Message from the 2018 USENIX Annual Technical Conference Program Co-Chairs

Welcome to the 2018 USENIX Annual Technical Conference.

We are excited for ATC '18. We have had some very high-quality submissions, and clearly there has been a lot of work on behalf of both the authors who have contributed content and reviewers who have thoroughly reviewed submissions. In particular, we want to thank the program committee members and external reviewers who were willing to volunteer their time and also willing to take on a larger-than-expected load to ensure proper reviewing.

The incredible dedication by this year's program committee resulted in a program of 76 refereed papers and one keynote. These papers and keynote present novel research contributions and practical insights that advance the state-of-the-art in systems from a wide range of perspectives, demonstrating new capabilities or improvements for a variety of platforms and application scenarios. Given the spectrum of topics covered in the program, you are likely to find interesting ideas addressing your favorite areas and challenges.

For the traditional refereed papers track, we received a record number of paper registrations and submissions this year. Authors registered 557 papers, of which 377 (a 33% increase over last year) were complete submissions. The program co-chairs rejected one paper up front due to serious formatting violations. Of the submitted papers, 30 were short papers, which had to be at most five pages long (plus references), and the other 347 were full-length papers, which had to be at most 11 pages long plus references.

We required authors to submit abstracts a week before the paper submission in the hope of ensuring proper subject area coverage by the program committee and to get an idea of the reviewing load. This did not work. We had over 550 submitted abstracts, meaning almost 40% of the submissions were abandoned. In the end, requiring abstracts to be submitted early did not help with planning due to such a large number of abstracts that did not result in a submission.

The program committee had 72 members, excluding the 2 co-chairs. 28 of them had affiliations with industrial organizations, 42 with academic organizations (one member had dual affiliations), and 2 with government lab organizations. The committee represented three continents and seven countries. Program committee members were allowed to submit papers. The program co-chairs did not submit any papers.

We followed standard rules for handling conflicts of interest: conflicted members (or co-chairs) left the room during the discussion of conflicted papers. We followed the tradition of single-blind reviews. It was not a decision we explicitly made. Given the issues surrounding single-blind reviews, it was a decision that we should have thought about and justified. Reviews were done by the program committee in two rounds with a few external reviews. The chairs did not participate in any of the reviews. In the first round, each of the 377 submitted papers received at least two reviews. 219 (58%) of the papers moved to the second round. Each paper in round two received at least two additional reviews.

One of our goals was to get a large enough program committee so that we would not overwhelm members with review load and to give members enough time to produce quality reviews. Lower reviews also enable access to more potential committee members. We also had a light (20 members) and heavy committee (52). The light committee had an expected load of 12 to 16 papers and were not expected to attend the in-person committee meeting. The heavy committee had an expected load of 14-18 papers and were expected to attend the in-person meeting. As the load is relatively similar between light and heavy PC, we do not distinguish them on the website. When we saw the higher than expected number of submissions, we grew the committee. Furthermore, for papers where we lacked reviewer expertise in the main PC, we solicited 43 external reviewers, each reviewing on average one paper. In the end our committee members reviewed the maximum expected number of papers with a few going over the expectation. Altogether, we had more than 1,230 reviews.

After two phases of reviews, an online discussion was conducted among reviewers, during which the program committee decided to pre-accept 26 highly-ranked papers and pre-reject 69 more papers. These papers were not discussed in the PC Meeting while the rest of the round 2 papers, 124 papers, were discussed during the in-person program committee meeting.

The PC meeting was held on April 16–17 at the Facebook campus in Menlo Park, CA; more than 50 PC members attended the meeting in person and many others called in. During the meeting, 50 additional papers were accepted. Among these 76 acceptances, four were short papers. Because of the large number of papers to discuss, we had two parallel meetings run by each chair. We would like to thank PhD students Huaicheng Li and Mingzhe Hao of the University of Chicago for optimizing the scheduling of discussions for the meetings and for acting as scribes during the meetings. We also would like to thank Facebook engineers and staff for helping with the logistics of the PC meeting.

We added to the program one keynote, chosen from recommendations made by members of the program committee. We were not able to have any additional sessions due to the large number of presentations for accepted papers.

We are very grateful to all who contributed to ATC '18. In addition to the authors who submitted their work for consideration, the program committee, and the external reviewers, we would like to thank the USENIX staff for their outstanding conference management. By taking care of all organizational details, they enabled us to focus on building a strong program. We would also like to thank Facebook for their generosity in hosting the PC meeting.

We hope that you enjoy the conference. Thank you for participating in the USENIX ATC community!

Tributary: spot-dancing for elastic services with latency SLOs

Aaron Harlap[§*] Andrew Chung[§*] Alexey Tumanov[†]
Gregory R. Ganger[§] Phillip B. Gibbons[§]
[§]*Carnegie Mellon University* [†]*UC Berkeley*

Abstract

The Tributary elastic control system embraces the uncertain nature of transient cloud resources, such as AWS spot instances, to manage elastic services with latency SLOs more robustly and more cost-effectively. Such resources are available at lower cost, but with the proviso that they can be preempted *en masse*, making them risky to rely upon for business-critical services. Tributary creates models of preemption likelihood and exploits the partial independence among different resource offerings, selecting collections of resource allocations that satisfy SLO requirements and adjusting them over time, as client workloads change. Although Tributary's collections are often larger than required in the absence of preemptions, they are cheaper because of both lower spot costs and partial refunds for preempted resources. At the same time, the often-larger sets allow unexpected workload bursts to be absorbed without SLO violation. Over a range of web service workloads, we find that Tributary reduces cost for achieving a given SLO by 81–86% compared to traditional scaling on non-preemptible resources, and by 47–62% compared to the high-risk approach of the same scaling with spot resources.

