GP model, BO selects a system configuration to benchmark next to further train the GP model. The selected configuration is expected to maximally improve the accuracy predicting the global optimum of the configuration-vs-performance space. The logic behind selecting the next trial is implemented by BO's acquisition function, and its design traditionally aims to balance exploitation (i.e., sampling regions with high probability of containing optimum) and exploration (i.e., sampling regions with high uncertainty). The model converges when BO believes that the GP model has sufficiently captured the configuration-vs-performance space global optimum, or the best-performing system configuration in our case.

BO conceptually realizes a form of progressive sampling, and it is suitable for scenarios where collecting system performance metrics of a single trial is resource-intensive or time-consuming (e.g., waiting for a system to warm up and stabilize).

3.3 Practical Challenges of Robustness

Running BO with GP requires the following practical considerations for robust system tuning.

Sampling configuration-vs-performance space without strong assumptions on the target system behavior. Given that system behavior can be difficult to be properly reasoned, Metis tries to learn the configuration-vs-performance space from selective sampling. In other words, based on system configurations already benchmarked, Metis selects the next system configuration to benchmark, which is expected to maximally improve the regression accuracy. To this end, we believe that existing efforts leave the following two gaps to fill.

First, balancing exploitation and exploration is still a non-trivial problem. Many proposed acquisition functions evaluate the potential improvement of a trial [19], and the community has shown their limitations in balancing exploitation and exploration [4, 17]. Expected Improvement (EI) is a widely popular choice of acquisition functions. It improves upon Maximum Probability of Improvement, by estimating the best-case improvement with both the mean and the uncertainty around a sampling point. However, Ryzhov et al. [14] showed that EI allocates only O(log n) samples to regions that are expected to be suboptimal, where n is the total number of trials. In other words, n needs to be significantly large for EI to balance exploitation and exploration.

Second, bootstrapping trials refer to the set of sampling points to initialize BO. Since BO decides the next trial with the GP model trained with past trial data points, prior data samples can influence how BO expects the posterior expectation to be. The main requirement for selecting bootstrapping trials should be exploration. Random sampling is a simple approach to pick bootstrapping trials, but it requires a large amount of sampling points to ensure coverage [12]. This is not ideal for time-consuming trials, where some systems need time to stabilize (e.g., system cache warm-up).

Handling non-Gaussian data noise. Most theoretical work on BO with GP assumes the trial data collected are noise-free (i.e., perfectly reproducible experiments), or susceptible to only the Gaussian noise [17]. Unfortunately, many system metrics such as tail latencies are sensitive to a wide range of noise sources in the real world, ranging from background daemons, local resource sharing, networking variability, etc. This is different from reproducible metrics such as classification accuracy. Since real-world data noise sources can be heterogeneous and non-trivial to model, the auto-tuning service should consider the benefits of removing potential outliers.

4 Improving Auto-Tuning Robustness

Given the challenges discussed in §3.3, we now discuss our customizations to Bayesian optimization to improve tuning robustness.

4.1 Bootstrapping Trials

To select sampling points to bootstrap Bayesian optimization for a given workload, Metis exercises Latin Hypercube Sampling (LHS) [12]. LHS is a type of stratified sampling. According to some assumed probability distribution, LHS divides the range of each of M parameters into I equally probable intervals, and randomly selects only *one* single data point from each interval. Since each interval of each parameter is selected only once, the number of bootstrapping trials chosen by LHS is exactly I, regardless of M. Furthermore, the maximum number of possible combinations for bootstrapping trials is only $(\prod_{i=0}^{I-1} I-i)^{M-1} = (I!)^{M-1}$.

LHS offers several desirable properties for bootstrapping Bayesian optimization. First, it has been shown that, compared to random sampling, stratified sampling can reduce the sample size required to achieve the same conclusion [12]. Second, compared to another well-known stratified sampling technique, Monte Carlo, LHS allows one to obtain a stable output with less samples [7]. And, while quasi-Monte Carlo can be an alternative approach, its output is a low discrepancy sequence which is not random, but uniformly deterministic [6]. Third, as LHS does not control the sampling of combinations of dimensions, the number of samples picked LHS is agnostic to the dimensionality of the parameter space.

A well-known concern of LHS is that it may exhibit a higher memory consumption, in order to keep track of parameter intervals that have already been sampled. However, we note that only a few sampling points are necessary to bootstrap Metis, and our current running system sets I to be 5.

4.2 Customized Acquisition Function

After obtaining bootstrapping sampling trials with LHS, Metis then runs Bayesian optimization to iteratively train the Gaussian process model. At each iteration, BO outputs the system configuration that is expected to offer the most improvement to the GP model, in terms of predicting the best-performing system configuration. This output represents the system configuration that Metis should sample in the next iteration of training. To produce this output, Metis customizes the acquisition function to balance three goals: *exploitation*, *exploration*, and *re-sampling*.

Our customized acquisition function works as a mixture of three separate sub-acquisition functions (c.f. §4.2.1) corresponding to each goal. At each iteration of BO, based on the GP model constructed so far, individual sub-acquisition functions compute the next system configuration to sample to maximize their own goal. Then, the acquisition function evaluates these candidates in terms of the improvement of the expected best-performing system configuration, and selects the candidate with the highest gain to sample next (c.f. §4.2.2).

Compared to related efforts, our acquisition function exhibits two differences. First, by introducing re-sampling as a possible action, we allow Metis to re-sample a trial whose previous results might be susceptible to non-Gaussian noise. Second, Metis decouples all three actions and runs separate acquisition functions for each action. This decoupling allows Metis to independently evaluate the potential information gain and regret aversion from taking each action in the next iteration.

4.2.1 Sub-acquisition functions

Metis decouples exploitation, exploration, and re-sampling into three separate sub-acquisition functions. Given past trials, each sub-acquisition function outputs a system configuration to maximize its own goal. These system configurations become candidates for the acquisition function.

Exploration. This sub-acquisition function looks for the sampling point whose expected observation would have with the highest uncertainty. Formally, in the GP regression model, this sampling point would exhibit the largest confidence interval.

Exploitation. This sub-acquisition function looks for the sampling point whose expected observation would most likely be the system optimum. While one simple approach is to consider the absolute observation of a sampling point as expected by the GP regression model, its accuracy can be impacted by GP's uncertainty of that sampling point. Therefore, Metis takes an approach inspired by TPE [5], and tries to estimate the probability of a sampling point giving near-optimum observation.

The exploitation sub-acquisition function works as follows. It first separates the past trials into two groups: the first group has best observations, and the second group has the rest. Then, we construct two Gaussian mixture models (GMM) to describe each group. With these two GMMs, we can evaluate the likelihood of a system configuration, c, being in either group, i.e., $P_1(c)$ and $P_2(c)$. The ratio of these two likelihood, or $\frac{P_1(c)}{P_2(c)}$, would give us a score of how likely a sampling point is in the first group, instead of second group.

Re-sampling. This sub-acquisition function looks for outliers in past trials, and suggest trials that should be re-sampled (i.e., system configurations that should be re-benchmarked).

The re-sampling sub-acquisition function works by creating the diagnostic model. To examine a data point, the diagnostic model quantifies the difference between the measured value and the expected value. To do so, the diagnostic model is a GP regression model trained without the examined data point. Then, the diagnostic model can calculate the expected value and 95% confidence interval. If the measured value falls outside the confidence interval, it is probable that the examined data point could be an outlier. The sub-acquisition function repeats the evaluation for all past trials, and it selects the trial that is farthest from the expected confidence interval.

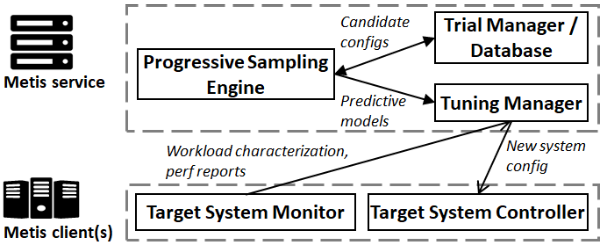

Figure 3: Components of Metis service implementation.

4.2.2 Evaluation of Candidates

Taking sub-acquisition function outputs as candidate configurations, our acquisition function computes their information gain with respect to how the prediction of optimal configuration changes. Conceptually, for each candidate, the GP model bounds the expected observation with a confidence interval. And, the upper and lower bound of this interval can help us estimate the potential information gain (if we were to actually select the corresponding candidate for benchmark).

The acquisition function starts by predicting the currently best-performing system configuration, c_{cur_best}, and this step searches for the sampling point with the lowest expected observation in the GP regression model. Then, to evaluate a candidate, $c_{candidate}$, we add its lower-bound confidence interval (i.e., best-case) to the GP regression model, and predict the would-be best-performing system configuration, c_{new_best}. The different between the expected observation of c_{cur_best} and c_{new_best} is the improvement, and 0 if the improvement is negative. Then, we repeat the process for upper-bound confidence interval (i.e., worst-case).

Finally, the acquisition function outputs the $c_{candidate}$ with the highest sum of improvement calculated with the lower-bound and the upper-bound confidence interval.

5 Implementation

Figure 3 illustrates the Metis system components implemented. Our current implementation is in Python, and this language choice allows us to use the popular Scikit-learn library for Gaussian process regression [16]. We choose the summation of Matern (3/2) and white noise as the covariance kernel [19].

Separation of logic and execution. Metis consists of a centralized web service and client stubs that sit on servers hosting the target system. Network communications happen over TCP, and the message format is JSON. Conceptually, the client stub hooks up to the target system, and it abstracts away system-specific interfaces and execution from the web services. While an alternative implementation is to place both the logic and execution in a local service on each server, the separation provides several benefits. First, the computation-intensive logic of Metis does not contend for resources on production servers. Second, being centralized, Metis has the global view of all status reports from all servers. This allows Metis to continuously improve the predictive model with new data points.

Metis web service. The web service trains one predictive regression model for each workload trace. And, these traces can be recorded in the production environment, or synthesized with tools such as YCSB [8]. Trial Manager replays each workload trace in simulators or real servers, and each replay represents one trial benchmarking one selected system configuration. Then, the training dataset consists of system configurations and corresponding performance benchmarks. In the case of BingKV, we built a simulator wrapping the production KV code binaries, to run trials.

From status reports uploaded by client stubs, if Tuning Manager detects that a server is experiencing a performance degradation above some user-specified thresholds (e.g., tail latencies have increased by more than 10% in the last six hours), it computes a new configuration and sends a command to the server's client stub.

Metis client stubs. The client stub deals with system-specific interfaces, ***(1)*** to periodically upload recent system performance measurements and workload characterization, and ***(2)*** to execute configuration change commands from the web service.

Most web-scale cloud systems already have an extensive logging mechanism for continuous performance monitoring, and Metis client stubs periodically retrieve relevant performance measurements from the same logging mechanism. While different systems have different workload characterization features, these features are either already available in the logging mechanism, or require additional code instrumentation. In the case of BingKV, our workload features are the size and query frequency of the top queried KV objects, and the incoming query traffic rate.

Upon receiving a configuration change command, Metis does not try to aggressively re-configure servers. Instead, it employs a guard time following a reconfiguration to allow the target system to warm up and stabilize. Other than time durations, this guard time can also be values of system states, e.g., cache occupancy.

	Selection of Configs	Modeling	DO
Random	Random		No
iTuned [10]	LHS + EI	BO w/ GP	No
CherryPick [3]	Random + EI	BO w/ GP	No
TPE [5]	Random + EI	GMM	No
Metis	LHS + Customized	BO w/ GP	Yes

Table 1: This table highlights differences among comparison baselines and Metis. The ”DO” column shows whether data outlier removal is considered.

6 Evaluation

Our major results include – ***(1)*** compared to baselines, Metis picks better configurations 84.67% of times in the presence of low data noises. ***(2)*** In the presence of data outliers, Metis has 56.77% more chance of picking better configuration. ***(3)*** Metis has a faster convergence time in searching for the best-performing configuration.

6.1 Methodology

We use the Bing Ads KV store (c.f. §2) as the target system. Our testbed machines have two 2.1 GHz CPUs (with 16 cores), 16 GB RAM, and a 256 GB SSD. These machines host the target system binaries, and simulate configurable key-value query arrival rates (or queries per second) for the given workload trace. We log performance metrics with asynchronous I/Os to minimize any artifact introduced by logging.

Datasets and workload traces. We obtained two 12-day key-value query traces, $Prod\_Trace_1$ and $Prod\_Trace_2$, from two Bing Ads KV store clusters, $BingKV_1$ and $BingKV_2$. These two real-world traces exhibit following characteristics – the average size of top 500 frequently queried KV objects can have a difference up to 9.49% from one week to another, and that of $Prod\_Trace_1$ is approximately two-times larger than $Prod\_Trace_2$.

For more controlled experiments, we also synthesized three workload traces containing ∼0.5 million query requests. Our workload generation tool is based on the Yahoo! Cloud Serving Benchmark (YCSB) [8]. However, while YCSB considers the key-value frequency distribution, it does not consider the key-value size distribution. To fill this gap, given a list of unique keys from YCSB (sorted in descending order of frequency), we assign key-value sizes according to some distributions. For $Synth\_Trace_1$, $Synth\_Trace_2$ and $Synth\_Trace_3$, we fix their size distribution to be Zipf, and we generate keys following the frequency distribution of Zipf, normal, and linear. Doing so allows us to examine different size distributions.

Comparison baselines. In addition to random search,

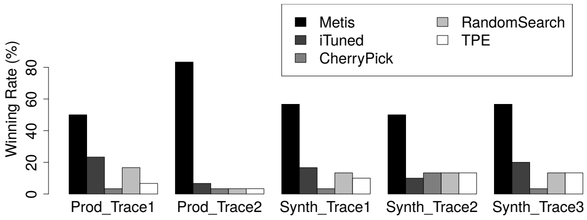

Figure 4: Chance that each approach picks the best configuration. Each experiment allows each approach to run 25 trials, and we repeat the experiment 30 times.

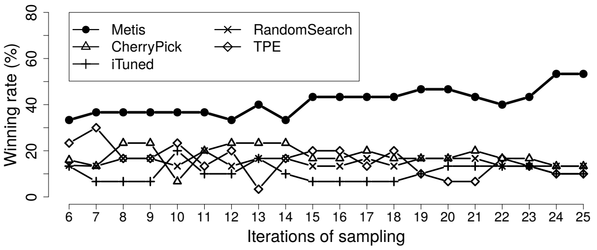

Figure 5: Chance that each approach picks the best configuration for $\mathit{Prod\_Trace}_1$, while changing the number of sampling points allowed.

we take state-of-the-art BO-driven approaches including iTuned [10], CherryPick [3], and TPE [5]. We configure these comparison baselines with the recommended setting, e.g., the Matern(5/2) kernel for CherryPick. At each iteration, these approaches output the configuration they expect to have lowest tail latency. Table 1 lists their differences. For the ground truth, we brute-force all possible configurations for $\mathit{Prod\_Trace}_1$.

6.2 Effectiveness of Metis

This section quantifies the likelihood that the system configuration selected by Metis outperforms those of other approaches. This relates to the auto-tuning correctness. We also discuss factors including time budgets (i.e., number of trials allowed) and data outliers.

Metis has a higher chance in picking system configurations that outperforms those of other approaches. Assuming a fixed time budget, we allow each approach to run 25 trials. We then rank approaches by the 99-percentile latency of their expectedly best-performing system configurations. We clean-install the machine to ensure minimal noise in measurements, and evaluate the case of data outliers later in this section. Experiments are repeated 30 times, to compensate for the randomness in some approaches. For random search, we take the best of all 25 trials for evaluation. We note that TPE requires at least 20 bootstrapping trials (from random sampling), and we allocate five bootstrapping trials to CherryPick, iTuned and Metis.

Figure 4 summarizes results when system benchmarks, or training data, are relatively noise-free. It shows that Metis has a higher chance of picking the winning configuration, i.e., the system configuration that outperforms those selected by comparison baselines. Depending on the synthesized workload trace, Metis can outperform 48.97% (for $\mathit{Synth\_Trace}_2$) to 84.67% (for $\mathit{Prod\_Trace}_2$) of times.

Furthermore, taking a closer look into cases where Metis failed to win, we note that Metis 99-percentile latency is within 1% of the winner. In addition, Metis observes the lowest difference of 99-percentile latency to the optimal, on average. This difference is 0.44% for Metis, which is 67.16% lower than CherryPick.

Metis has a faster convergence time than other approaches. Regardless of the parameter tuning approach, the effectiveness in finding the optimal configuration should ideally increase with the number of data points already sampled, or configurations benchmarked. One natural question is how Metis converges to the optimal system configuration, as compared to other approaches. To this end, we try to answer two questions: ***(1)*** at each iteration, what is the likelihood that Metis selects the system configuration that outperforms those of other approaches? ***(2)*** how fast does Metis converge to the optimal system configuration?

Figure 5 shows that the chance for Metis to pick the winning configurations is high at all iteration. We repeat this experiment 30 times, due to the randomness in some approaches. This result is desirable for auto-tuning under limited time budget, as system benchmarks can consume a long time. In addition, the figure shows that, as the number of sampled data points increase, Metis is able to better model the configuration-vs-performance space, which increases the likelihood of picking the winning configuration. Furthermore, looking at configurations that CherryPick and iTuned pick, we observe that they lean towards exploitation. On the other hand, Metis independently evaluates the potential information gain from exploitation and exploration.

Following Figure 5, Figure 6 illustrates how each approach converges to the global optimum of the configuration-vs-performance space. The figure calculates the average 99-percentile latency of selected configurations from 30 repeated experiments. Compared to other approaches, Metis has a faster convergence time, as it is able to benchmark system configurations that would iteratively improve modeling the configuration-vs-performance space. We note that the effectiveness of TPE significantly improves after 20 iterations, as its Gaussian Mixture Models require many training data. Fi-

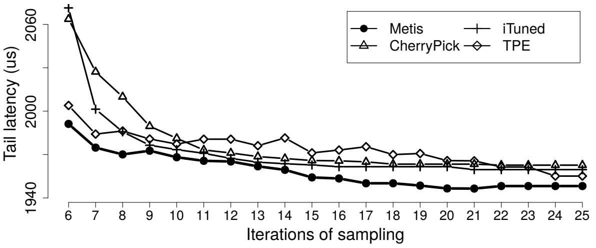

Figure 6: The search path visualizes the tail latency of system configurations that BO-driven approaches select at each iteration.

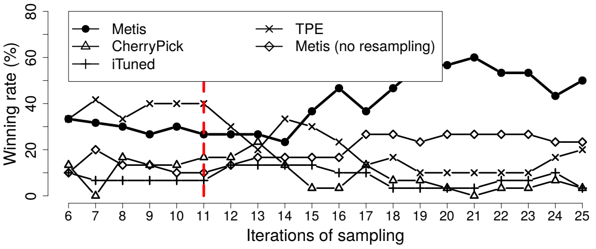

Figure 7: Chance that each approach picks the winning configuration for $Prod\_Trace_1$. The test machine has intermittent background activities that result in data outliers. The red line marks when Metis has sufficient data points for re-sampling.

nally, we also note that Figure 6 suggests that iTuned and CherryPick have a higher chance of exploiting local optimum, and thus their acquisition function would require more iterations to find the global optimum.

Metis maintains high chance of picking the winning configuration in the presence of data outliers. Building on the discussion so far, we now demonstrate the robustness of Metis to data outliers. We repeat the previous experiment where we allow each approach to iteratively select 25 trials to benchmark. The machine is a production Bing Ads server, which runs intermittent background activities for software updates, monitoring, and periodic database updates. Resulting noises in the measurement can not reasonably modeled by normal distribution. Unlike comparison baselines, Metis proactively looks for potential data outliers after a sufficient amount of data points is collected, or 10 in our case.

Figure 7 illustrates that Metis has a higher chance of picking the optimal configuration in the presence of data outliers. The red line shows when Metis stops marking all sampled data points as potential data outliers (due to insufficient data collected). The effectiveness of Metis improves after the red line. The figure also shows the effectiveness of Metis without re-sampling, and removing outliers improves Metis's winning rate by 33.33%.

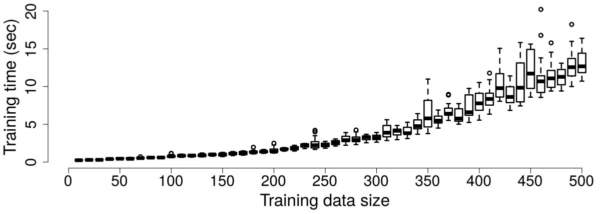

Figure 8: Impact of training data size on the training time of GP models.

6.3 Overhead of Metis

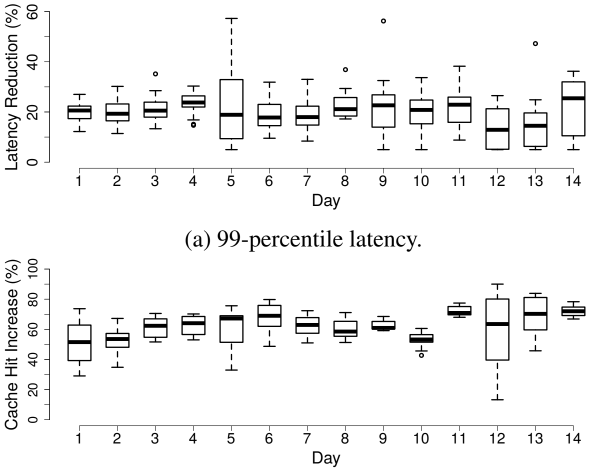
It is known that benchmarking configurations can be time-consuming due to system warm-up and stabilization. Another potential source of overhead is the predictive regression model – both in training and configuration selection. To quantify this overhead, we randomly generate the training data for individual experiment runs, and repeat each experiment 50 times.

Model training time. This is the time for Metis to fit a Gaussian process model over all sampled data points. We note that the community has shown that training the Gaussian process model can exhibit a complexity of $O(N^3 + N^2 D)$ [21], where N and D are the number and the dimensionality of training data points, respectively. This suggests that the number of training data points largely determines the training time. Our goal is to understand whether the training complexity will limit Metis's practicality in the real-world. Figure 8 shows that the training time increases with the number of sampled data points (for a training data set with a dimension of 20, and parameter values range between 1 and 1,000). When the number of sampled data points increases to 500, the training time reaches 12.33 seconds. However, this training time is still practical in real-world deployments.

Configuration selection time. This is the time for Metis to predict a sampling point that is expected to maximize the given acquisition function. It has been shown that the time complexity for prediction with the Gaussian process model is $O(N^2 + ND)$ [21], where N and D are the number and the dimensionality of training data points, respectively. When the training data size increases to 500, predicting the observation of an unsampled point takes $\sim$10.25 msec. This time suggests that the predictive model is feasible for real-world usages.

7 Case Study: BingKV

With a year of Metis operational experience, there are observations and lessons learned from adopting auto-tuning in Microsoft services. This section presents measurements and experiences from our running ex-



(a) 99-percentile latency.

(b) Cache hit rate.

Figure 9: Performance comparison between the previous LRU-based data store and the Metis-tuned BingKV, based on 14-day hourly performance logs.

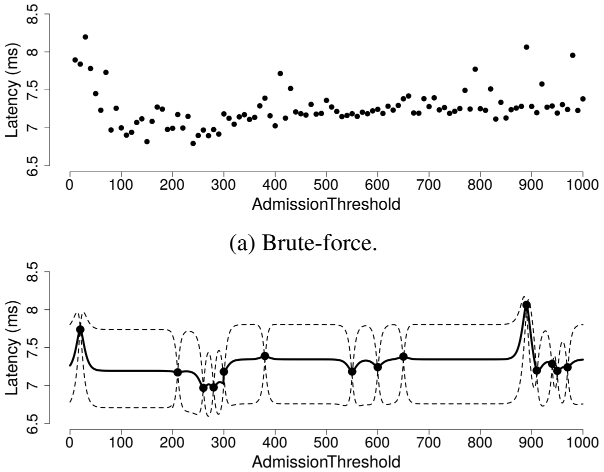
ample, Bing Ads KV store clusters (c.f. §2.1). The KV store evolved from LRU, expert-tuned BingKV, to Metis-tuned BingKV. We study measurements from two KV store clusters – $BingKV_1$ (∼700 servers handling ∼4.14 billion key queries per day) and $BingKV_2$ (∼1,700 servers handling ∼3.18 billion key queries per day). Each server of clusters has an in-memory cache capacity of 512 MB, and an SSD as the persistent data store.

Metis-tuned BingKV reduces the 99-percentile query lookup latency by an average of 20.4%, as compared to LRU. We start by comparing Metis-based KV store with the previously LRU-based KV store, under Bing Ads $BingKV_1$ production workload. The comparison is based on 14-day hourly logs of the 99-percentile query lookup latency and the cache hit rate (CHR). Figure 9 presents results for $BingKV_1$ – Figure 9a shows that Metis helps to reduce the 99-percentile latency by 20.4% on average (with a standard deviation of 8.4), and Figure 9b shows a CHR improvement of 60.6% (with a standard deviation of 11.7). This translates to a 22.76% reduction in disk I/O reads.

Metis-tuned BingKV reports a 3.43% lower 99-percentile latency, as compared to expert-tuned BingKV. Our human expert is one of the lead programmers for Bing Ads key-value store, with years of experience operating the system. As it is infeasible for the human expert to continuously tune the KV store, this subsection focuses on picking a single best-performing configuration. We note that the human expert did not have any time budget limitations, and manual tuning took about four weeks in a testing environment. The next subsection delves into the system tuning time comparison.

Perf metrics	**Differences**	
	$BingKV_1$	$BingKV_2$
99-percentile latency	-2.99%	-3.43%
Cache hit rate	2.43%	0.49%

Table 2: Performance comparison of expert-tuned and Metis-tuned BingKV-based data store, under 14-day Bing Ads workloads. Metis-tuned configurations outperform expert-tuned configurations, while reducing the tuning time from weeks to hours.



(a) Brute-force.

(b) Metis.

Figure 10: On average, Metis reduces the configuration tuning time by 98.41% for BingKV. For illustration, this figure shows a one-dimensional case of sampling points selected by Metis, as compared to brute-force.

Table 2 shows that Metis-tuning outperforms human-tuning under two weeks of production traffic: ***(1)*** the Metis-tuned configuration reports a 2.99% and 3.43% lower 99-percentile latency for $BingKV_1$ and $BingKV_2$, respectively. ***(2)*** Metis-tuned configuration reports a 2.43% and 0.49% higher CHR for $BingKV_1$ and $BingKV_2$, respectively.

Metis reduces the overall tuning time by 98.41%, as compared to manual tuning by human experts. While humans are typically guided by intuition based on their knowledge of the system, much of the manual tuning process mostly resembles the random search. In fact, the problem exacerbates as the dimensionality of the parameter space increases, especially in the case where parameters have dependencies. For reference, in one scenario deployment, manual-tuning took about 3 weeks, while Metis-tuning took about 8 hours (including sampling, modeling and prediction).

To illustrate how predictive modeling reduces the tuning time, Figure 10 shows that Gaussian process regression for a one-dimensional case. GP regression is able to estimate the impact of ShadowAdmissionSize without sampling the entire parameter space. We note that dotted lines in Figure 10b mark the 95% confidence interval for each point, which can guide both the space exploration and the stopping criteria. Finally, we note that GP regression operations are negligible as compared to system benchmarking – training typically takes ∼1.02 sec, and predicting the expected value of an unsampled data points takes ∼0.53 msec.

8 Related Work

Black-box parameter tuning services. Google Vizier [11] is an ongoing research project, and it supplies core capabilities to optimize hyper-parameters of machine learning models across Google. Similar to Google Vizier, SigOpt [18] is a startup that tunes hyper-parameters of ML models, but little technical details have been disclosed. Google Slicer [1] is a sharding service that dynamically generates the optimal resource assignment, but its goals are not parameter space exploration and sampling. Like Metis, BestConfig [23] uses stratified sampling. However, it heavily leans towards exploitation, as it assumes a high probability of finding better-performing configurations around the currently best-performing one.

In contrast, Metis focuses on providing a robust auto-tuning algorithm for cloud systems, and addresses challenges that systems introduce to the optimization problem. Metis has been used to tune parameters of Microsoft services and networking infrastructure.

Parameter tuning with Bayesian optimization. Metis builds on previous efforts that demonstrate the potential of applying Bayesian optimization and Gaussian process to auto-tuning. iTuned [10] uses Latin Hypercube Sampling (LHS) to sample the parameter space, and model the parameter space with Gaussian process models. OtterTune [2] uses a combination of supervised and unsupervised machine learning methods to reduce the parameter dimension, characterize observed workloads, and recommend configurations. CherryPick [3] follows a similar approach to BO and GP in selecting the best-performing cloud configuration for a given machine learning workload.

TPE [5] uses Bayesian optimization with Gaussian mixture model, instead of Gaussian process. It is suitable for cases where there are some dependencies among parameters. However, since TPE trains with a subset of the training data, it needs a larger amount of data to be collected for training effectively. Smart Hill-Climbing [22] improves Latin Hypercube Sampling, but the GP-based approach has been shown to outperform [10].

Metis introduces customizations to the framework of BO with GP. These include the diagnostic model to find potential data outliers for re-sampling, and a mixture of acquisition functions to balance exploitation, exploration and re-sampling.

9 Discussion

We now discuss limitations concerning the applicability of Metis to systems in general.

Support of different system parameter types. Some types of system parameters can be non-trivial to model with regression models – First, categorical parameters take on one of a fixed number of non-integer values such as boolean. Since categorical parameters are not continuous in nature, it can be difficult to model the relationship among possible values. While categorical parameters are out of scope for this paper, our current implementation conceptually treats each categorical value as a new target system. Second, some systems have multi-step parameters, where one single configuration requires the system to go through a specific sequence of value changes for one or more parameters. Metis does not currently support multi-step parameters.

Costs of changing system configurations. Applying configuration changes can incur costs for some systems. First, server reboots might be necessary after a configuration change, thus service interruptions. To handle this case, system administrators can decide to push a configuration change only if the new configuration is predicted to offer a certain level of performance improvement (e.g., 10% latency reduction). Administrators can also bound the cost of reconfiguration, e.g., by performing reconfigurations gradually over time, or by bounding the parameter space exploration by the distance from the current running configuration. Second, mis-predictions can result in system performance degradation. Fortunately, Gaussian Process offers two ways to gain insights regarding uncertainties – GP offers a confidence interval for each prediction, and a log-marginal likelihood score [15] to quantify the model fitness with respect to the training dataset.

10 Conclusion

This paper reports the design, implementation, and deployment of Metis, an auto-tuning service used by several Microsoft services for robust system tuning. We demonstrate the effectiveness of Metis with controlled experiments and real-world system workloads. Furthermore, real-world deployments show that Metis can significantly reduce the system tuning time.

Abstract

We present NoveLSM, a persistent LSM-based key-value storage system designed to exploit non-volatile memories and deliver low latency and high throughput to applications. We utilize three key techniques – a byte-addressable skip list, direct mutability of persistent state, and opportunistic read parallelism – to deliver high performance across a range of workload scenarios. Our analysis with popular benchmarks and real-world workload reveal up to a 3.8x and 2x reduction in write and read access latency compared to LevelDB. Storing all the data in a persistent skip list and avoiding block I/O provides more than 5x and 1.9x higher write throughput over LevelDB and RocksDB. Recovery time improves substantially with NoveLSM's persistent skip list.

1 Introduction

Persistent key-value stores based on log-structured merged trees (LSM), such as BigTable [13], LevelDB [4], HBase [2], Cassandra [1], and RocksDB [3], play a crucial role in modern systems for applications ranging from web-indexing, e-commerce, social networks, down to mobile applications. LSMs achieve high throughput by providing in-memory data accesses, buffering and batching writes to disk, and enforcing sequential disk access. These techniques improve LSM's I/O throughput but are accompanied with additional storage and software-level overheads related to logging and compaction costs. While logging updates to disk before writing them to memory is necessary to recover from application or power failure, compaction is required to restrict LSM's DRAM buffer size and importantly commit non-persistent in-memory buffer to storage. Both logging and compaction add software overheads in the critical path and contribute to LSM's read and write latency. Recent proposals have mostly focused on redesigning LSMs for SSD to improve throughput [23, 30, 40].

Adding byte-addressable, persistent, and fast non-volatile memory (NVM) technologies such as PCM in the storage stack creates opportunities to improve latency, throughput, and reduce failure-recovery cost. NVMs are expected to have near-DRAM read latency, 50x-100x faster writes, and 5x higher bandwidth compared to SSDs. These device technology improvements shift performance bottlenecks from the hardware to the software stack, making it critical to reduce and eliminate software overheads from the critical path of device accesses. When contrasting NVMs to current storage technologies, such as flash memory and hard-disks, NVMs exhibit the following properties which are not leveraged in current LSM designs: (1) random access to persistent storage can deliver high performance; (2) in-place update is low cost; and (3) the combination of low-latency and high bandwidth leads to new opportunities for improving application-level parallelism.