1 Introduction

Elastic web services have been a cloud computing staple from the beginning, adaptively scaling the number of machines used over time based on time-varying client workloads. Generally, an adaptive scaling policy seeks to use just the number of machines required to achieve its *Service Level Objectives (SLOs)*, which are commonly focused on response latency and ensuring that a given percentage (*e.g.*, 95%) of requests are responded to in under a given amount of time [17, 28, 19]. Too many machines results in unnecessary cost, and too few results in excess customer dissatisfaction. As such, much research and development has focused on doing this well [20, 14, 11, 12, 26].

Elastic service scaling schemes generally assume independent and infrequent failures, which is a relatively safe assumption for high-priority allocations in private clouds and *non-preemptible* allocations in public clouds (e.g., on-demand instances in AWS EC2 [3]). This assumption enables scaling schemes to focus on client workload and server responsiveness variations in determining changes to the number of machines needed to meet SLOs.

Modern clouds also offer transient, *preemptible* resources (e.g., EC2 Spot Instances [1]) at a discount of 70–80% [6], creating an opportunity for cheaper service deployments. But, simply using standard scaling schemes fails to address the risks associated with such resources. Namely, preemptions should be expected to be more frequent than failures and, more importantly, preemptions often occur in bulk. Akin to co-occurring failures, bulk preemptions can cause traditional scaling schemes to have sizable gaps in SLO attainment.

This paper describes Tributary, a new elastic control system that exploits transient, preemptible resources to reduce cost and increase robustness to unexpected workload bursts. Tributary explicitly recognizes the bulk preemption risk, and it exploits the fact that preemptions are often not highly correlated across different pools of resources in heterogeneous clouds. For example, in AWS EC2, there is a separate spot market for each instance type in each availability zone, and researchers have noted that they often move independently: while preemptions within each spot market are correlated, across spot markets they are not [16]. To safely use preemptible resources, Tributary acquires collections of resources drawn from multiple pools, modified as resource prices change and preemptions occur, while endeavoring to ensure that no single bulk preemption would cause SLO violation. We refer to this dynamic use of multiple preemptible resource pools as *spot-dancing*.

AcquireMgr is Tributary's component that decides the resource collection's makeup. It works with any traditional scaling policy that determines (reactively or predictively) how many cores or machines are needed for each successive period of time, based on client load variation. AcquireMgr decides *which* instances will provide sufficient likelihood of meeting each time period's target at the lowest expected cost. Its probabilistic algorithm combines resource cost and preemption probability predictions for each pool to decide how many resources to include from each pool, and at what price to bid for any new resources (relative to the current market price).

[*] Equal contribution

Given that a preemption occurs when a market's spot price exceeds the bid price given at resource acquisition time, AcquireMgr can affect the preemption probability via the delta between its bid price and the current price, informed by historical pricing trends. In our implementation, which is specialized to AWS EC2, the predictions use machine learning (ML) models trained on historical EC2 Spot Price data. The expected cost of the computation takes into account EC2's policy of partial refunds for preempted instances, which often results in AcquireMgr choosing high-risk instances and achieving even bigger savings than just the discount for preemptibility.

In addition to the expected cost savings, Tributary's spot-dancing provides a burst tolerance benefit. Any elastic control scheme has some reaction delay between an unexpected burst and any resulting addition of resources, which can cause SLO violations. Because Tributary's resource collection is almost always bigger than the scaling policy's most recent target in order to accommodate bulk preemptions, extra resources are often available to handle unexpected bursts. Of course, traditional elastic control schemes can also acquire extra resources as a buffer against bursts, but only at a cost, whereas the extra resources when using Tributary are a bonus side-effect of AcquireMgr's robust cost savings scheme.

Results for four real-world web request arrival traces and real AWS EC2 spot market data demonstrate Tributary's cost savings and SLO benefits. For each of three popular scaling policies (one reactive and two predictive), Tributary's exploitation of AWS spot instances reduces cost by 81–86% compared to traditional scaling with on-demand instances for achieving a given SLO (e.g., 95% of requests below 1 second). Compared to unsafely using traditional scaling with spot instances (*AWS AutoScale* [2]) instead of on-demand instances, Tributary reduces cost by 47–62% for achieving a given SLO. Compared to other recent systems' policies for exploiting spot instances to reduce cost [24, 16], Tributary provides higher SLO attainment at significantly lower cost.

This paper makes four primary contributions. First, it describes Tributary, the first resource acquisition system that takes advantage of preemptible cloud resources for elastic services with latency SLOs. Second, it introduces AcquireMgr algorithms for composing resource collections of preemptible resources cost-effectively, exploiting the partial refund model of EC2's spot markets. Third, it introduces a new preemption prediction approach that our experiments with EC2 spot market price traces show is significantly more accurate than previous preemption predictors. Fourth, we show that Tributary's approach yields significant cost savings and robustness benefits relative to other state-of-the-art approaches.

2 Background and Related Work

Elastic services dynamically acquire and release machine resources to adapt to time-varying client load. We distinguish two aspects of elastic control, the *scaling policy* and the *resource acquisition scheme*. The scaling policy determines, at any point in time, *how many* resources the service needs in order to satisfy a given SLO. The resource acquisition scheme determines *which* resources should be allocated and, in some cases, aspects of how (e.g., bid price or priority level). This section discusses AWS EC2 spot instances and resource acquisition strategies to put Tributary and its new approach to resource acquisition into context.

2.1 Preemptible resources in AWS EC2

In addition to non-preemptible, or *reliable* resources, most cloud infrastructures offer preemptible resources as a way to increase utilization in their datacenters. Preemptible resources are made available, on a best-effort basis, at decreased cost (in for-pay settings) and/or at lower priority (in private settings). This subsection describes preemptible resources in AWS EC2, both to provide a concrete example and because Tributary and most related work specialize to EC2 behavior.