Given the characteristics of these new technologies, one might consider designing a new data structure from scratch to optimally exploit the device characteristics. However, we believe it worthwhile to explore how to redesign LSMs to work well with NVM for the following reasons. First, NVMs are expected to co-exist with large-capacity SSDs for the next few years [27] similar to the co-existence of SSDs and hard disks. Hence, it is important to redesign LSMs for heterogeneous storage in ways that can exploit the benefits of NVMs without losing SSD and hard disk optimizations. Second, redesigning LSMs provides backward compatibility to thousands of applications. Third, maintaining the benefits of batched, sequential writes is important even for NVMs, given the 5x-10x higher-than-DRAM write latency. Hence in this paper, we redesign existing LSM implementations.

Our redesign of LSM technology for NVM focuses on the following three critical problems. First, existing LSMs maintain different in-memory and persistent storage form of the data. As a result, moving data across storage and memory incurs significant serialization and deserialization cost, limiting the benefits of low latency NVM. Second, LSMs and other modern applications [1–4, 13] only allow changes to in-memory data structures and make the data in persistent storage immutable. However, memory buffers are limited in their capacity and must be frequently compacted, which increases stall time. Buffering data in memory can result in loss of data after a system failure, and hence updates must be logged; this increases latency, and leads to I/O read and write amplification. Finally, adding NVM to the LSM hierarchy increases the number of levels in the storage hierarchy which can increase read-access latency.

To address these limitations, we design **NoveLSM**, a persistent LSM-based key-value store that exploits the byte-addressability of NVMs to reduce read and write latency and consequently achieve higher throughput. NoveLSM achieves these performance gains through three key innovations. First, NoveLSM introduces a *persistent NVM-based memtable*, significantly reducing the serialization and deserialization costs which plague standard LSM designs. Second, NoveLSM makes the *persistent NVM memtables mutable*, thus allowing direct updates; this significantly reduces application stalls due to compaction. Further, direct updates to NVM memtable are committed in-place, avoiding the need to log updates; as a result, recovery after a failure only involves mapping back the persistent NVM memtable, making it three orders of magnitude faster than LevelDB. Third, NoveLSM introduces *optimistic parallel read*s to simultaneously access multiple levels of the LSM that can exist in NVM or SSD, thus reducing the latency of read requests and improving the throughput of the system.

We build NoveLSM by redesigning LevelDB, a widely-used LSM-based key-value store [4]. NoveLSM's design principles can be easily extended to other LSM implementations [1–3]. Our analysis reveals that NoveLSM significantly outperforms traditional LSMs when running on an emulated NVM device. Evaluation of NoveLSM with the popular DBbench [3,4] shows up to 3.8x improvement in write and up to 2x improvement in read latency compared to a vanilla LevelDB running on an NVM. Against state-of-the-art RocksDB, NoveLSM reduces write latency by up to 36%. When storing all the data in a persistent skip list and avoiding block I/O to SSTable, NoveLSM provides more than 5x and 1.9x gains over LevelDB and RocksDB. For the real-world YCSB workload, NoveLSM shows a maximum of 54% throughput gain for scan workload and an average of 15.6% across all workloads over RocksDB. Finally, the recovery time after a failure reduces significantly.

2 Background

We next provide background on LSM trees and on the design of popular LSM stores, LevelDB [4] and RocksDB [3], used extensively in this work. We also present a background on persistent memory and our method of emulating it.

2.1 Log Structured Merge Trees

An LSM-tree proposed by O'Neil et al. [32] is a persistent structure that provides efficient indexing for a key-value store. LSMs achieve higher write throughput by first staging data in memory and then across multiple levels on disk to avoid random disk writes. In LSMs, the levels have an increasing size; for example, in LevelDB, each level is at least ten times larger than the previous level. During an insert operation, the keys are first inserted into an in-memory level, and as this level fills up, the data slowly trickles down to disk-friendly block structures of the lower levels, where data is always sorted. Before every insert operation into the memory level, the data (key-value pairs) is logged in the persistent storage for recovery after a failure; the logs are garbage collected after data is safely flushed and persisted to on-disk structures. Next, the search and read operations proceed from the top memory level to the disk levels and their latency increases with increasing number of levels. In general, LSMs are update-friendly data structures and read operations are comparatively slower to other NoSQL designs.

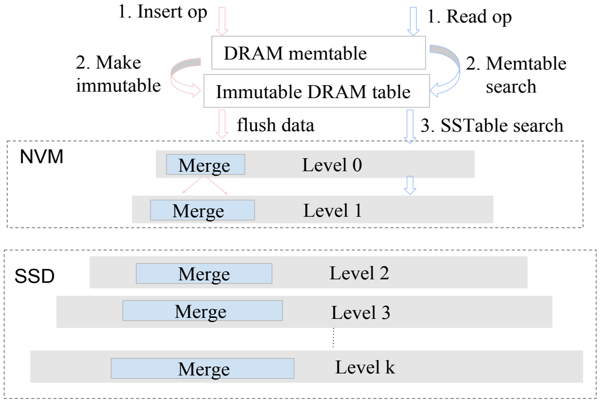

Figure 1: **Naive LevelDB design with NVM.** *Figure shows a simple method to add NVM to the LSM hierarchy. NVM is used only as a replacement to disk for storing SSTables. Shaded blocks show immutable storage, grey and red arrows show steps for read operation search and the background compaction.*

2.2 Popular LSM Stores

LevelDB is a popular LSM-based key-value store derived from Google's BigTable implementation and is widely-used from browsers to datacenter applications. Figure 1 shows LevelDB's design with NVM added to the storage hierarchy. During an insert operation, LevelDB buffers updates in a memory-based skip list table (referred to as memtable hereafter) and stores data on multiple levels of on-disk block structures know as sorted string tables (SSTable). After the memtable is full, it is made immutable and a background compaction thread moves the immutable memtable data to on-disk SSTable by serializing the data to disk-based blocks. Only two levels of memory tables (mutable and immutable) exist. With an exception to memtables, all lower levels are mutually exclusive and do not maintain redundant data.

The SSTables are traditional files with a sequence of I/O blocks that provide a persistent and ordered immutable mapping from keys to values, as well as interfaces for sequential, random, and range lookup operations. The SSTable file also has a block index for locating a block in $O(1)$ time. A key lookup can be performed with a single disk seek to read the block and binary search inside the block. In LevelDB, for read operations, the files with SSTables are memory-mapped to reduce the POSIX file system block-access overheads.

RocksDB is an LSM implementation that extends LevelDB to exploit SSD's high bandwidth and multicore parallelism. RocksDB achieves this by supporting multithreaded background compaction which can simultaneously compact data across multiple levels of LSM hierarchy and extracts parallelism with multi-channel SSDs. RocksDB is highly configurable, with additional features such as compaction filters, transaction logs, and incremental replication. The most important feature of RocksDB that can be beneficial for NVM is the use of a Cuckoo hashing-based SST table format optimized for random lookup instead of the traditional I/O block-based format with high random-access overheads.

In this work, we develop NoveLSM by extending LevelDB. We choose LevelDB due to its simplicity as well as its broad usage in commercial deployments. The optimizations in RocksDB over LevelDB are complementary to the proposed NoveLSM design principles.

2.3 Byte-addressable NVMs

NVM technologies such as PCM are byte-addressable persistent devices expected to provide 100x lower read and write latency and up to 5x-10x higher bandwidth compared to SSDs [7, 12, 17, 22]. Further, NVMs can scale to 2x-4x higher density than DRAM [5]. These attributes make NVM a suitable candidate for replacing SSDs. Additionally, NVMs are expected to be placed in parallel with DRAM connected via the memory bus, thereby providing memory-like load/store access interface that can avoid POSIX-based block access supported in current storage devices. Further, the read (load) latency of NVMs is comparable to DRAM, but the write latency is expected be to 5x slower.

2.4 NVM Emulation

Since byte-addressable NVMs are not available commercially, we emulate NVMs similarly to prior research [12, 17, 22, 26] and our emulation methodology uses a 2.8 GHz, 32-core Intel Nehalem platform with 25 MB LLC, dual NUMA socket with each socket containing 16 GB DDR3 memory, and an Intel-510 Series SSD. We use Linux 4.13 kernel running DAX-enabled Ext4 [6] file system designed for persistent memory. We use one of the NUMA sockets as NVM node, and to emulate lower NVM bandwidth compared to DRAM, we thermal throttle the NUMA socket [25]. To emulate higher write latency, we use a modified version of NVM emulator [37] and inject delay by estimating the number of processor store cache misses [12, 17, 22]. For our experiments, we emulate 5x higher NVM write latency compared to DRAM access latency and keep the NVM read latency same as the DRAM latency. We vary NVM bandwidth from 2 GB/s to 8 GB/s; the 8 GB/s bandwidth is same as DRAM's per-channel bandwidth and is considered an ideal case.

3 Motivation

NVMs are expected to provide an order of magnitude lower latency and up to 8x higher bandwidth compared to SSDs; but can the current LSM software stack fully exploit the hardware performance benefits of NVM? To understand the impact of using NVM in current LSM designs, we analyze LevelDB's performance by using NVM for its persistent storage. We use the widely-used DBbench [4, 30, 35] benchmark with the total key-value database size set to 16 GB, and the value size set to 4 KB. Figure 2 compares the latency of sequential and random LSM write and read operations. We configure the maximum size of each SSTable file to 64 MB, a feature recently added to LevelDB to improve read performance [4].

As shown in Figure 2, although NVM hardware provides 100x faster read and write compared to SSD, LevelDB's sequential and random insert latency (for 5 GB/sec bandwidth) reduce by just 7x and 4x, respectively; the sequential and random read (fetch) latency reduces by less than 50%. The results show that *current LSMs do not fully exploit the hardware benefits of NVM and suffer from significant software overheads*. We next decipher the sources of these overheads.

Insert latency. A key-value pair insert (or update) operation to LSM is first buffered in the memory – mutable memtable (skip list in LevelDB) – before writing the key-value pair to the storage layer (SSTables). However, a power failure or a system crash can lead to data loss (buffered in memory). To avoid data loss, the key-value pairs and their checksum are first added to a sequential log in the persistent storage before inserting them to the memtable. When the memtable is full, it is made immutable, and a new mutable memtable is created to which new inserts continue. A background thread compacts the immutable memtable to storage; however, if the new mutable memtable also fills up before the completion of background compaction, all new inserts to LSM are stalled. Current LSM designs suffer from high compaction cost because compaction involves iterating the immutable memtable skip list, serializing data to disk-compatible (SSTable) format, and

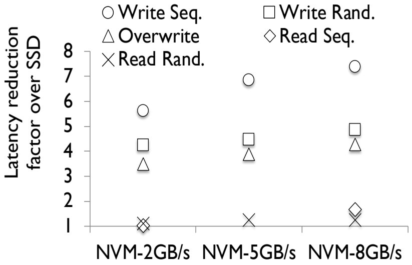

Figure 2: **Latency reduction factor.** *Analysis shows LevelDB using NVM for storage compared to SSD for 4 KB values; x-axis varies NVM bandwidth.*

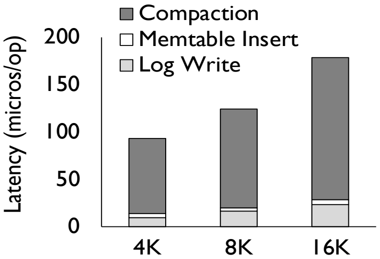

Figure 3: **Write latency cost split-up.** *Compaction happens in the background but stalls LSM when memtables are full and compaction is not complete.*

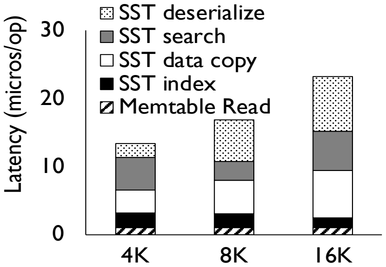

Figure 4: **Read latency cost split-up.** *SST denotes SSTable, and the graph shows time spent on memtable and different SSTable methods.*

finally committing them to the storage. Besides, the storage layer (SSTable) comprises of multiple levels, and the memtable compaction can trigger a chain of compaction across these levels, stalling all foreground updates.

Figure 3 shows the cost breakup for insert operations with 4 KB, 8 KB, and 16 KB values. As shown in the figure, data compaction dominates the cost, increasing latency by up to 83%, whereas log writes and checksum calculations add up to 17% of the total insert latency. Increasing the in-memory buffer (memtable) can reduce compaction frequency; however, this introduces several drawbacks. First, DRAM usage increases by two times: memory must be increased for both mutable and immutable memtables. Second, only after the immutable memtable is compacted, log updates can be cleaned, leading to a larger log size. Third, LSMs such as LevelDB and RocksDB do not enforce commits (sync) when writing to a log; as a result, an application crash or power-failure could lead to data loss. Fourth, a larger log also increases recovery time after a failure. Finally, the cost of checksumming and logging also increases.

Read operation latency. A read operation involves hierarchically searching the smaller in-memory mutable and immutable memtables, followed by searching multiple SSTable levels. Searching a memtable involves traversing the skip list without the need to deserialize data. However, searching a SSTable is complicated for the following reason: the SSTable contains multiple levels that store key-value pairs sorted by their key hash, and each level is searched using a binary search. After locating the blocks containing a key-value pair, the blocks are copied into a memory buffer and then deserialized from disk to an in-memory format. The search cost increases moving top-down across SSTable levels because each SSTable level is at least 10x larger than the previous level. To reduce SSTable search cost, LSMs such as LevelDB and RocksDB maintain an index table at each level which uses a Bloom filter to cache recently searched keys, which is useful only for workloads with high re-access rates (e.g., Zipfian distribution). Figure 4 breaks down the cost of a read operation for 4 KB, 8 KB, and 16 KB values. For small values, searching the SSTable dominates the cost, followed by copying disk blocks to memory and deserializing block contents to in-memory key-value pairs; the deserialization cost increases with increasing value size (e.g., 16 KB). Reducing data copy, search, and deserialization cost can significantly reduce read latencies.

Summary. To summarize, existing LSMs suffer from high software overheads for both insert and read operations and fail to exploit NVM's byte-addressability, low latency, and high storage bandwidth. The insert operations suffer mainly from high compaction and log update overheads, and the read operations suffer from sequential search and deserialization overheads. Reducing these software overheads is critical for fully exploiting the hardware benefits of NVMs.

4 Design

Based on the analyses presented earlier, we first formulate NoveLSM's design principles and then discuss the details on how these principles are incorporated to NoveLSM's design.

4.1 NoveLSM Design Principles

NoveLSM exploits NVMs byte addressability, persistence, and large capacity to reduce serialization and deserialization overheads, high compaction cost, and logging overheads. Further, NoveLSM utilizes NVM's low latency and high bandwidth to parallelize search operations and reduce response time.

Principle 1: Exploit byte-addressability to reduce serialization and deserialization cost. NVMs provide byte-addressable persistence; therefore, in-memory structures can be stored in NVM as-is without the need to serialize them to disk-compatible format or deserialize them to memory format during retrieval. To exploit this, NoveLSM provides a persistent NVM memtable by designing a persistent skip list. During compaction, the DRAM memtable data can be directly moved to the NVM memtable without requiring serialization or deserialization.

Principle 2: Enable mutability of persistent state and leverage large capacity of NVM to reduce compaction cost. Traditionally, software designs treat data in the storage as immutable due to high storage access latency; as a result, to update data in the storage, data must be read into a memory buffer before making changes and writing them back (mostly in batches). However, NVM byte-addressability provides an opportunity to directly update data on the storage without the need to read them to a memory buffer or write them in batches. To exploit mutability of persistent state, NoveLSM designs a large mutable persistent memtable to which applications can directly add or update new key-value pairs. The persistent memtable allows NoveLSM to alternate between small DRAM and large NVM memtable without stalling for background compaction to complete. As a result compaction cost significantly reduces.

Principle 3: Reduce logging overheads and recovery cost with in-place durability. Current LSM designs must first write updates to a log, compute the checksum and append them, before inserting them into the memtable. Most LSMs compromise crash consistency for performance by not committing the log updates. Further, recovery after an application failure or system crash is expensive; each log entry must be deserialized before adding it to the memtable. In contrast, NoveLSM avoids logging by immediately committing updates to the persistent memtable in-place. Recovery is fast and only requires memory mapping the entire NVM memtable without deserialization.

Principle 4: Exploit the low latency and high bandwidth of NVM to parallelize data read operations. LSM stores data in a hierarchy with top in-memory levels containing new updates, and older updates in the lower SSTables levels. With an increase in the number of key-value pairs in a database, the number of storage levels (i.e., SSTables) increases. Adding NVM memtables further increases the number of LSM levels. LSMs must be sequentially searched from top to bottom, which can add significant search costs. NoveLSM exploits NVMs' low latency and high bandwidth by parallelizing search across the memory and storage levels, without affecting the correctness of read operations.

4.2 Addressing (De)serialization Cost

To reduce serialization and deserialization cost in LSMs, we first introduce an immutable persistent memtable. During compaction, each key-value pair from the DRAM memtable is moved (via *memcpy()*) to the NVM memtable without serialization. The NVM memtable skip list nodes (that store key-value pairs) are linked by their relative offsets in a memory-mapped region instead of virtual address pointers and are committed in-place; as a result, the persistent NVM skip list can be safely recovered and rebuilt after a system failure. Figure 5.a shows the high-level design of an LSM with NVM memtable placed behind DRAM memtable.

Immutable NVM skip list-based memtable. We design a persistent memtable by extending LevelDB's skip list and adding persistence support. A skip list is a multi-dimensional linked-list that provides fast probabilistic insert and search operation avoiding the need to visit all elements of a linked list [33]. Popular LSM implementations, such as LevelDB and RocksDB, use a skip list because they perform consistently well across sequential, random, and scan workloads. We extend the skip list for persistence because it enables us to reuse LevelDB's skip list-specific optimizations such as aligned memory allocation and faster range queries.

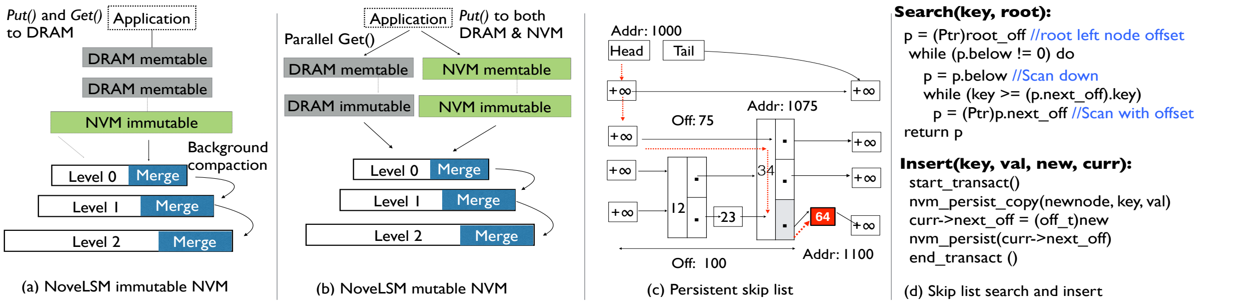
In a persistent skip list, the nodes are allocated from a large contiguous memory-mapped region in the NVM. As shown in Figure 5.d, each skip list node points to a next node using physical offset relative to the starting address of the root node, instead of a virtual address. Iterating the persistent skip list requires root node's offset from starting address of the memory-mapped region. After a restart or during failure recovery, the persistent region is remapped, and the root offset is recovered from a log file; using the root node, all skip list nodes are recovered.

To implement a persistent skip list, we modify LevelDB's memtable with a custom persistent memory NVM allocator that internally uses the Hoard allocator [10]. Our allocator internally maps a large region of NVM pages on a DAX filesystem [6] and manages the pages using persistent metadata similar to Intel's NVML library [24]. Each skip list node maintains a physical offset pointer and a virtual address pointer to the next node, which are updated inside a transaction during an insert or update operation, as shown in Figure 5.d. A power or application failure in the middle of a key-value pair insertion or the offset update can compromise durability. To address this, we provide ordered persistent updates by using hardware memory barriers and cacheline flush instructions [15, 16, 22, 38]. Note that NoveLSM extends existing LSMs for NVMs rather than completely redesigning their data structures; this is complementary to prior work that focuses on optimizing LSMs' in-memory data structures [9, 34].

4.3 Reducing Compaction Cost

Although the immutable NVM design can reduce serialization cost and read latency, it suffers from several limitations. First, the NVM memtable is just a replica of the DRAM memtable. Hence, the compaction frequency is dependent on how fast the DRAM memtables fill. For applications with high insert rates, compaction cost dominates the performance.

Mutability for persistent memtable. To address the issue of compaction stalls, NoveLSM makes the NVM memtable mutable, thereby allowing direct updates to the NVM memtable (Figure 5.(b)); when the in-memory



(a) NoveLSM immutable NVM

(b) NoveLSM mutable NVM

(c) Persistent skip list

```
Search(key, root):
  p = (Ptr)root_off //root left node offset
   while (p.below != 0) do
     p = p.below //Scan down
     while (key >= (p.next_off).key)
       p = (Ptr)p.next_off //Scan with offset
  return p

Insert(key, val, new, curr):
   start_transact()
   nvm_persist_copy(newnode, key, val)
   curr->next_off = (off_t)new
   nvm_persist(curr->next_off)
   end_transact ()
```

(d) Skip list search and insert

Figure 5: **NoveLSM's immutable and mutable NVM memtable design.** *(a) shows the immutable memtable design, where NVM memtable is placed below DRAM memtable to only store compaction data. (b) shows mutable memtable design where inserts can be directly updated to NVMs persistent skip list. (c) shows an example of inserting a key 64 to persistent NVM memtable at offset 100 from the root node with address 1000. Next pointer of node with key 34 contains offset 100. (d) shows NVM persistent skiplist search and insert pseudocode. Read operation searches for a key using the offset of node instead of pointer. Offsets represent the location of a node in a memory-mapped file. Inserts to NVM memtable are committed in-place and avoid separate logging.*

memtable is full, application threads can alternate to using the NVM memtable without stalling for the in-memory memtable compaction to complete.

The working of the mutable NVM design can be summarized as follows. During initialization, NoveLSM creates a volatile DRAM memtable and a mutable persistent NVM memtable. Current LSM implementations use a smaller memtable size to reduce DRAM consumption and avoid data loss after a failure. In contrast, NoveLSM uses a large NVM memtable; this is because NVMs can scale up to 4x larger than DRAM and also maintain persistence. To insert a key-value pair, first, the DRAM memtable is made active; the key-value pairs and their checksum are written to a log and then inserted into the DRAM memtable. When the DRAM memtable is full, it is made immutable, and the background compaction thread is notified to move data to the SSTable. Instead of stalling for compaction to complete, NoveLSM makes NVM memtable active (mutable) and keys are directly added to mutable NVM memtable. The large capacity of NVM memtable provides sufficient time for background compaction of DRAM and NVM immutable memtables without stalling foreground operations; as a result, NoveLSM's mutable memtable design significantly reduces compaction cost leading to lower insert/update latency. For read operations, the most recent value for a key is fetched by first searching the current active memtable, followed by immutable memtables and SSTables.

4.4 Reducing Logging Cost

NoveLSM eliminates logging for inserts added to mutable NVM memtable by persisting updates in-place. As a result, NoveLSM reduces the number of writes for each key-value pair and also reduces recovery time. We next discuss the details.

Logging. In current LSM implementations, each key-value pair and its 32-bit CRC checksum is first appended to a persistent log, then inserted into the DRAM memtable, and finally compacted to an SSTable, leading to high write amplification. Further, popular implementations such as LevelDB and RocksDB only append but do not commit (*fsync()*) data to the log; as a result, they compromise durability for better performance.

In contrast, for NoveLSM, when inserting into the mutable persistent memtable in NVM, all updates are written and committed in-place without requiring a separate log; as a result, NoveLSM can reduce write amplification. Log writes are avoided only for updates to NVM memtable, whereas, all inserts to the DRAM memtable are logged. Our evaluations show that using a large NVM memtable with direct mutability reduces logging to a small fraction of the overall writes, thereby significantly reducing logging cost and recovery time. Additionally, because all NVM updates are committed in-place, NoveLSM can provide stronger durability guarantees compared to existing implementations. Figure 5.d shows the pseudocode for NVM memtable insert. First, a new transaction is initiated and persistent memory for a key-value pair is allocated. The key-value pair is copied persistently by ordering the writes using memory store barrier and cache line flush of the destination addresses, followed by a memory store barrier [24, 38, 41]. As an additional optimization, small updates to NVM (8-byte) are committed with atomic store instruction not requiring a barrier. Finally, for overwrites, the old nodes are marked for lazy garbage collection.

Recovery. Recovering from a persistent NVM memtable requires first mapping the NVM memtable (a file) and identifying the root pointer of the skip list. Therefore, the NVM memtable root pointer offset and 20-bytes of skip list-related metadata are stored in a separate file. With a volatile DRAM and persistent NVM memtable, a failure can occur while a key with version V_i in the persistent NVM memtable is getting overwritten in the DRAM memtable to version V_{i+1}. A failure can also occur while a key with version V_i in the DRAM memtable, not yet compacted to storage, is getting overwritten to version V_{i+1} in the NVM. To maintain correctness, NoveLSM must always recover from the greatest committed version of the key. To achieve version correctness, NoveLSM performs the following steps: (1) a new log file is created every time a new DRAM memtable is allocated and all updates to DRAM memtable are logged and made persistent; (2) when the NVM memtable (which is a persistent skip list on a memory-mapped file) is made active, inserts are not logged, and the NVM memtable is treated as a log file; (3) the NVM log files are also named with an incremental version number similar to any other log file. During LSM restart or failure recovery, NoveLSM starts recovering from the active versions of log files in ascending order. A key present in a log file log_{i+1}, which could be either a DRAM log or NVM memtable, is considered as the latest version of the key. Note that recovering data from NVM memtable only involves memory-mapping the NVM region (a file) and locating the skip list root pointer. Therefore, recovering from even a large NVM memtable is fast with almost negligible cost of mapping pages to the page tables.

4.5 Supporting Read Parallelism

NoveLSM leverages NVM low latency and high bandwidth to reduce the latency of each read operation by parallelizing search across memtables and SSTables. In this pursuit, NoveLSM does not compromise the correctness of read operation. In current LSMs, read operations progress top-down from memtable to SSTables. A read miss at each level increases read latency. Other factors such as deserializing data from the SSTable also add to read overheads.

Reducing read latency. To reduce read latency, NoveLSM takes inspiration from the processor design, which parallelizes cache and TLB lookup to reduce memory access latency for cache misses; NoveLSM parallelizes search across multiple levels of LSM: DRAM and NVM mutable memtables, DRAM and NVM immutable tables, and SSTables. Our design manages a pool of worker threads that search memtables or the SSTable. Importantly, NoveLSM uses only one worker thread for searching across the mutable DRAM and NVM memtable because of the relatively smaller DRAM memtable size compared to the NVM memtable.

With this design, the read latency is reduced from $T_{read} \approx T_{mem_{DRAM}} + T_{mem_{NVM}} + T_{imm} + T_{SST}$ to $T_{read\_parallel} \approx max(T_{mem_{DRAM}} + T_{mem_{NVM}}, T_{imm}, T_{SST}) + C$. $T_{mem_{DRAM}}$, $T_{mem_{NVM}}$, T_{imm}, and T_{SST} represent the read time to search across the DRAM and NVM mutable memtable, the immutable memtable, and the SSTable, and C represents a constant corresponding to the time to stop other worker threads once a key has been found.

Guaranteeing version correctness for reads. Multiple versions of a key can exist across different LSM levels, with a newer version (V_{i+1}) of the key at the top LSM level (DRAM or NVM mutable memtable) and older versions ($V_i, V_{i-1}, ...$) in the lower immutable memtable and SSTables. In traditional designs, search operations sequentially move from the top memtable to lower SSTables, and therefore, always return the most recent version of a key. In NoveLSM, search operations are parallelized across different levels and a thread searching the lower level can return with an older version of the key; this impacts the correctness of read operation. To guarantee version correctness, NoveLSM always considers the value of a key returned by a thread accessing the highest level of LSM as the correct version. To satisfy this constraint, a worker thread T_i accessing L_i is made to wait for other worker threads accessing higher levels L_0 to L_{i-1} to finish searching, and only if higher levels do not contain the key, the value fetched by T_i is returned. Additionally, stalling higher-level threads to wait for the lower-level threads to complete can defeat the benefits of parallelizing read operation. To overcome this problem, in NoveLSM, once a thread succeeds in locating a key, all lower-level threads are immediately suspended.

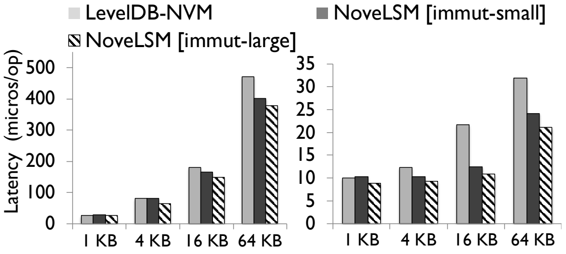
Optimistic parallelism and management. Introducing parallelism for each read operation is only beneficial when the overheads related to thread management cost are significantly lower than the actual cost to search and read a key-value pair. NoveLSM uses an optimistic parallelism technique to reduce read latency.

Thread management cost. In NoveLSM, the main LSM thread adds a client's read request to a job pool, notifies all worker threads to service the request, and finally, returns the value for a key. NoveLSM always colocates the master and the worker threads to the same CPU socket to avoid the lock variable bouncing across processor caches on different sockets. Further, threads dedicated to parallelize read operation are bound to separate CPUs from threads performing backing compaction. These simple techniques are highly effective in reducing thread management cost.

Optimistic parallelism. While the thread pool optimizations reduce overheads, using multiple threads for keys that are present in DRAM or NVM memtable only adds more overheads. To avoid these overheads, we implement a Bloom filter for NVM and DRAM memtable. The Bloom filter predicts likeliness of a key in the memtable, and read parallelism is enabled only when a key is predicted to miss the DRAM or NVM memtable; false positives (keys that are predicted to be in memtable but are not present) only make the read operations sequential without compromising correctness.

5 Evaluation

Our evaluation of NoveLSM aims to demonstrate the design insights in reducing write and read latency and increasing throughput when using NVMs. We answer the following important questions.



(a) Write latency (b) Read latency

Figure 6: **Write and Read latency.** *Impact of NVM immutable for random writes and reads. Database size is constant.*

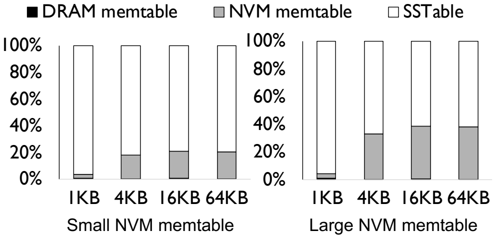


Figure 7: **NoveLSM immutable memtable hits.** *Figure shows percentage split of keys read from different LSM levels when using the immutable memtable design.*

1. What are the benefits of introducing a persistent immutable NVM memtable for different access patterns?
2. Does enabling mutability for NVM memtable reduce compaction cost and improve performance?
3. How effective is NoveLSM's optimistic parallelism in reducing read latency?
4. What is the impact of splitting NoveLSM across NVM and SSD compared to state-of-the-art approaches?
5. Is NoveLSM effective in exploiting NVMs byte-addressability to make failure recovery faster?

We first describe our evaluation methodology, and then evaluate NoveLSM with benchmarks and realistic workloads.

5.1 Methodology and Workloads

For our evaluation, we use the same platform described earlier § 2.4. NoveLSM reserves and uses 16 GB (a memory socket) to emulate NVM with 5 GB/sec NVM bandwidth and the read and write latency set to 100ns and 500ns respectively, similarly to [12, 17, 22], using methodology described earlier. We evaluate NoveLSM using DBbench [3, 4, 30] and the YCSB cloud benchmark [18]. The total LSM database size is restricted to 16 GB to fit in the NUMA socket that emulates NVM. The key size (for all key-values) is set to 16 bytes and only the value size is varied. We turn off database compression to avoid any undue impact on the results, as done previously [30].