EC2 offers "on-demand instances", which are reliable VMs billed at a flat per-second rate. EC2 also offers the same VM types as "spot instances", which are preemptible but are usually billed at prices significantly lower (70% - 80%) than the corresponding on-demand price. EC2 may preempt spot instances at any time, thus presenting users with a trade-off between reliability (on-demand) and cost savings (spot).

There are several properties of the AWS EC2 spot market behavior that affect customer cost savings and the likelihood of instance preemption. (1) Each instance type in each availability zone has a unique AWS-controlled spot market associated with it, and AWS's spot markets are not truly free markets [9]. (2) Price movements among spot markets are not always correlated, even for the same instance type in a given region [23]. (3) Customers specify a bid in order to acquire a spot instance. The bid is the maximum price a customer is willing to pay for an instance in a specific spot market; once a bid is accepted by AWS, it cannot be modified. (4) A customer is billed the spot market price (not the bid price) for as long as the spot market price for the instance does not exceed the bid price or until the customer releases it voluntarily. (5) As of Oct 2nd, 2017, AWS charges for the usage of an EC2 instance up to the second, with one exception: if the spot market price of an instance exceeds the bid price during its first hour, the customer is refunded fully for its usage. No refund is given if the spot instance is revoked in any subsequent hour. We define the period where preemption makes the instance free as the *preemption window*.

When using EC2 spot instances, the bidding strategy plays an important role in both cost and preemption probability. Many bidding strategies for EC2 spot instances have been studied [9, 33, 30]. The most popular strategy by far is to bid the on-demand price to minimize the odds of preemption [23, 21], since AWS charges the market price rather than the bid price.

2.2 Cloud Resource Acquisition Schemes

Given a target resource count from a scaling policy, a resource acquisition scheme decides *which* resources to acquire based on attributes of resources (e.g., bid price or priority level). Many elastic control systems assume that all available resources are equivalent, such as would be true in a homogeneous cluster, which makes the acquisition scheme trivial. But, some others address resource selection and bidding strategy aspects of multiple available options. Tributary's AcquireMgr employs novel resource acquisition algorithms, and we discuss related work here.

AWS AutoScale [2] is a service provided by AWS that maintains the resource footprint according to the target determined by a scaling policy. At initialization time, if using on-demand instances, the user specifies an instance type and availability zone. Whenever the scaling target changes, AutoScale acquires or releases instances to reach the new target. If using spot instances, the user can use a so-called "spot fleet"[4] consisting of multiple instance type and availability zone options. In this case, the user configures AutoScale to use one of two strategies. The *lowestPrice* strategy will always select cheapest current spot price of the specified options. The *diversified* strategy will use an equal number of instances from each option. Tributary bids aggressively and diversifies based on predicted preemption rates and observed inter-market correlation, resulting in both higher SLO attainment and lower cost than AutoScale.

Kingfisher [26] uses a cost-aware resource acquisition scheme based on using integer linear programming to determine a service's resource footprint among a heterogeneous set of non-preemptible instances with fixed prices. Tributary also selects from among heterogeneous options, but addresses the additional challenges and opportunities introduced by embracing preemptible transient resources. Several works have explored ways of selecting and using spot instances. HotSpot [27] is a resource container that allows an application to suspend and automatically migrate to the most cost-efficient spot instance. While HotSpot works for single-instance applications, it is not suitable for elastic services since its migrations are not coordinated and it does not address bulk preemptions.

SpotCheck [25] proposes two methods of selecting spot markets to acquire instances in while always bidding at a configurable multiple of the spot instance's corresponding on-demand price. The first method is *greedy cheapest-first*, which picks the cheapest spot market. The second method is *stability-first*, which chooses the most price-stable market based on past market price movement. SpotCheck relies on VM migration and hot spares (on-demand or otherwise) to address revocations, which incurs additional cost, while Tributary uses a diverse pool of spot instances to mitigate revocation risk.

BOSS [32] hosts key-value stores on spot instances by exploiting price differences across pools in different data-centers and creating an online algorithm to dynamically size pools within a constant bound of optimality. Tributary also constructs its resource footprint from different pools, within and possibly across data-centers. Whereas BOSS assumes non-changing storage capacity requirements, Tributary dynamically scales its resource footprint to maintain the specified latency SLO while adapting to changes in client workload.

Wang et al. [31] explore strategies to decide whether, in the face of changing application behavior, it is better to reserve discounted resources over longer periods or lease resources at normal rates on a shorter term basis. Their solution combines on-demand and "reserved" (long term rental at discount price) instances, neither of which are ever preempted by Amazon.

ExoSphere [24] is a virtual cluster framework for spot instances. Its instance acquisition scheme is based on market portfolio theory, relying on a specified risk averseness parameter (α). ExoSphere formulates the *return* of a spot instance acquisition as the difference between the on-demand cost and the expected cost based on past spot market prices. It then tries to maximize the return of a set of instance allocations with respect to risk, considering market correlations and α, determining the fraction of desired resources to allocate in each spot market being considered. For a given virtual cluster size, ExoSphere will acquire the corresponding number of instances from each market at the on-demand price. Unsurprisingly, since it was created for a different usage model, ExoSphere's scheme is not a great fit for elastic services with latency SLOs. We implement ExoSphere's scheme and show in Section 5.6 that Tributary achieves lower cost, because it bids aggressively (resulting in more preemptions), and higher SLO attainment, because it explicitly predicts preemptions and selects resource sets based on sufficient tolerance of bulk preemptions.