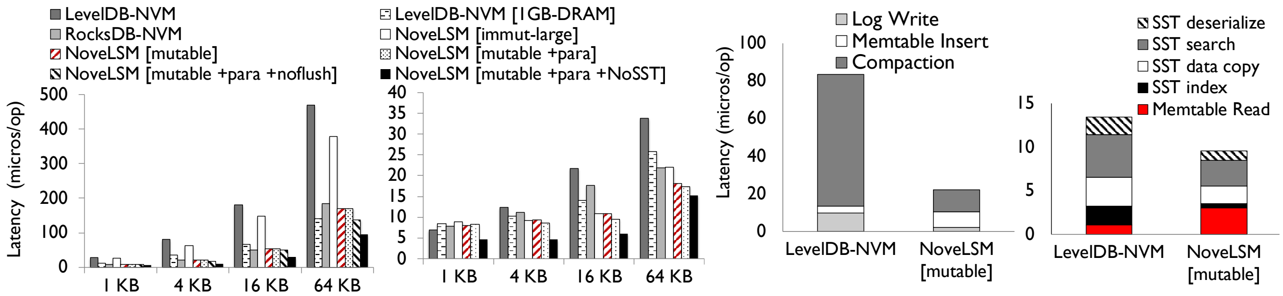
5.2 Impact of NVM-immutable Memtable

We begin by evaluating the benefits and implications of adding a persistent NVM immutable to the LSM hierarchy. We study two versions of NoveLSM: NoveLSM with a small (2 GB) immutable NVM memtable (NoveLSM+immut-small), and NoveLSM with a large (4 GB) immutable NVM memtable (NoveLSM+immut-large). The remaining NVM space is used for storing SSTables. For comparison, we use a vanilla LevelDB that stores all its non-persistent data in a DRAM memtable and persistent SSTables in the NVM (LevelDB-NVM). Figures 6.a and 6.b show the average random write and read latency as a function of the value sizes in X-axis.

Random write latency. Figure 6.a compares the random write latency. For the naive LevelDB-NVM, when the in-memory (DRAM) immutable memtable is full, a compaction thread first serializes data to SSTable. In contrast, NoveLSM uses a persistent NVM immutable memtable (a level below the 64 MB DRAM immutable memtable). When the DRAM immutable memtable is full, first data is inserted and flushed to NVM memtable skip list without requiring any serialization. When NVM memtable is also full, its contents are serialized and flushed to SSTable by a background thread. Using a larger NVM memtable (NoveLSM+immut-large) as a buffer reduces the memory to disk format compaction cost but without compromising crash consistency. Therefore, the NVM immutable design achieves up to 24% reduction in latency for 64 KB value compared to LevelDB-NVM. However, due to lack of direct NVM memtable mutability, the compaction frequency is dependent on the DRAM memtable capacity, which impacts immutable NVM designs performance.

Random read latency. Figure 6.b shows the read latency results. In case of LevelDB-NVM, reading a key-value pair from SSTable requires first locating the SSTable level, searching for the key within a level, reading the corresponding I/O blocks, and finally deserializing disk blocks to in-memory data. NoveLSM's immutable memtable skip list also incurs search cost; however, it avoids indexing, disk block read, and deserialization cost. Figure 7 shows the NVM immutable table hit rate for different value sizes when using small and large NVM tables. For 4 KB value size, the memtable hit rate (DRAM or NVM) for small NVM memtable is less than 17% and the additional search in the NVM memtable increases latency. However, for NoveLSM+immut-large, the hit rate is around 29% and the read latency reduces by 33% compared to LevelDB-NVM. Because we keep the database size constant and vary the value size, for larger value sizes (e.g., 64 KB), the number of key-values in the database is less, increasing hit rate by up to 38% and reducing latency by up to 53%. For single-threaded DBbench, the throughput gains are same as latency reduction gains; hence, we do not show throughput results.

Summary. NoveLSM's immutable memtable reduces write latency by 24% and read latency by up



(a) Write latency (b) Read latency (c) 4 KB Write latency cost (d) 4 KB Read latency cost

Figure 8: **NVM mutability impact.** *Figure shows (a) write latency, (b) read latency. LevelDB-NVM and RocksDB-NVM use NVM for SSTable. LevelDB-NVM [1GB-DRAM] uses a large DRAM memtable; [mutable + para] shows read parallelism. [mutable + para + noflush] shows NoveLSM without persistent flush, [mutable + para + NoSST] shows using only NVM memtable without SSTable. Figure (c) and (d) show NoveLSM Write and Read operation latency cost splitup for 4 KB values.*

to 53%. Lack of direct NVM memtable mutability and frequent compaction impacts write performance.

5.3 NVM Memtable Mutability

To understand the effectiveness of NoveLSM's mutable memtable in reducing compaction cost, we begin with NoveLSM+immut-large discussed in the previous result, and analyze four other NoveLSM techniques: NoveLSM+mutable uses a large (4 GB) NVM memtable which is placed in parallel with the DRAM memtable and allows direct transactional updates (without logging) supported by persistent processor cache flushes; NoveLSM+mutable+para enables read parallelism; NoveLSMmutable+para+noflush shows the latency without persistent processor cache flushes; and finally, NoveLSM+mutable+NoSST uses only persistent NVM memtable for the entire database without SSTables. For comparison, in addition to LevelDB-NVM, we also compare the impact of increasing the vanilla LevelDB-NVM DRAM memtable size to 1GB (LevelDB-NVM+1GB-DRAM) and RocksDB-NVM [3] by placing all its SSTable in NVM. RocksDB-NVM is configured with default configuration values used in other prior work [9, 30]. For our experimentation, we set the DRAM memtable to 64 MB for all configuration except LevelDB-NVM+1GB-DRAM. Figure 8.c and Figure 8.d show the cost split up for a 4 KB random write and read operation.

Write performance. Figure 8.a shows the average write latency as a function of value size. When the mutable NVM memtable is active, its large capacity provides background threads sufficient time to finish compaction, consequently reducing foreground stalls. For 4 KB values, NoveLSM+mutable reduces latency by more than 3.8x compared to LevelDB-NVM and NoveLSM+immut-large, due to reduction of both compaction and log write cost as shown in Figure 8.c. For 64 KB value size, write latency reduces by 2.7x compared to LevelDB-NVM. While increasing the vanilla LevelDB-NVM's DRAM memtable size (1GB-DRAM) improves performance, however, (1) DRAM consumption increases by twice (DRAM memtable and immutable table), (2) increases log size and recovery time (discussed shortly), and importantly, (3) compromises crash consistency because both LevelDB and RocksDB do not commit log updates to storage by default.

For smaller value sizes, RocksDB-NVM marginally reduces write latency compared to mutable NoveLSM (NoveLSM+mutable) design that provides in-place commits (with processor cache flushes). RocksDB benefits come from using a Cuckoo hash-based SST [11] that improves random lookups (but severely impacts scan operations), parallel compaction to exploit SSD parallelism, and not flushing log updates to storage. While incorporating complementary optimizations, such as Cuckoo hash-based SST and parallel compaction, can reduce latency, even avoiding persistent cache flush (NoveLSM+mutable+para+noflush) reduces latency compared to RocksDB. For larger values, NoveLSM reduces latency by 36% compared to RocksDB-NVM providing the same durability guarantees. Finally, NoveLSM+mutable+NoSST, by using large NVM memtable and adding the entire database to the skip list, eliminates compaction cost reducing the write latency by 5x compared to LevelDB-NVM and more than 1.9x compared to RocksDB-NVM.

Read parallelism. Figure 8.b shows the read latency for all configurations. First, compared to LevelDB-NVM, NoveLSM+mutable reduces read latency for 4 KB value size by 30%. RocksDB-NVM with a random-access friendly Cuckoo-hash SSTable significantly reduces memtable miss latency cost, providing better performance for smaller values. For smaller values (1 KB, 4 KB), NoveLSM's optimistic parallelism shows no gains compared to RocksDB because the cost of thread management suppresses benefits of parallel read. However, for larger value sizes, NoveLSM's parallelism combined with the reduction in deserialization cost reduces NoveLSM's read latency by 2x and 24% compared to LevelDB-NVM and RocksDB respectively. In-

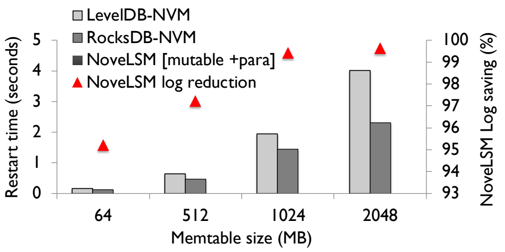


Figure 9: **Failure recovery performance.** *The figure shows recovery time as a function of memtable size in X-axis. For LevelDB and RocksDB, DRAM memtable size is increased, whereas for NoveLSM, NVM memtable increased, and DRAM memtable size is kept constant at 64 MB.*

corporating RocksDB's optimized SSTable can further improve NoveLSM's read performance. As a proof, the NoveLSM-NoSST case reduces the read latency by 45% compared to RocksDB.

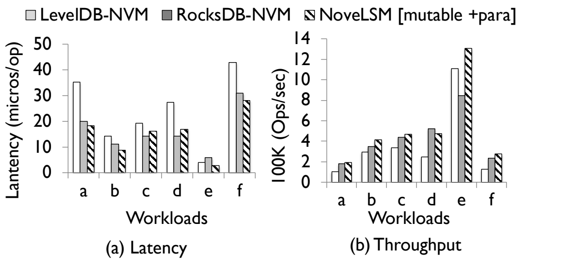
Splitting LSMs across NVM and SSDs. NoveLSM can support large LSMs that spill over to SSD when NVM capacity is full. To understand the performance impact, we set the LSM database size to 16 GB. We compare two approaches: (1) LevelDB-NVM-SSD that splits SSTable across NVM (8 GB) and SSD (8 GB), (2) NoveLSM-mutable-SSD that uses a half-and-half configuration with 4 GB NVM for mutable memtable, 4 GB NVM for higher levels of SSTable, and 8 GB SSTable on SSD. We do not consider RocksDB because of the complexity involved in supporting multiple storage devices for a complex compaction mechanism, which is beyond the scope of this work. When evaluating the two configurations, we determine that LevelDB-NVM-SSD suffers from high compaction cost. For larger value sizes, memtables fill-up quickly, triggering a chain of compaction across both NVM and SSD SSTables. In contrast, NoveLSM's mutable NVM memtable reduces compaction frequency allowing background threads with sufficient time to compact, thus reducing stalls; consequently, NoveLSM reduces latency by more than 45% for 64 KB values compared to LevelDB-NVM-SSD.

Summary. The results highlight the benefits of using a mutable memtable for write operations and supporting parallelism for read operations in both NVM-only and NVM+SSD configurations. Incorporating RocksDB's SSTable optimizations can further improve NoveLSM's performance.

5.4 Failure Recovery

NoveLSM's mutable persistence provides in-place commits to NVM memtable and avoids log updates. In Figure 9, we analyze the impact of memtable size on recovery time after a failure. To emulate failure, we crash DBbench's random write workload after inserting half the keys. On the X-axis, for LevelDB-NVM and RocksDB-NVM, we increase DRAM memtable size, whereas, for NoveLSM-mutable, the DRAM memtable size is kept constant at 64 MB and only the NVM mutable memtable size is varied.

For LevelDB-NVM and RocksDB-NVM, all updates to DRAM memtable are also logged; hence, increasing the DRAM memtable size also increases the log size that must be read during recovery, thereby increasing the recovery time. Recovery involves iterating the log, verifying checksums, serializing logged key-value pairs to an SSTable disk block, and inserting them to the top level of the SSTable which is merged with lower levels. As a result, for a 1 GB DRAM memtable size, LevelDB-NVM's recovery is as high as 4 seconds; RocksDB-NVM recovers faster than LevelDB due to its specialized SST format. For NoveLSM, recovery involves identifying a correct version of the persistent memtable before the crash, memory-mapping the NVM memtable's persistent skip list, and modifying the root pointer to the current virtual address of the application. As a result, restart performance for NoveLSM is more than three orders faster. Importantly, NoveLSM logs only the updates to DRAM memtable, thereby reducing logging writes by up to 99%.



(a) Latency

(b) Throughput

Figure 10: **YCSB (a) latency and (b) throughput.** *Results only shown for run-phase after warm-up. NoveLSM's mutable memtable size set to 4 GB. Workload A has 50-50% update-read ratio, B is read-intensive with 95% reads and 5% updates (overwrites); C is read-only, D is also read-only, with the most recently inserted records being most popular, E is scan-intensive (95% scan, and 5% insert), and F has 50% reads and 50% write-modify-reads.*

5.5 Impact on YCSB

To understand the benefits and implication for cloud workloads, we run the widely-used YCSB [18] benchmark and compare LevelDB-NVM, RocksDB-NVM, and NoveLSM-mutable-para approaches. We use the six workloads from the YCSB cloud suite with different access patterns. YCSB has a warm-up (write-only) and a run phase, and we show the run phase results when using 4-client threads. Figure 10 shows the 95th percentile latency and throughput (in 100K operations per second). We use 4 KB value size and 16 GB database. The SSTables are placed in NVM for all cases, and NoveLSM's mutable memtable is set to 4 GB. First, for workload A, with the highest write ratio

(50%), NoveLSM's direct mutability improves throughput by 6% over RocksDB and 81% over LevelDB-NVM, even for small 4 KB value sizes. Both workload B and workload C are read-intensive, with high random reads. NoveLSM's read parallelism is effective in simultaneously accessing data across multiple LSM levels for four client threads. For workload D, most accesses are recently inserted values, resulting in high mutable and immutable memtable hits even for RocksDB. NoveLSM checks the bloom filter for each access for enabling read parallelism (parallelism is not required as keys are present in memtable), and this check adds around $1\mu s$ overhead per key resulting in a slightly lower throughput compared to RocksDB. Next, for the scan-intensive workload E, LevelDB and NoveLSM's SSTable are highly scan-friendly; in contrast, RocksDB's SSTable optimized for random-access performs poorly for scan operations. As a result, NoveLSM shows 54% higher throughput compared to RocksDB-NVM. Finally, workload F with 50% updates (overwrites) adds significant logging and compaction-related serialization overhead. NoveLSM's direct mutability reduces these cost improving throughput by 17% compared to RocksDB and more than 2x over LevelDB-NVM.

Summary. NoveLSM's direct mutability and read parallelism provide high-performance for both random and sequential workloads.

6 Related Work

Key-value store and storage. Prior works such as SILT [29], FlashStore [20], SkimpyStash [21] design key-value stores specifically targeting SSDs. FlashStore and SkimpyStas treat flash as an intermediate cache and place append-only logs to benefit from the high sequential write performance of SSD. SILT reduces DRAM usage by splitting in-memory log across the DRAM and SSD and maintaining a sorted log index in the memory. In summary, prior works enforce sequentiality by batching and adding software layers for improving throughput. In contrast, we design NoveLSM to reduce I/O access latency with heap-based persistent structures.

Application redesign for persistent memory. Byte addressability, low latency, and high bandwidth make NVMs a popular target for redesigning data structures and applications originally designed for block storage. Venkatraman et al. [36] were one of the first to explore the benefits of persistence-friendly B-trees for NVMs. Since then, several others have redesigned databases [8], key-value stores [31], B-trees [14], and hashtables [19].

LSM and redesign for storage. Several prior works have redesigned LSMs for SSD. Wang et al [39] expose SSD's I/O channel information to LevelDB to exploit the parallel bandwidth usage. WiscKey [30] redesigns LSMs for reducing the read and write amplification and exploiting SSD bandwidth. VT-tree [35] design proposes a file system and a user-level key-value store for workload-independent storage. In NoveLSM, we reduce the write latency with a mutable persistent skip list and the read latency by parallelizing reads across the LSM levels.

LSM redesign for NVM. NoveLSM is focused on extending existing LSMs for NVMs rather than completely redesigning their data structures; this is complementary to projects such as FloDB and PebblesDB [9, 34]. We were recently made aware of a concurrently developed effort with similar goals as NoveLSM. NVM-Rocks [28] shares similar ideas on using a persistent mutable memtable to reduce access latencies and recovery costs. To improve read latencies, it introduces a hierarchy of read caches. NoveLSM retains the in-DRAM memtable of the original LSM design, benefiting latencies for both cached reads and writes, and introduces parallelism *within* read operations to reduce read latency. We look forward to gaining access to NVMrocks and analyzing the tradeoffs that each technique contributes to the overall LSM performance.

7 Conclusion

We present NoveLSM, an LSM-based persistent key-value store that exploits NVM byte-addressability, persistence, and large capacity by designing a heap-based persistent immutable NVM skip list. The immutable NVM skip list facilitates DRAM memtable compaction without incurring memory to I/O data serialization cost and also accelerates reads. To reduce the compaction cost further, we introduce direct mutability of NVM memtables, which allow applications can to directly commit data to NVM memtable with stronger durability and avoid logging. Reducing compaction and logging overheads reduces random write latency by up to 3.8x compared to LevelDB running on NVM. To reduce read latency, we design opportunistic parallelism, which reduces read latency by up to 2x. Finally, the persistent memtable makes the restarts three orders of magnitude faster. As storage moves closer to memory, and storage bottlenecks shifts towards software, increased effort to optimize such software will undoubtedly be required to realize further performance gains.

Abstract

Persistent key-value (KV) stores mostly build on the Log-Structured Merge (LSM) tree for high write performance, yet the LSM-tree suffers from the inherently high I/O amplification. *KV separation* mitigates I/O amplification by storing only keys in the LSM-tree and values in separate storage. However, the current KV separation design remains inefficient under update-intensive workloads due to its high garbage collection (GC) overhead in value storage. We propose HashKV, which aims for high update performance atop KV separation under update-intensive workloads. HashKV uses *hash-based data grouping*, which deterministically maps values to storage space so as to make both updates and GC efficient. We further relax the restriction of such deterministic mappings via simple but useful design extensions. We compare HashKV with state-of-the-art KV stores via extensive testbed experiments, and show that HashKV achieves 4.6× throughput and 53.4% less write traffic compared to the current KV separation design.

1 Introduction

Persistent key-value (KV) stores are an integral part of modern large-scale storage infrastructures for storing massive structured data (e.g., [4, 6, 10, 18]). While real-world KV storage workloads are mainly read-intensive (e.g., the Get/Update ratio can reach 30:1 in Facebook's Memcached workloads [3]), *update-intensive* workloads are also dominant in many storage scenarios, including online transaction processing [37] and enterprise servers [17]. For example, Yahoo! reports that its low-latency workloads increasingly move from reads to writes [33].

Modern KV stores optimize the performance of writes (including inserts and updates) using the Log-Structured Merge (LSM) tree [29]. Its idea is to maintain sequentiality of random writes through a log-structured (append-only) design [31], while supporting efficient queries including individual key lookups and range scans. In a nutshell, the LSM-tree buffers written KV pairs and flushes them into a multi-level tree, in which each node is a fixed-size file containing sorted KV pairs and their metadata. The recently written KV pairs are stored at higher tree levels, and are merged with lower tree levels via *compaction*. The LSM-tree design not only improves write performance by avoiding small random updates (which are also harmful to the endurance of solid-state drives (SSDs) [2, 27]), but also improves range scan performance by holding sorted KV pairs in each node.

However, the LSM-tree incurs high I/O amplification in both writes and reads. As the LSM-tree receives more writes of KV pairs, it will trigger frequent compaction operations, leading to tremendous extra I/Os due to rewrites across levels. Such *write amplification* can reach a factor of at least 50× [23, 39], which is detrimental to both write performance and the endurance of SSDs [2, 27]. Also, as the LSM-tree grows in size, reading the KV pairs at lower levels incurs many disk accesses. Such read amplification can reach a factor of over 300× [23], leading to low read performance.

In order to mitigate the compaction overhead, many research efforts focus on optimizing LSM-tree indexing (see §5). One approach is *KV separation* from WiscKey [23], in which keys and metadata are still stored in the LSM-tree, while values are separately stored in an append-only circular log. The main idea of KV separation is to reduce the LSM-tree size, while preserving the indexing feature of the LSM-tree for efficient inserts/updates, individual key lookups, and range scans.

In this work, we argue that KV separation itself still cannot fully achieve high performance under update-intensive workloads. The root cause is that the circular log for value storage needs frequent garbage collection (GC) to reclaim the space from the KV pairs that are deleted or superseded by new updates. However, the GC overhead is actually expensive due to two constraints of the circular log. First, the circular log maintains a strict GC order, as it always performs GC at the beginning of the log where the least recently written KV pairs are located. This can incur a large amount of unnecessary data relocation (e.g., when the least recently written KV pairs remain valid). Second, the GC operation needs to query the LSM-tree to check the validity of each KV pair. These queries have high latencies, especially when the LSM-tree becomes sizable under large workloads.

We propose HashKV, a high-performance KV store tailored for update-intensive workloads. HashKV builds on KV separation and uses a novel *hash-based data grouping* design for value storage. Its idea is to divide value storage into fixed-size partitions and deterministically map the value of each written KV pair to a partition by hashing its key. Hash-based data grouping supports lightweight updates due to deterministic mapping. More importantly, it significantly mitigates GC overhead, since each GC operation not only has the flexibility to select a partition to reclaim space, but also eliminates the queries to the LSM-tree for checking the validity of KV pairs.

On the other hand, the deterministic nature of hash-based data grouping restricts where KV pairs are stored. Thus, we propose three novel design extensions to relax the restriction of hash-based data grouping: (i) *dynamic reserved space allocation*, which dynamically allocates reserved space for extra writes if their original hash partitions are full given the size limit; (ii) *hotness awareness*, which separates the storage of hot and cold KV pairs to improve GC efficiency as inspired by existing SSD designs [19,27]; and (iii) *selective KV separation*, which keeps small-size KV pairs in entirety in the LSM-tree to simplify lookups.

We implement our HashKV prototype atop LevelDB [15], and show via testbed experiments that HashKV achieves 4.6× throughput and 53.4% less write traffic compared to the circular log design in WiscKey under update-intensive workloads. Also, HashKV generally achieves higher throughput and significantly less write traffic compared to modern KV stores, such as LevelDB and RocksDB [12], in various cases.

Our work makes a case of augmenting KV separation with a new value management design. While the key and metadata management of HashKV now builds on LevelDB, it can also adopt other KV stores with new LSM tree designs (e.g., [30,33,35,39,41,42]). How HashKV affects the performance of various LSM-tree-based KV stores under KV separation is posed as future work. The source code of HashKV is available for download at: **http://adslab.cse.cuhk.edu.hk/software/hashkv**.

2 Motivation

We use LevelDB [15] as a representative example to explain the write and read amplification problems of LSM-tree-based KV stores. We show how KV separation [23] mitigates both write and read amplifications, yet it still cannot fully achieve efficient updates.

2.1 LevelDB

LevelDB organizes KV pairs based on the LSM-tree [29], which transforms small random writes into sequential writes and hence maintains high write performance. Figure 1 illustrates the data organization in LevelDB. It divides the storage space into k levels (where $k > 1$) denoted by L_0, L_1, $\cdots$, L_{k-1}. It configures the capacity of each level L_i to be a multiple (e.g., 10×) of that of its upper level L_{i-1} (where $1 \leq i \leq k-1$).

For inserts or updates of KV pairs, LevelDB first stores the new KV pairs in a fixed-size in-memory buffer called *MemTable*, which uses a skip-list to keep all buffered KV pairs sorted by keys. When the MemTable is full, LevelDB makes it *immutable* and flushes it to disk at level L_0 as a file called *SSTable*. Each SSTable has a size of around 2 MiB and is also immutable. It stores indexing metadata, a Bloom filter (for quickly checking if a KV pair exists in the SSTable), and all sorted KV pairs.

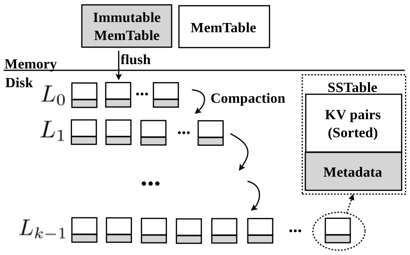

Figure 1: Data organization in LevelDB.

If L_0 is full, LevelDB flushes and merges its KV pairs into L_1 via *compaction*; similarly, if L_1 is full, its KV pairs are flushed and merged into L_2, and so on. The compaction process comprises three steps. First, it reads out KV pairs in both L_i and L_{i+1} into memory (where $i \geq 0$). Second, it sorts the valid KV pairs (i.e., newly inserted or updated) by keys and reorganizes them into SSTables. It also discards all invalid KV pairs (i.e., deleted or superseded by new updates). Finally, it writes back all SSTables with valid KV pairs to L_{i+1}. Note that all KV pairs in each level, except L_0, are sorted by keys. In L_0, LevelDB only keeps KV pairs sorted within each SSTable, but not across SSTables. This improves performance of flushing from the MemTable to disk.

To perform a key lookup, LevelDB searches from L_0 to L_{k-1} and returns the first associated value found. In L_0, LevelDB searches all SSTables. In each level between L_1 and L_{k-1}, LevelDB first identifies a candidate SSTable and checks the Bloom filter in the candidate SSTable to determine if the KV pair exists. If so, LevelDB reads the SSTable file and searches for the KV pair; otherwise, it directly searches the lower levels.

Limitations: LevelDB achieves high random write performance via the LSM-tree-based design, but suffers from both *write and read amplifications*. First, the compaction process inevitably incurs extra reads and writes. In the worst case, to merge one SSTable from L_{i-1} to L_i, it reads and sorts 10 SSTables, and writes back all SSTables. Prior studies show that LevelDB can have an overall write amplification of at least 50× [23,39], since it may trigger more than one compaction to move a KV pair down multiple levels under large workloads.

In addition, a lookup operation may search multiple levels for a KV pair and incur multiple disk accesses. The reason is that the search in each level needs to read the indexing metadata and the Bloom filter in the associated SSTable. Although the Bloom filter is used, it may introduce false positives. In this case, an SSTable is still unnecessarily read from disk even though the KV pair actually does not exist. Thus, each lookup typically incurs multiple disk accesses. Such read amplification further aggravates under large workloads, as the LSM-tree builds up in levels. Measurements show that the read amplification reaches over 300× in the worst case [23].

2.2 KV Separation

KV separation, proposed by WiscKey [23], decouples the management of keys and values to mitigate both write and read amplifications. The rationale is that storing values in the LSM-tree is unnecessary for indexing. Thus, WiscKey stores only keys and metadata (e.g., key/value sizes, value locations, etc.) in the LSM-tree, while storing values in a separate append-only, circular log called *vLog*. KV separation effectively mitigates write and read amplifications of LevelDB as it significantly reduces the size of the LSM-tree, and hence both compaction and lookup overheads.

Since vLog follows the log-structured design [31], it is critical for KV separation to achieve lightweight *garbage collection (GC)* in vLog, i.e., to reclaim the free space from invalid values with limited overhead. Specifically, WiscKey tracks the *vLog head* and the *vLog tail*, which correspond to the end and the beginning of vLog, respectively. It always inserts new values to the vLog head. When it performs a GC operation, it reads a chunk of KV pairs from the vLog tail. It first queries the LSM-tree to see if each KV pair is valid. It then discards the values of invalid KV pairs, and writes back the valid values to the vLog head. It finally updates the LSM-tree for the latest locations of the valid values. To support efficient LSM-tree queries during GC, WiscKey also stores the associated key and metadata together with the value in vLog. Note that vLog is often over-provisioned with extra reserved space to mitigate GC overhead.

Limitations: While KV separation reduces compaction and lookup overheads, we argue that it suffers from the substantial GC overhead in vLog. Also, the GC overhead becomes more severe if the reserved space is limited. The reasons are two-fold.

First, vLog can only reclaim space from its vLog tail due to its circular log design. This constraint may incur unnecessary data movements. In particular, real-world KV storage often exhibits strong locality [3], in which a small portion of *hot* KV pairs are frequently updated, while the remaining *cold* KV pairs receive only few or even no updates. Maintaining a strict sequential order in vLog inevitably relocates cold KV pairs many times and increases GC overhead.

Also, each GC operation queries the LSM-tree to check the validity of each KV pair in the chunk at the vLog tail. Since the keys of the KV pairs may be scattered across the entire LSM-tree, the query overhead is high and increases the latency of the GC operation. Even though KV separation has already reduced the size of the LSM-tree, the LSM-tree is still sizable under large workloads, and this aggravates the query cost.

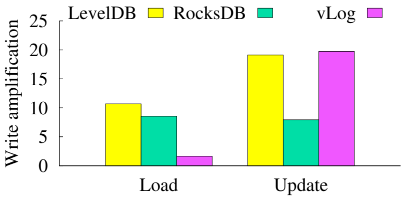

Figure 2: Write amplifications of LevelDB, RocksDB, and vLog in the Load and Update phases.

To validate the limitations of KV separation, we implement a KV store prototype based on vLog (see §3.8) and evaluate its write amplification. We consider two phases: Load and Update. In the Load phase, we insert 40 GiB of 1-KiB KV pairs into vLog that is initially empty; in the Update phase, we issue 40 GiB of updates to the existing KV pairs based on a Zipf distribution with a Zipfian constant of 0.99. We provision 40 GiB of space for vLog, and an additional 30% (12 GiB) of reserved space. We also disable the write cache in our prototype (see §3.2). Figure 2 shows the write amplification results of vLog in the Load and Update phases, in terms of the ratio of the total device write size to the actual write size due to inserts or updates. For comparison, we also consider two modern KV stores, LevelDB [15] and RocksDB [12], based on their default parameters. In the Load phase, vLog has sufficient space to hold all KV pairs and does not trigger GC, so its write amplification is only 1.6× due to KV separation. However, in the Update phase, the updates fill up the reserved space and start to trigger GC. We see that vLog has a write amplification of 19.7×, which is close to LevelDB (19.1×) and higher than RocksDB (7.9×).

To mitigate GC overhead in vLog, one approach is to partition vLog into segments and choose the best candidate segments that minimize GC overhead based on the cost-benefit policy or its variants [26, 31, 32]. However, the hot and cold KV pairs can still be mixed together in vLog, so the chosen segments for GC may still contain cold KV pairs that are unnecessarily moved.

To address the mixture of hot and cold data, a better approach is to perform *hot-cold data grouping* as in SSD designs [19, 27], in which we separate the storage of hot and cold KV pairs into two regions and apply GC to each region individually (more GC operations are expected to be applied to the storage region for hot KV pairs). However, the direct implementation of hot-cold data grouping inevitably increases the update latency in KV separation. As a KV pair may be stored in either hot or cold regions, each update needs to first query the LSM-tree for the exact storage location of the KV pair. Thus, a key motivation of our work is to enable hotness awareness without LSM-tree lookups.

3 HashKV Design

HashKV is a persistent KV store that specifically targets update-intensive workloads. It improves the management of value storage atop KV separation to achieve high update performance. It supports standard KV operations: PUT (i.e., writing a KV pair), GET (i.e., retrieving the value of a key), DELETE (i.e., deleting a KV pair), and SCAN (i.e., retrieving the values of a range of keys).

3.1 Main Idea

HashKV follows KV separation [23] by storing only keys and metadata in the LSM-tree for indexing KV pairs, while storing values in a separate area called the *value store*. Atop KV separation, HashKV introduces several core design elements to achieve efficient value storage management.

- **Hash-based data grouping:** Recall that vLog incurs substantial GC overhead in value storage. Instead, HashKV maps values into fixed-size partitions in the value store by hashing the associated keys. This design achieves: (i) *partition isolation*, in which all versions of value updates associated with the same key must be written to the same partition, and (ii) *deterministic grouping*, in which the partition where a value should be stored is determined by hashing. We leverage this design to achieve flexible and lightweight GC.
- **Dynamic reserved space allocation:** Since we map values into fixed-size partitions, one challenge is that a partition may receive more updates than it can hold. HashKV allows a partition to grow *dynamically* beyond its size limit by allocating fractions of reserved space in the value store.
- **Hotness awareness:** Due to deterministic grouping, a partition may be filled with the values from a mix of hot and cold KV pairs, in which case a GC operation unnecessarily reads and writes back the values of cold KV pairs. HashKV uses a *tagging* approach to relocate the values of cold KV pairs to a different storage area and separate the hot and cold KV pairs, so that we can apply GC to hot KV pairs only and avoid re-copying cold KV pairs.
- **Selective KV separation:** HashKV differentiates KV pairs by their value sizes, such that the small-size KV pairs can be directly stored in the LSM-tree without KV separation. This saves the overhead of accessing both the LSM-tree and the value store for small-size KV pairs, while the compaction overhead of storing the small-size KV pairs in the LSM-tree is limited.

Remarks: HashKV maintains a single LSM-tree for indexing (instead of hash-partitioning the LSM-tree as in the value store) to preserve the ordering of keys and the range scan performance. Since hash-based data grouping spreads KV pairs across the value store, it incurs random writes; in contrast, vLog maintains sequential writes with a log-structured storage layout. Our HashKV prototype (see §3.8) exploits both multi-threading and batch writes to limit random write overhead.