Proteus [16] is an elastic ML system that combines on-demand resources with aggressive bidding of spot resources to complete batch ML training jobs faster and cheaper. Rather than bidding the on-demand price, it bids close to market price and aggressively selects spot markets and bid prices that it predicts will result in preemption, in hopes of getting many partial hours of free resources. The few on-demand resources are used to maintain a copy of the dynamic state as spot instances come and go, and acquisitions are made and used to scale the parallel computation whenever they would reduce the average cost per unit work. Although Tributary uses some of the same mindset (aggressive use of preemptible resources), elastic services with latency SLOs are different than batch processing jobs; elastic services have a target resource quantity for each point in time, and having fewer usually leads to SLO violations, while having more often provides no benefit. Unsurprisingly, therefore, we find that Proteus's scheme is not a great fit for such services. We implement Proteus's acquisition scheme and show in Section 5.6 that Tributary achieves much higher SLO attainment, because it understands the resource target and explicitly uses diversity to mitigate bulk preemption effects. Tributary also uses a new and much more accurate preemption predictor.

3 Elastic Control in Tributary

AcquireMgr is Tributary's resource acquisition component, and its approach differentiates Tributary from previous elastic control systems. It is coupled with a scaling policy, any of many popular options, which provides the time-varying resource quantity target based on client load. AcquireMgr uses ML models to predict the preemption probability of resources and exploits the relative independence of AWS spot markets to account for potential bulk preemptions by acquiring a diverse mix of preemptible resources collectively expected to satisfy the user-specified latency SLO. This section describes how AcquireMgr composes the resource mix while targeting minimal cost.

Resource Acquisition. AcquireMgr interacts with AWS to request and acquire resources. To do so, AcquireMgr builds sets of request vectors. Each request vector specifies the instance type, availability zone, bid price, and number of instances to acquire. We call this an *allocation request*. An *allocation* is defined as a set of instances of the same type acquired at the same time and price. AcquireMgr's *total footprint*, denoted with the variable A, is a set of such allocations. Resource acquisition decisions are made under four conditions: (1) a periodic (one-minute) clock event fires, (2) an allocation reaches the end of its preemption window, (3) the scaling policy specifies a change in resource requirement, and/or (4) a preemption occurs. We term these conditions *decision points*.

AcquireMgr abstracts away the resource type which is being optimized for. For the workloads described in this paper, virtual CPUs (VCPUs) are the bottleneck resource; however, it is possible to optimize for memory, network bandwidth, or other resource types instead. A service using Tributary provides its resource scaling characteristics to AcquireMgr in the form of a *utility function* $\upsilon()$. This *utility function* maps the number of resources to the percentage of requests expected to meet the target latency, given the load on the web service. The shape of a utility function is service-specific and depends on how the service scales, for the expected load, with respect to the number of resources. In the simplest case where the web service is embarrassingly parallel, the utility function is linear with respect to the number of resources offered until 100% of the requests are expected to be satisfied, at which point the function turns into a horizontal line. As a concrete example, if an embarrassingly parallel service specifies that 100 instances are required to handle 10000 requests per second without any of the requests missing the target latency, a linear utility function will assume that 50 instances will allow the system to meet the target latency on 50% of the requests. Tributary allows applications to customize the utility function so as to accommodate the resource requirements of applications with various scaling characteristics.

In addition to providing $\upsilon()$, the service also provides the application's target SLO in terms of a percentage of requests required to meet the target latency. By exposing the target SLO as a customizable input, Tributary allows the application to control the Cost-SLO tradeoff. Upon receiving this information, AcquireMgr acquires enough resources to meet SLO in expectation while optimizing for expected cost. In deciding which resources to acquire, AcquireMgr uses the prediction models described in Sec. 3.1 to predict the probability that each allocation would be preempted. Using these predictions, AcquireMgr can compute the expected cost and the expected utility of a set of allocations (Sec. 3.2). AcquireMgr greedily acquires allocations until the expected utility is greater than or equal to the SLO percentage requirement (Sec. 3.3).

3.1 Prediction Models

When acquiring spot instances on AWS, there are three configurable parameters that affect preemption probability: instance type, availability zone and bid price. This section describes the models used by AcquireMgr to predict allocation preemption probabilities.

Previous work [16] proposed taking the historical median probability of preemption based on the instance type, availability zone and bid price. This approach does not consider time of day, day of week, price fluctuations and several other factors that affect preemption probabilities. AcquireMgr trains ML models considering such features to predict resource reliability.

Training Data and Feature Engineering. The prediction models are trained ahead of time with data derived from AWS spot market price histories. Each sample in the training dataset is a *hypothetical bid*, and the *target variable*, `preempted`, of our model is whether or not an instance acquired with the hypothetical bid is preempted before the end of its preemption window (1 hr). We use the following method to generate our data set: For each instance and *bid delta* (bid price above the market price with range $[0.00001, 0.2]$) we generate a set of hypothetical bids with the bid starting at a random point in the spot market history. For each bid, we look forward in the spot market price history. If the market price of the instance rises above the bid price at any point within the hour, we mark the sample as `preempted`. For each historical bid, we also record the ten prices immediately prior to the random starting point and their time-stamps.

To increase prediction accuracy, AcquireMgr engineers features from AWS spot market price histories. Our engineered features include: (1) Spot market price; (2) Average spot market price; (3) Bid delta; (4) Frequency of spot market price changing within past hour; (5) Magnitude of spot market price fluctuations within past two, ten, and thirty minutes; (6) Day of the week; (7) Time of day; (8) Whether the time of day falls within working hours (separate feature for all three time zones). These features allow AcquireMgr to construct a more complex prediction model, leading to a higher prediction accuracy (Sec. 5.7).