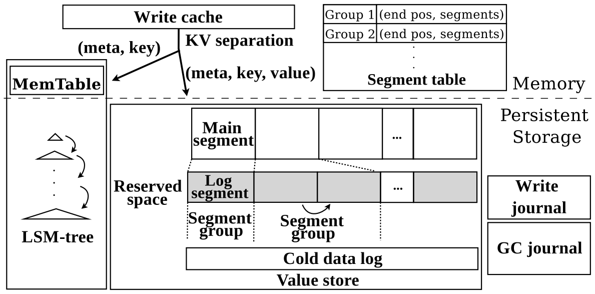

Figure 3: HashKV architecture.

3.2 Storage Management

Figure 3 depicts the architecture of HashKV. It divides the logical address space of the value store into fixed-size units called *main segments*. Also, it over-provisions a fixed portion of reserved space, which is again divided into fixed-size units called *log segments*. Note that the sizes of main segments and log segments may differ; by default, we set them as 64 MiB and 1 MiB, respectively.

For each insert or update of a KV pair, HashKV hashes its key into one of the main segments. If the main segment is not full, HashKV stores the value in a log-structured manner by appending the value to the end of the main segment; on the other hand, if the main segment is full, HashKV dynamically allocates a free log segment to store the extra values in a log-structured manner. Again, it further allocates additional free log segments if the current log segment is full. We collectively call a main segment and all its associated log segments a *segment group*. Also, HashKV updates the LSM-tree for the latest value location. To keep track of the storage status of the segment groups and segments, HashKV uses a global in-memory *segment table* to store the current end position of each segment group for subsequent inserts or updates, as well as the list of log segments associated with each segment group. Our design ensures that each insert or update can be directly mapped to the correct write position without issuing LSM-tree lookups on the write path, thereby achieving high write performance. Also, the updates of the values associated with the same key must go to the same segment group, and this simplifies GC. For fault tolerance, HashKV checkpoints the segment table to persistent storage.

To facilitate GC, HashKV also stores the key and metadata (e.g., key/value sizes) together with the value for each KV pair in the value store as in WiscKey [23] (see Figure 3). This enables a GC operation to quickly identify the key associated with a value when it scans the value store. However, our GC design inherently differs from vLog used by WiscKey (see §3.3).

To improve write performance, HashKV holds an in-memory *write cache* to store the recently written KV pairs, at the expense of degrading reliability. If the key of a new KV pair to be written is found in the write cache, HashKV directly updates the value of the cached key in-place without issuing the writes to the LSM-tree and the value store. It can also return the KV pairs from the write cache for reads. If the write cache is full, HashKV flushes all the cached KV pairs to the LSM-tree and the value store. Note that the write cache is an optional component and can be disabled for reliability concerns.

HashKV supports hotness awareness by keeping cold values in a separate *cold data log* (see §3.4). It also addresses crash consistency by tracking the updates in both *write journal* and *GC journal* (see §3.7).

3.3 Garbage Collection (GC)

HashKV necessitates GC to reclaim the space occupied by invalid values in the value store. In HashKV, GC operates in units of segment groups, and is triggered when the free log segments in the reserved space are running out. At a high level, a GC operation first selects a candidate segment group and identifies all valid KV pairs (i.e., the KV pairs of the latest version) in the group. It then writes back all valid KV pairs to the main segment, or additional log segments if needed, in a log-structured manner. It also releases any unused log segments that can be later used by other segment groups. Finally, it updates the latest value locations in the LSM-tree. Here, the GC operation needs to address two issues: (i) which segment group should be selected for GC; and (ii) how the GC operation quickly identifies the valid KV pairs in the selected segment group.

Unlike vLog, which requires the GC operation to follow a strict sequential order, HashKV can flexibly choose which segment group to perform GC. It currently adopts a *greedy* approach and selects the segment group with the largest amount of writes. Our rationale is that the selected segment group typically holds the hot KV pairs that have many updates and hence has a large amount of writes. Thus, selecting this segment group for GC likely reclaims the most free space. To realize the greedy approach, HashKV tracks the amount of writes for each segment group in the in-memory segment table (see §3.2), and uses a *heap* to quickly identify which segment group receives the largest amount of writes.

To check the validity of KV pairs in the selected segment group, HashKV sequentially scans the KV pairs in the segment group without querying the LSM-tree (note that it also checks the write cache for any latest KV pairs in the segment group). Since the KV pairs are written to the segment group in a log-structured manner, the KV pairs must be sequentially placed according to their order of being updated. For a KV pair that has multiple versions of updates, the version that is nearest to the end of the segment group must be the latest one and correspond to the valid KV pair, while other versions are invalid. Thus, the running time for each GC operation only depends on the size of the segment group that needs to be scanned. In contrast, the GC operation in vLog reads a chunk of KV pairs from the vLog tail (see §2.2). It queries the LSM-tree (based on the keys stored along with the values) for the latest storage location of each KV pair in order to check if the KV pair is valid [23]. The overhead of querying the LSM-tree becomes substantial under large workloads.

During a GC operation on a segment group, HashKV constructs a temporary in-memory hash table (indexed by keys) to buffer the addresses of the valid KV pairs being found in the segment group. As the key and address sizes are generally small and the number of KV pairs in a segment group is limited, the hash table has limited size and can be entirely stored in memory.

3.4 Hotness Awareness

Hot-cold data separation improves GC performance in log-structured storage (e.g., SSDs [19, 27]). In fact, the current hash-based data grouping design realizes some form of hot-cold data separation, since the updates of the hot KV pairs must be hashed to the same segment group and our current GC policy always chooses the segment group that is likely to store the hot KV pairs (see §3.3). However, it is inevitable that some cold KV pairs are hashed to the segment group selected for GC, leading to unnecessary data rewrites. Thus, a challenge is to fully realize hot-cold data separation to further improve GC performance.

HashKV relaxes the restriction of hash-based data grouping via a *tagging* approach (see Figure 4). Specifically, when HashKV performs a GC operation on a segment group, it classifies each KV pair in the segment group as hot or cold. Currently, we treat the KV pairs that are updated at least once since their last inserts as hot, or cold otherwise (more accurate hot-cold data identification approaches [16] can be used). For the hot KV pairs, HashKV still writes back their latest versions to the same segment group via hashing. However, for the cold KV pairs, it now writes their values to a separate storage area, and keeps their metadata only (i.e., without values) in the segment group. In addition, it adds a *tag* in the metadata of each cold KV pair to indicate its presence in the segment group. Thus, if a cold KV pair is later updated, we know directly from the tag (without querying the LSM-tree) that the cold KV pair has already been stored, so that we can treat it as hot based on our classification policy; the tagged KV pair will also become invalid. Finally, at the end of the GC operation, HashKV updates the latest value locations in the LSM-

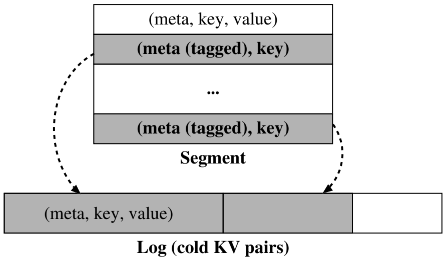

Figure 4: Tagging in HashKV.

tree, such that the locations of the cold KV pairs point to the separate area.

With tagging, HashKV avoids storing the values of cold KV pairs in the segment group and rewriting them during GC. Also, tagging is only triggered during GC, and does not add extra overhead to the write path. Currently, we implement the separate storage area for cold KV pairs as an append-only log (called the *cold data log*) in the value store, and perform GC on the cold data log as in vLog. The cold data log can also be put in secondary storage with a larger capacity (e.g., hard disks) if the cold KV pairs are rarely accessed.

3.5 Selective KV Separation

HashKV supports workloads with general value sizes. Our rationale is that KV separation reduces compaction overhead especially for large-size KV pairs, yet its benefits for small-size KV pairs are limited, and it incurs extra overhead of accessing both the LSM-tree and the value store. Thus, we propose *selective* KV separation, in which we still apply KV separation to KV pairs with large value sizes, while storing KV pairs with small value sizes in *entirety* in the LSM-tree. A key challenge of selective KV separation is to choose the KV pair size threshold of differentiating between small-size and large-size KV pairs (assuming that the key size remains fixed). We argue that the choice depends on the deployment environment. In practice, we can conduct performance tests for different value sizes to see when the throughput gain of selective KV separation becomes significant.

3.6 Range Scans

One critical reason of using the LSM-tree for indexing is its efficient support of range scans. Since the LSM-tree stores and sorts KV pairs by keys, it can return the values of a range of keys via sequential reads. However, KV separation now stores values in separate storage space, so it incurs extra reads of values. In HashKV, the values are scattered across different segment groups, so range scans will trigger many random reads that degrade performance. HashKV currently leverages the *read-ahead* mechanism to speed up range scans by prefetching values into the page cache. For each scan request, HashKV iterates over the range of sorted keys in the LSM-tree, and issues a read-ahead request to each value (via `posix_fadvise`). It then reads all values and returns the sorted KV pairs.

3.7 Crash Consistency

Crashes can occur while HashKV issues writes to persistent storage. HashKV addresses crash consistency based on *metadata journaling* and focuses on two aspects: (i) flushing the write cache and (ii) GC operations.

Flushing the write cache involves writing the KV pairs to the value store and updating metadata in the LSM-tree. HashKV maintains a *write journal* to track each flushing operation. It performs the following steps when flushing the write cache: (i) flushing the cached KV pairs to the value store; (ii) appending metadata updates to the write journal; (iii) writing a commit record to the journal end; (iv) updating keys and metadata in the LSM-tree; and (v) marking the flush operation free in the journal (the freed journaling records can be recycled later). If a crash occurs after step (iii) completes, HashKV replays the updates in the write journal and ensures that the LSM-tree and the value store are consistent.

Handling crash consistency in GC operations is different, as they may overwrite existing valid KV pairs. Thus, we also need to protect existing valid KV pairs against crashes during GC. HashKV maintains a *GC journal* to track each GC operation. It performs the following steps after identifying all valid KV pairs during a GC operation: (i) appending the valid KV pairs that are overwritten as well as metadata updates to the GC journal; (ii) writing all valid KV pairs back to the segment group; (iii) updating the metadata in the LSM-tree; and (iv) marking the GC operation free in the journal.

3.8 Implementation Details

We prototype HashKV in C++ on Linux. We use LevelDB v1.20 [15] for the LSM-tree. Our prototype contains around 6.7K lines of code (without LevelDB).

Storage organization: We currently deploy HashKV on a RAID array with multiple SSDs for high I/O performance. We create a software RAID volume using `mdadm` [22], and mount the RAID volume as an Ext4 file system, on which we run both LevelDB and the value store. In particular, HashKV manages the value store as a large file. It partitions the value store file into two regions, one for main segments and another for log segments, according to the pre-configured segment sizes. All segments are aligned in the value store file, such that the start offset of each main (resp. log) segment is a multiple of the main (resp. log) segment size. If hotness awareness is enabled (see §3.4), HashKV adds a separate region in the value store file for the cold data log. Also, to address crash consistency (see §3.7), HashKV uses separate files to store both write and GC journals.

Multi-threading: HashKV implements multi-threading via `threadpool` [36] to boost I/O performance when flushing KV pairs in the write cache to different segments (see §3.2) and retrieving segments from segment groups in parallel during GC (see §3.3).

To mitigate random write overhead due to deterministic grouping (see §3.1), HashKV implements batch writes. When HashKV flushes KV pairs in the write cache, it first identifies and buffers a number of KV pairs that are hashed to the same segment group in a *batch*, and then issues a sequential write (via a thread) to flush the batch. A larger batch size reduces random write overhead, yet it also degrades parallelism. Currently, we configure a batch write threshold, such that after adding a KV pair into a batch, if the batch size reaches or exceeds the batch size threshold, the batch will be flushed; in other words, HashKV directly flushes a KV pair if its size is larger than the batch write threshold.

4 Evaluation

We compare via testbed experiments HashKV with several state-of-the-art KV stores: LevelDB (v1.20) [15], RocksDB (v5.8) [12], HyperLevelDB [11], PebblesDB [30], and our own vLog implementation for KV separation based on WiscKey [23]. For fair comparison, we build a unified framework to integrate such systems and HashKV. Specifically, all written KV pairs are buffered in the write cache and flushed when the write cache is full. For LevelDB, RocksDB, HyperLevelDB, and PebblesDB, we flush all KV pairs in entirety to them; for vLog and HashKV, we flush keys and metadata to LevelDB, and values (together with keys and metadata) to the value store. We address the following questions:

- How is the update performance of HashKV compared to other KV stores under update-intensive workloads? (Experiment 1)
- How do the reserved space size and RAID configurations affect the update performance of HashKV? (Experiments 2 and 3)
- What is the performance of HashKV under different workloads (e.g., varying KV pair sizes and range scans)? (Experiments 4 and 5)
- What are the performance gains of hotness awareness and selective KV separation? (Experiments 6 and 7)
- How does the crash consistency mechanism affect the update performance of HashKV? (Experiment 8)
- How do parameter configurations (e.g., main segment size, log segment size, and write cache size) affect the update performance of HashKV? (Experiment 9)

In our technical report [5], we present results of additional experiments on the storage space usage, update performance, and range scan performance of HashKV and state-of-the-art KV stores.

4.1 Setup

Testbed: We conduct our experiments on a machine running Ubuntu 14.04 LTS with Linux kernel 3.13.0. The machine is equipped with a quad-core Xeon E3-1240v2, 16 GiB RAM, and seven Plextor M5 Pro 128 GiB SSDs. We attach one SSD to the motherboard as the OS drive, and attach six SSDs to the LSI SAS 9201-16i host bus adapter to form a RAID volume (with a chunk size of 4 KiB) for the KV stores (see §3.8).

Default setup: For LevelDB, RocksDB, HyperLevelDB, and PebblesDB, we use their default parameters. We allow them to use all available capacity in our SSD RAID volume, so that their major overheads come from read and write amplifications in the LSM-tree management.

For vLog, we configure it to read 64 MiB from the vLog tail (see §2.2) in each GC operation. For HashKV, we set the main segment size as 64 MiB and the log segment size as 1 MiB. Both vLog and HashKV are configured with 40 GiB of storage space and over-provisioned with 30% (or 12 GiB) of reserved space, while their key and metadata storage in LevelDB can use all available storage space. Here, we provision the storage space of vLog and HashKV to be close to the actual KV store sizes of LevelDB and RocksDB based on our evaluation (see Experiment 1).

We mount the SSD RAID volume under RAID-0 (no fault tolerance) by default to maximize performance. All KV stores run in asynchronous mode and are equipped with a write cache of size 64 MiB. For HashKV, we set the batch write threshold (see §3.8) to 4 KiB, and configure 32 and 8 threads for write cache flushing and segment retrieval in GC, respectively. We disable selective KV separation, hotness awareness, and crash consistency in HashKV by default, except when we evaluate them.

4.2 Performance Comparison

We compare the performance of different KV stores under update-intensive workloads. Specifically, we generate workloads using YCSB [7], and fix the size of each KV pair as 1 KiB, which consists of the 8-B metadata (including the key/value size fields and reserved information), 24-B key, and 992-B value. We assume that each KV store is initially empty. We first load 40 GiB of KV pairs (or 42 M inserts) into each KV store (call it Phase P0). We then repeatedly issue 40 GiB of updates over the existing 40 GiB of KV pairs *three* times (call them Phases P1, P2, and P3), accounting for 120 GiB or 126 M updates in total. Updates in each phase follow a heavy-tailed Zipf distribution with a Zipfian constant of 0.99. We issue the requests to each KV store as fast as possible to stress-test its performance.

Note that vLog and HashKV do not trigger GC in P0. In P1, when the reserved space becomes full after 12 GiB of updates, both systems start to trigger GC; in both P2

(a) Throughput

(b) Total write size

(c) Latency breakdown (‘V’= vLog; ‘H’= HashKV)

Figure 6: Experiment 2: Impact of reserved space size.

and P3, updates are issued to the fully filled value store and will trigger GC frequently. We include both P2 and P3 to ensure that the update performance is stable.

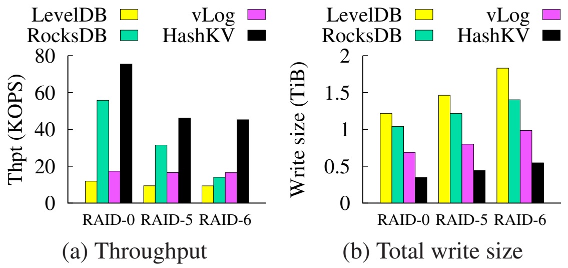
Experiment 1 (Load and update performance): We evaluate LevelDB (LDB), RocksDB (RDB), HyperLevelDB (HDB), PebblesDB (PDB), vLog, and HashKV (HKV), under update-intensive workloads. We first compare LevelDB, RocksDB, vLog, and HashKV; later, we also include HyperLevelDB and PebblesDB into our comparison.

Figure 5(a) shows the performance of each phase. For vLog and HashKV, the throughput in the load phase is higher than those in the update phases, as the latter is dominated by the GC overhead. In the load phase, the throughput of HashKV is 17.1× and 3.0× over LevelDB and RocksDB, respectively. HashKV's throughput is 7.9% slower than vLog, due to random writes introduced to distribute KV pairs via hashing. In the update phases, the throughput of HashKV is 6.3-7.9×, 1.3-1.4×, and 3.7-4.6× over LevelDB, RocksDB, and vLog, respectively. LevelDB has the lowest throughput among all KV stores due to significant compaction overhead, while vLog also suffers from high GC overhead.

Figures 5(b) and 5(c) show the total write sizes and the KV store sizes of different KV stores after all load and update requests are issued. HashKV reduces the total write sizes of LevelDB, RocksDB and vLog by 71.5%, 66.7%, and 49.6%, respectively. Also, they have very similar KV store sizes.

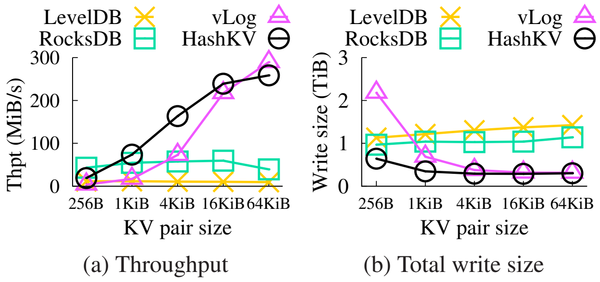
For HyperLevelDB and PebblesDB, both of them have high load and update throughput due to their low compaction overhead. For example, PebblesDB appends fragmented SSTables from the higher level to the lower level, without rewriting SSTables at the lower level [30]. Both HyperLevelDB and PebblesDB achieve at least twice throughput of HashKV, while incurring lower write sizes than HashKV. On the other hand, they incur significant storage overhead, and their final KV store sizes are 2.2× and 1.7× over HashKV, respectively. The main reason is that both HyperLevelDB and PebblesDB compact only selected ranges of keys to reduce write amplification, such that there may still remain many invalid KV pairs after compaction. They also trigger compaction operations less frequently than LevelDB. Both factors lead to high storage overhead. We provide more detailed analysis on the high storage costs of HyperLevelDB and PebblesDB in [5]. In the following experiments, we focus on LevelDB, RocksDB, vLog, and HashKV, as they have comparable storage overhead.

Experiment 2 (Impact of reserved space): We study the impact of reserved space size on the update performance of vLog and HashKV. We vary the reserved space size from 10% to 90% (of 40 GiB). Figure 6 shows the performance in Phase P3, including the update throughput, the total write size, and the latency breakdown. Both vLog and HashKV benefit from the increase in reserved space. Nevertheless, HashKV achieves 3.1-4.7× throughput of vLog and reduces the write size of vLog by 30.1-57.3% across different reserved space sizes. As shown in Figure 6(c), the queries to the LSM-tree during GC incur substantial performance overhead to vLog. We observe that HashKV spends less time on updating metadata during GC (“Meta-GC”) in the LSM-tree with the increasing reserved space size due to less frequent GC operations.



(a) Throughput (b) Total write size

Figure 7: Experiment 3: Different RAID configurations.



(a) Throughput (b) Total write size

Figure 8: Experiment 4: Performance of KV stores under different KV pair sizes.

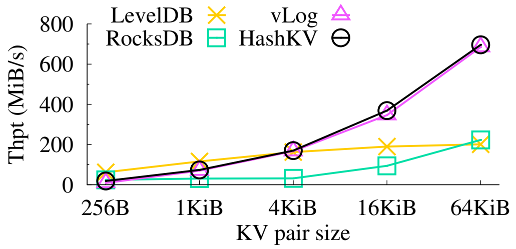


Figure 9: Experiment 5: Range scan performance of different KV stores.

Experiment 3 (Impact of parity-based RAID): We evaluate the impact of the fault tolerance configuration of RAID on the update performance of LevelDB, RocksDB, vLog, and HashKV. We configure the RAID volume to run two parity-based RAID schemes, RAID-5 (single-device fault tolerance) and RAID-6 (double-device fault tolerance). We include the results under RAID-0 for comparison. Figure 7 shows the throughput in Phase P3 and the total write size. RocksDB and HashKV are more sensitive to RAID configurations (larger drops in throughput), since their performance is write-dominated. Nevertheless, the throughput of HashKV is higher than other KV stores under parity-based RAID schemes, e.g., 4.8×, 3.2×, and 2.7× over LevelDB, RocksDB, and vLog, respectively, under RAID-6. The write sizes of KV stores under RAID-5 and RAID-6 increase by around 20% and 50%, respectively, compared to RAID-0, which match the amount of redundancy of the corresponding parity-based RAID schemes.

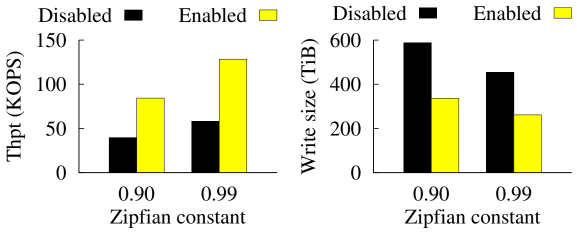
4.3 Performance under Different Workloads

We now study the update and range scan performance of HashKV for different KV pair sizes.

Experiment 4 (Impact of KV pair size): We study the impact of KV pair sizes on the update performance of KV stores. We vary the KV pair size from 256 B to 64 KiB. Specifically, we increase the KV pair size by increasing the value size and keeping the key size fixed at 24 B. We also reduce the number of KV pairs loaded or updated, such that the total size of KV pairs is fixed at 40 GiB. Figure 8 shows the update performance of KV stores in Phase P3 versus the KV pair size. The throughput of LevelDB and RocksDB remains similar across most KV pair sizes, while the throughput of vLog and HashKV increases as the KV pair size increases. Both vLog and HashKV have lower throughput than LevelDB and RocksDB when the KV pair size is 256 B, since the overhead of writing small values to the value store is more significant. Nevertheless, HashKV can benefit from selective KV separation (see Experiment 7). As the KV pair size increases, HashKV also sees increasing throughput. For example, HashKV achieves 15.5× and 2.8× throughput over LevelDB and RocksDB, respectively, for 4-KiB KV pairs. HashKV achieves 2.2-5.1× throughput over vLog for KV pair sizes between 256 B and 4 KiB. The performance gap between vLog and HashKV narrows as the KV pair size increases, since the size of the LSM-tree decreases with fewer KV pairs. Thus, the queries to the LSM-tree of vLog are less expensive. For 64-KiB KV pairs, HashKV has 10.7% less throughput than vLog.

When the KV pair size increases, the total write sizes of LevelDB and RocksDB increase due to the increasing compaction overhead, while those of HashKV and vLog decrease due to fewer KV pairs in the LSM-tree. Overall, HashKV reduces the total write sizes of LevelDB, RocksDB, and vLog by 43.2-78.8%, 33.8-73.5%, and 3.5-70.6%, respectively.

Experiment 5 (Range scans): We compare the range scan performance of KV stores for different KV pair sizes. Specifically, we first load 40 GiB of fixed-size KV pairs, and then issue scan requests whose start keys follow a Zipf distribution with a Zipfian constant of 0.99. Each scan request reads 1 MiB of KV pairs, and the total scan size is 4 GiB. Figure 9 shows the results. HashKV has similar scan performance to vLog across KV pair sizes. However, HashKV has 70.0% and 36.3% lower scan throughput than LevelDB for 256-B and 1-KiB KV pairs, respectively, mainly because HashKV needs to issue reads to both the LSM-tree and the value store and there is also high overhead of retrieving small values from the value store via random reads. Nevertheless, for KV pairs of 4 KiB or larger, HashKV outperforms LevelDB, e.g., by 94.2% for 4-KiB KV pairs. The lower



(a) Throughput (b) Total write size

Figure 10: Experiment 6: Hotness awareness.

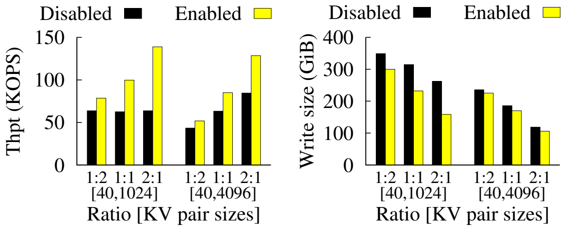
scan performance for small KV pairs is also consistent with that of WiscKey (see Figure 12 in [23]). Note that the read-ahead mechanism (see §3.6) is critical to enabling HashKV to achieve high range scan performance. For example, the range scan throughput of HashKV increases by 81.0% for 256-B KV pairs compared to without read-ahead. We also evaluate the range scan performance of HashKV after we issue update-intensive workloads in [5].

4.4 HashKV Features

We study the two optimizations of HashKV, hotness awareness and selective KV separation, and the crash consistency mechanism of HashKV. We report the throughput in Phase P3 and the total write size. We consider 20% of reserved space to show that the optimized performance of smaller reserved space can match the unoptimized performance of larger reserved space.

Experiment 6 (Hotness awareness): We evaluate the impact of hotness awareness on the update performance of HashKV. We consider two Zipfian constants, 0.9 and 0.99, to capture different skewness in workloads. Figure 10 shows the results when hotness awareness is disabled and enabled. When hotness awareness is enabled, the update throughput increases by 113.1% and 121.3%, while the write size reduces by 42.8% and 42.5%, for Zipfian constants 0.9 and 0.99, respectively.

Experiment 7 (Selective KV separation): We evaluate the impact of selective KV separation on the update performance of HashKV. We consider three ratios of small-to-large KV pairs, including 1:2, 1:1, and 2:1. We set the small KV pair size as 40 B, and the large KV pair size as 1 KiB or 4 KiB. Figure 11 shows the results when selective KV separation is disabled or enabled. When selective KV separation is enabled, the throughput increases by 23.2-118.0% and 19.2-52.1% when the large KV pair size is 1 KiB and 4 KiB, respectively. We observe higher performance gain for workloads with a higher ratio of small KV pairs, due to the high update overhead of small KV pairs stored under KV separation. Also, selective KV separation reduces the total write size by 14.1-39.6% and 4.1-10.7% when the large KV pair size is 1 KiB and 4 KiB, respectively.



(a) Throughput (b) Total write size

Figure 11: Experiment 7: Selective KV separation.

	Disabled	Enabled
Throughput (KOPS)	58.0	54.3
Total write size (GiB)	454.6	473.7

Table 1: Experiment 8: Performance of HashKV with crash consistency disabled and enabled.

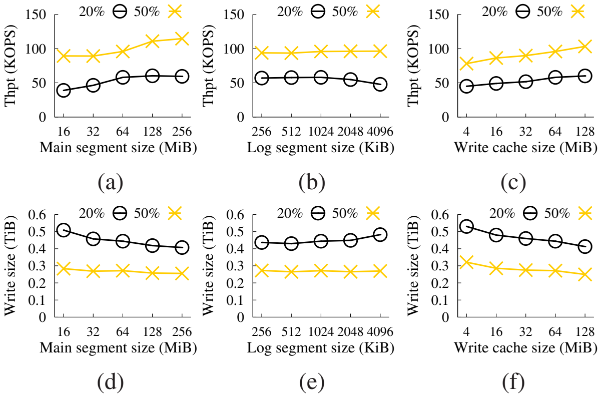
Experiment 8 (Crash consistency): We study the impact of the crash consistency mechanism on the performance of HashKV. Table 1 shows the results. When the crash consistency mechanism is enabled, the update throughput of HashKV in Phase P3 reduces by 6.5% and the total write size increases by 4.2%, which shows that the impact of crash consistency mechanism remains limited. Note that we verify the correctness of the crash consistency mechanism by crashing HashKV via code injection and unexpected terminations during runtime.

4.5 Parameter Choices

We further study the impact of parameters, including the main segment size, the log segment size, and the write cache size on the update performance of HashKV. We vary one parameter in each test, and use the default values for other parameters. We report the update throughput in Phase P3 and the total write size. Here, we focus on 20% and 50% of reserved space.

Experiment 9 (Impact of main segment size, log segment size, and write cache size): We first consider the main segment size. Figures 12(a) and 12(d) show the results versus the main segment size. When the main segment size increases, the throughput of HashKV increases, while the total write size decreases. The reason is that there are fewer segment groups for larger main segments, so each segment group receives more updates in general. Each GC operation can now reclaim more space from more updates, so the performance improves. We see that the update performance of HashKV is more sensitive to the main segment size under limited reserved space. For example, the throughput increases by 52.5% under 20% of reserved space, but 28.3% under 50% of reserved space, when the main segment size increases from 16 MiB to 256 MiB.

We next consider the log segment size. Figures 12(b)



(a) (b) (c)

(d) (e) (f)

Figure 12: Experiment 9: Throughput and total write size of HashKV versus the main segment size ((a) and (d)), the log segment size ((b) and (e)), and the write cache size ((c) and (f)).

and 12(e) show the results versus the log segment size. We see that when the log segment size increases from 256 KiB to 4 MiB, the throughput of HashKV drops by 16.1%, while the write size increases by 10.4% under 20% of reserved space. The reason is that the utilization of log segments decreases as the log segment size increases. Thus, each GC operation reclaims less free space, and the performance drops. However, when the reserved space size increases to 50%, we do not see significant performance differences, and both the throughput and the write size remain almost unchanged across different log segment sizes.

We finally consider the write cache size. Figures 12(c) and 12(f) show the results versus the write cache size. As expected, the throughput of HashKV increases and the total write size drops as the write cache size increases, since a larger write cache can absorb more updates. For example, under 20% of reserved space, the throughput of HashKV increases by 29.1% and the total write size reduces by 16.3% when the write cache size increases from 4 MiB to 64 MiB.

5 Related Work

General KV stores: Many KV store designs are proposed for different types of storage backends, such as DRAM [1, 13, 14, 21], commodity flash-based SSDs [8,9,20,23], open-channel SSDs [34], and emerging non-volatile memories [25, 40]. The above KV stores and HashKV are designed for a single server. They can serve as building blocks of a distributed KV store (e.g., [28]).

LSM-tree-based KV stores: Many studies modify the LSM-tree design for improved compaction performance. bLSM [33] proposes a new merge scheduler to prevent compaction from blocking writes, and uses Bloom filters for efficient indexing. VT-Tree [35] stitches already sorted blocks of SSTables to allow lightweight compaction overhead, at the expense of incurring fragmentation. LSM-trie [39] maintains a trie structure and organizes KV pairs by hash-based buckets within each SSTable. It also organizes large Bloom filters in clustered disk blocks for efficient I/O access. LWC-store [41] decouples data and metadata management in compaction by merging and sorting only the metadata in SSTables. SkipStore [42] pushes KV pairs across non-adjacent levels to reduce the number of levels traversed during compaction. PebblesDB [30] relaxes the restriction of keeping disjoint key ranges in each level, and pushes partial SSTables across levels to limit compaction overhead.

KV separation: WiscKey [23] employs KV separation to remove value compaction in the LSM-tree (see §2.2). Atlas [18] also applies KV separation in cloud storage, in which keys and metadata are stored in an LSM-tree that is replicated, while values are separately stored and erasure-coded for low-redundancy fault tolerance. Cocytus [43] is an in-memory KV store that separates keys and values for replication and erasure coding, respectively. HashKV also builds on KV separation, and takes one step further to address efficient value management.

Hash-based data organization: Distributed storage systems (e.g., [10, 24, 38]) use hash-based data placement to avoid centralized metadata lookups. NVMKV [25] also uses hashing to map KV pairs in physical address space. However, it assumes sparse address space to limit the overhead of resolving hash collisions, and incurs internal fragmentation for small-sized KV pairs. In contrast, HashKV does not cause internal fragmentation as it packs KV pairs in each main/log segment in a log-structured manner. It also supports dynamic reserved space allocation when the main segments become full.

6 Conclusion

This paper presents HashKV, which enables efficient updates in KV stores under update-intensive workloads. Its novelty lies in leveraging hash-based data grouping for deterministic data organization so as to mitigate GC overhead. We further enhance HashKV with several extensions including dynamic reserved space allocation, hotness awareness, and selective KV separation. Testbed experiments show that HashKV achieves high update throughput and reduces the total write size.