Model Design. To capture the temporal nature of the EC2 spot market, AcquireMgr uses a *Long Short-Term Memory Recurrent Neural Network (LSTM RNN)* to predict instance preemptions. The LSTM RNN is a popular model for workloads where the ordering of training examples is important to prediction accuracy [29]. Examples of such workloads include language modeling, machine translation, and stock market prediction. Unlike feed forward neural networks, LSTM models take previous inputs into account when classifying input data. Modeling the EC2 spot market as a *sequence* of events significantly improves prediction accuracy (Sec. 5.7). The output of the model is the probability of the resource being preempted within the hour.

3.2 AcquireMgr

To make decisions about which resources to acquire or release, AcquireMgr computes the expected cost and expected utility of the set of instances it is considering at each decision point. Calculations of the expected values are based on probabilities of preemption computed by AcquireMgr's trained LSTM model. This section describes how AcquireMgr computes these values.

Definitions. To aid in discussion, we first define the notion of a *resource pool*. Each instance type in each availability zone forms its own *resource pool*—in the context of the EC2 spot instances, each such resource pool has its own spot market. Given a *set of allocations* A, where A is formulated as a jagged array, let A_i be defined as the i^{th} entry of A corresponding to an array of allocations from resource pool i sorted by bid price in ascending order. We define allocation $a_{i,j}$ as an allocation from resource pool i (*i.e.*, $a_{i,j} \in A_i$) with the j^{th} lowest bid in that resource pool. We further denote $p_{i,j}$ as the bid price of allocation $a_{i,j}$, $\beta_{i,j}$ as the probability of preemption of allocation $a_{i,j}$, and $t_{i,j}$ as the time remaining in the preemption window for allocation $a_{i,j}$. Note that $p_{i,j} \geq p_{i,j-1}$, which also implies $\beta_{i,j-1} \geq \beta_{i,j}$. Finally, we define a *size*(A) function that returns the size of A's major dimension. See Table 1 for symbol reference.

A	Set of allocations as jagged array
A_i	Sorted array of allocations from resource pool i
$a_{i,j}$	Set of instances allocated from resource pool i
$\beta_{i,j}$	Probability that allocation $a_{i,j}$ is preempted
$t_{i,j}$	Time left in the preemption window for $a_{i,j}$
$k_{i,j}$	Number of instances in allocation $a_{i,j}$
$P_{i,j}$	Market price of allocation $a_{i,j}$
$p_{i,j}$	Bid price of allocation $a_{i,j}$
$size(y)$	Size of the major dimension of array y
$resc(y)$	Counts the total number of resources in y
λ_i	Regularization term for diversity
$P(R=r)$	Probability that r resources remain in A
$\upsilon(r)$	The utility of having r resources remain in A
V_A	The expected utility of a set of allocations A
C_A	Expected cost of a set of allocations ($)

Table 1: Summary of parameters used by AcquireMgr

Expected Cost. The total expected cost for a given footprint A is calculated as the sum over the expected cost of individual allocations $C_A[a_{i,j}]$:

$$C_A = \sum_{i=1}^{size(A)} \sum_{j=1}^{size(A_i)} C_A[a_{i,j}] \tag{1}$$

AcquireMgr calculates the *expected* cost of an allocation by considering the probability of preemption within the preemption window $\beta_{i,j}$ for a given allocation $a_{i,j}$ at a given *bid delta*. There are exactly two possibilities: an allocation will either be preempted with probability $\beta_{i,j}$ or it will reach the end of its preemption window in the remaining $t_{i,j}$ minutes with probability $1-\beta_{i,j}$, in which case we would voluntarily release the allocation. The expected cost can then be written down as:

$$C_A[a_{i,j}] = (1-\beta_{i,j}) * P_{i,j} * k_{i,j} * t_{i,j} + \beta_{i,j} * 0 * k_{i,j} * t_{i,j} \tag{2}$$

where $k_{i,j}$ is the number of instances in the allocation. and $P_{i,j}$ is the market price for instance of type i at the time of acquisition.

Expected Utility. In addition to computing expected cost for a set of allocations, AcquireMgr computes the *expected utility* for a set of allocations. The *expected utility* is the expected percentage of requests that will meet the latency target given the set of allocations A. Expected utility takes into account the probability of allocation preemptions, providing AcquireMgr with a metric for quantifying the expected contribution that each allocation should make to meet the resource target. The expected utility V_A of the set of allocations A is calculated as follows:

$$V_A = \sum_{r=0}^{resc(A)} P(R=r) * \upsilon(r) \tag{3}$$

where $P(R)$ is the probability mass function of the discrete random variable R that denotes the number of resources not preempted within the next hour, υ is the utility function provided by the service, and $resc(A)$ is the function that reports the number of resources in a set of allocations A. $resc(A)$ computes the *total amount of resources* in A, while $size(A)$ only computes the *size* of A's major dimension.

Eq. 3 computes the expected utility over the next hour given a workload, as though Tributary just bid for all its allocations. This works, even though there will usually be complex overlapping expiration windows across an hour, because it only needs to hold true until recomputed at the next decision point, which is never more than a minute away. To derive $P(R)$, AcquireMgr starts off with the original set of allocations A and generates all possible subsets of A. Each possible subset $S \subseteq A$, S marks some allocations in A as preempted ($\in S$) and the remaining allocations as not preempted ($\notin S$). To formalize the notion, we define the indicator variable $d_{i,j}$, where $d_{i,j} = 1$ if allocation $a_{i,j} \in S$ and $d_{i,j} = 0$ otherwise.

To compute the probability of S being the set of preempted resources ($P(S)$), AcquireMgr separates all allocations by resource pools, as each resource pool within AWS has its own spot market. We leverage the following localizing property. Within each resource pool A_i, the probability of preempting an allocation $a_{i,j}$ is only dependent on whether the allocation with the next lowest bid price, $a_{i,j-1}$, in the same resource pool is preempted. Note that $P(a_{i,1}) = \beta_{i,1}$ for allocation $a_{i,1}$ for all resource pools i. Consider two allocations $a_{i,j}, a_{i,j-1} \in A$ from resource pool A_i. We observe the following properties: (1) $a_{i,j}$ cannot be preempted unless $a_{i,j-1}$ is preempted, (2) the probability that both $a_{i,j}$ and $a_{i,j-1}$ are preempted is the probability that $a_{i,j}$ is preempted, and (3) the probability that $a_{i,j}$ is preempted without $a_{i,j-1}$ being preempted is 0. With Bayes' Rule, we observe that:

$$P(a_{i,j}|a_{i,j-1}) = \frac{P(a_{i,j} \wedge a_{i,j-1})}{P(a_{i,j-1})} = \frac{\beta_{i,j}}{\beta_{i,j-1}}. \tag{4}$$

Thus, for an allocation $a_{i,j}$ given subset $S \subseteq A$,

$$P(a_{i,j}|a_{i,j-1}) = \begin{cases} 0 & \text{if allocation } a_{i,j-1} \notin S, \\ \beta_{i,j}/\beta_{i,j-1} & \text{else.} \end{cases} \tag{5}$$

Tributary further introduces a regularization term λ_i to encourage bidding in markets with low correlation. Having instances spread across lowly correlated markets is important for avoiding high-risk footprints. If the resource footprint has too many instances from correlated resource pools, Tributary becomes exposed to having too many resources being lost to a correlated price spike, potentially causing an SLO violation. In order obtain price correlation across spot markets, we periodically keep track of fix-sized moving windows of spot markets and compute the Pearson correlation between each pair of spot markets. When computing *expected utility*, Tributary increases an allocation in A_i's probability of preemption $\beta_{i,j}$ by λ_i:

$$\lambda_i = \gamma * \sum_{l=1}^{size(A)} \rho_{i,l} * \frac{resc(A_i) + resc(A_l)}{2 * resc(A)} \tag{6}$$

where $\rho_{i,l}$ is the Pearson correlation between resource pools i and l, and $\gamma \in \mathbb{R} \geq 0$ is the configurable penalty multiplier. Essentially, we add a weighted penalty to an allocation based on its Pearson correlation scores with the rest of our resources in different resource pools. In our experiments, we set $\gamma = 0.01$. The regularization term leads to Tributary creating a diversified resource pool, thus reducing the probability that a significant portion of the resources are preempted simultaneously. Having a high probability of maintaining the majority of the resource pool at any point time, allows Tributary to avoid SLO violations with a high probability.

Let's denote $P(S)$ as the probability of S being the set of resources preempted from A. AcquireMgr computes it by taking the product of the conditional probability of each allocation having the outcome specified in S. If the allocation is preempted ($d_{i,j} = 1$) the conditional probability of the allocation being preempted ($P(a_{i,j}|a_{i,j-1})$) is used, otherwise ($d_{i,j} = 0$) the product uses the conditional probability of the allocation not being preempted $(1 - P(a_{i,j}|a_{i,j-1}))$.

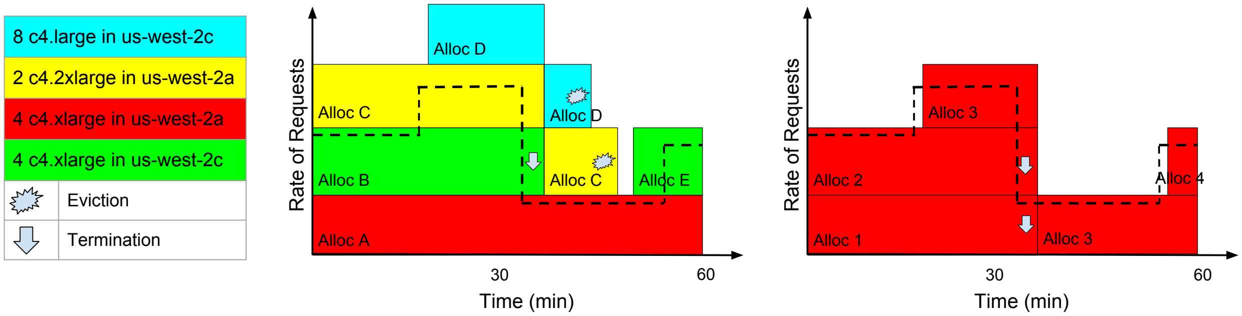
$$P(S) = \prod_{i=1}^{size(A)} \prod_{j=1}^{size(A_i)} \Big(d_{i,j} * P(a_{i,j}|a_{i,j-1}) + (1 - d_{i,j}) * (1 - P(a_{i,j}|a_{i,j-1})) \Big) \tag{7}$$

Finally, AcquireMgr formulates the probability of r resources remaining after preemption $P(R = r)$ (Eq. 3) as the sum of the probabilities of all sets S where the number of resources not preempted in S equals to r:

$$P(R=r) = \sum_{S \subseteq A, resc(S) = resc(A) - r} P(S) \tag{8}$$

which it uses to calculate the expected utility of a set of allocations A (Eq. 3).

Computational tractability. AcquireMgr's algorithm is exponentially computationally expensive as the number of spot markets considered increases. When considering more markets, it is possible to reduce computational complexity by grouping similar, correlated spot



(a) Legend (b) Tributary (c) AutoScale

Figure 1: Figures (b) and (c) show how Tributary and AutoScale handle a sample workload respectively. Figure (a) is the legend for (b) and (c), color-coding each allocation. The black dotted lines in (b) and (c) signify the request rates over time. At **minute 15**, the request rate unexpectedly spikes and AutoScale experiences “slow” requests until completing integration of additional resources with *3*. Tributary, meanwhile, had extra resources meant to address preemption risk in *C*, providing a natural buffer of resources that is able to avoid “slow” requests during the spike. At **minute 35**, when the request rate decreases, Tributary terminates *B*, since it believes that *B* has the lowest probability of getting the free partial hour. It does not terminate *D* since it has a high probability of eviction and is likely to be free; it also does not terminate *C* since it needs to maintain resources. AutoScale, on the other hand, terminates both *2* and *3*, incurring partial cost. At **minute 52**, the request rate increases and Tributary again benefits from the extra buffer while AutoScale misses its latency SLO. In this example, Tributary has less “slow” requests and achieves lower cost than AutoScale because AutoScale pays for *3* and for the partial hour for both *1* and *2* while Tributary only pays for *A* and the partial hour for *B* since *C* and *D* were preempted and incur no cost.

markets, and performing revocation analysis with a representative market. Although this would potentially decrease the precision of the preemption analysis, it would allow AcquireMgr to further improve performance by considering a larger number of markets.

3.3 Scaling Out

Resource Acquisition. When Tributary starts, the user specifies a *target SLO* in terms of percentage of requests that respond within a certain latency for Tributary to target. AcquireMgr uses this target SLO to acquire resources. At each decision point, AcquireMgr’s objective is to acquire resources until the expected utility θ_A is greater than or equal to the target SLO. If the expected utility is greater than or equal to the target SLO, no action is taken; otherwise, AcquireMgr computes the expected cost (Eq. 2) and utility of the current set of allocations (Eq. 3). AcquireMgr then calculates the missing number of resources (M) required to meet the target SLO and builds a set of possible allocations (Λ) that consists of allocations from different resource pools at different bid prices (from \$0.0001 to \$0.2 above the current price). For each possible allocation Λ_i, AcquireMgr records the new expected utility divided by the new expected cost of $A \cup \Lambda_i$, choosing the allocation Λ_{chosen} that maximizes this value. AcquireMgr continues to add possible allocations until it achieves the target SLO in expectation.

Buffers of Transient Resources. To accommodate potential resource preemptions, Tributary inherently acquires more than the required amount of resources if any of its allocations have a preemption probability greater than zero, which is always the case with spot instances. The amount of additional resources acquired depends on the target SLO and the probabilities of allocation preemptions (Eq. 3). While the primary goal of these additional resources is to account for preemptions, they often have the added benefit handling unexpected increases in load. Experiments with Tributary show that these resource buffers both increase the fraction of requests meeting latency targets and decrease cost (Sec. 5.3).

3.4 Scaling In

Aside from preemptions, Tributary also tries to scale in voluntarily. As described earlier, each allocation is considered only for the duration of the preemption window. When an allocation reaches the end of its preemption window, it is terminated and replaced with a new allocation if required. When resource requirements decrease, Tributary considers terminating allocations for allocations least likely to be preempted. During this process Tributary chooses the allocation with the least time remaining in the hour, computes the expected utility θ_A without this allocation, and if it is greater than the target SLO, Tributary terminates the allocation. Tributary continues to try and terminate allocations as long as θ_A remains greater than the target SLO.

3.5 Example and Future Consideration

Example. Fig. 1 shows how Tributary and AutoScale handle a sample workload, including how the extra resources Tributary acquires to handle preemption events can also handle an unexpected request rate increase and how aggressive allocation selection can get some resources for free due to preemptions.

Future. Tributary lowers cost and meets SLO requirements by taking advantage of low-cost spot instances and uncorrelated prices across different spot instance markets. Mass adoption of systems like Tributary could change these characteristics. While a detailed analysis of mass adoption's potential effects on EC2 spot-markets is outside the scope of this paper, we evaluate the effects of two potential changes to the spot-market policies in Section 5.5.

4 Tributary Implementation

Figure 2 shows Tributary's high-level system architecture. This section describes the main components, how they fit together, and how they interact with AWS.

Preemption Prediction Models. The *prediction models* are trained offline using TensorFlow [8] and deployed using Tensorflow Serving [7]. A separate model is used for each resource pool. To service run time predictions Tributary launches a *Prediction Serving Proxy* that receives all prediction queries from AcquireMgr, forwards them to their respective models, aggregates the results, and returns the predictions to AcquireMgr.

Resource Footprint Management. In Tributary, AcquireMgr takes primary responsibility for managing the resource footprint. AcquireMgr acquires instances, terminates instances, and monitors AWS for instance preemption notifications. AcquireMgr considers modifying the resource footprint at every *decision point*, and it follows the procedure described in Sec. 3.3 when additional resources are needed. Once AcquireMgr selects a set of instances to acquire, it sends instance requests to AWS via *boto.ec2* API calls. AWS responds with a set of spot request ids, which corresponds to the EC2 instances allocated to AcquireMgr. Once the instances are in a running state, AcquireMgr sends the instance ids associated with the new instances to Resource Manager. Instance removal follows a similar procedure.

Scaling Policy. The *Scaling Policy* component determines dynamic sizing of the resource target. Through a simple event-driven API, users can implement their own scaling policies that access metrics provided by the Monitoring Manager and specify the resource target.

Monitoring Manager (MonMgr). The *Monitoring Manager* orchestrates monitoring of service system resources. The Scaling Policy can register for metrics such as total number of requests and average CPU utilization of instances. The MonMgr queries requested metrics using AWS CloudWatch each *monitoring period* and forwards them to the scaling policy.

Resource Manager (ResMgr). The *Resource Manager* is a proxy for AcquireMgr. Using resource targets provided by the Scaling Policy, the ResMgr generates the utility function used by AcquireMgr to make resource acquisition decisions.[1] The ResMgr also receives instance allocations and termination notices from AcquireMgr and forwards them to the Service Manager.

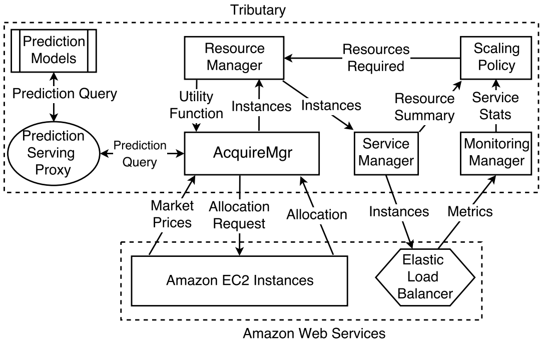


Figure 2: Tributary architecture.

5 Evaluation

This section evaluates Tributary's effectiveness. The results support a number of important findings: (1) Tributary's exploitation of AWS spot market instances reduces cost by 81%–86% compared to on-demand instances and simultaneously decrease SLO latency misses; (2) Compared to standard bidding policies for spot instances, Tributary reduces cost by up to 41% and decreases SLO latency misses by 31%–65%; (3) Compared to extending those standard policies to use enough extra (buffer) resources to match Tributary's number of SLO latency misses, Tributary reduces cost by 47%–62%; (4) Tributary outperforms state-of-the-art resource managers in running elastic services; (5) Tributary's preemption prediction models improve accuracy significantly, resulting in 37% lower cost than previous prediction approaches.

5.1 Experimental Setup

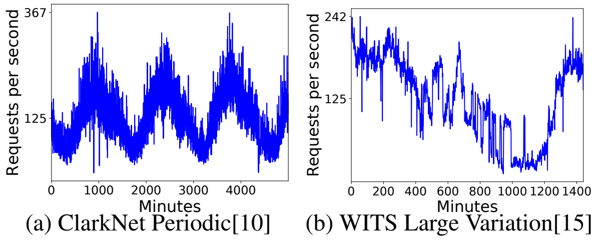
Experimental Platform. We report results for use of three AWS EC2 spot instance types: *c4.large*, *c4.xlarge*, and *c4.2xlarge*. The results correspond to the *us-west-2* region, which consists of three availability zones. Using the three instance types in each availability zone, our experiments involve nine resource pools.

Workload. The simulated workload uses a real-world trace for request arrival times, with each request consisting of the derivation of the PBKDF2 [18] key of a password. The calculation of a PBKDF2 key is CPU-heavy, with no network overhead and minimal memory overhead. With the CPU performance being the bottleneck, the resource requirement can be characterized in requests-per-second-per-VCPU.

Environment. In the simulation framework, each instance is characterized with a number of VCPUs, and the request processing time is configured to the measured time for one request on an EC2 instance ($\approx$100ms). Each instance server maintains a queue of requests, and we simulate the queueing effects using the discrete event simulation library SimPy [22]. The simulation framework takes into account resource start-up time, with newly acquired instances not able to service requests for two hundred seconds following their launch.

SLO and Scaling. The target service latency is set to

[1] Process of constructing the utility function is described in Sec. 5.2.



(a) ClarkNet Periodic[10] (b) WITS Large Variation[15]

Figure 3: Traces used in system evaluation.

one second, and we verified on EC2 that a VCPU can handle roughly 10 requests per second without violating the latency target. So, the requests-per-second-per-VCPU is ten, and the queue size per server instance is ten times the number of VCPUs in the instance. Tributary is not overly sensitive to the target latency setting.

Traces. We use four real-world request arrival traces with differing characteristics. *Berkeley* is from the Berkeley Home IP proxy service and *ClarkNet* is from the ClarkNet ISP's HTTP servers [10]. Both exhibit a periodic, diurnal pattern. We use the first 2000 minutes of these two traces, which covers an entire period. *WITS* is a sampled trace from the Waikato Internet Traffic Storage (WITS) [15]. The trace lasts for roughly a day, from April 6th to April 7th of the year 2000. This trace exhibits large variation of request rates throughout the day, as can be seen in Fig. 3b. *WorldCup98* is the arrival trace of the workload on the 1998 FIFA World Cup HTTP Servers [10] on day 75 of the World Cup. All traces are scaled to have an average of 125 requests per second in order to generate sufficient load for the experiments.

5.2 Scaling Policies Evaluated

We implement three popular scaling policies: *Reactive*, *Predictive Moving Window Average (MWA)*, and *Predictive Linear Regression (LR)* to evaluate our system. The utility function provided by the service is linear for all three policies. We make this assumption since our workload characteristic is embarrassingly parallel — if a workload exhibits different scaling characteristics, a different utility function can be employed.

The *Reactive Policy* scales out immediately when demand reported by the MonMgr is greater than what the available resources are able to handle. It scales in slowly (only after three minutes of low demand), as recommended by Gandhi et al. [12], to prevent premature scale-in in case the demand fluctuates widely in a short period of time. The *MWA Policy* maintains a sliding window of a fixed size, with each window entry consisting of the number of requests received in each monitoring period. The policy takes the average of the window entries to predict the number of requests on the next monitoring period. The policy then adjusts the utility and scaling functions according to the predicted number of requests, and reports the updated functions to the ResMgr to scale in expectation of future requests. The *LR Policy* also maintains a sliding window of a fixed size, but rather than using the average in the window for prediction, the policy performs linear regression on data points in the window to estimate the expected number of requests in the next monitoring period. Our experiments show that regardless of the scaling policy used, Tributary beats its competitors in both meeting the service latency target and cost.

5.3 Improvements with Tributary

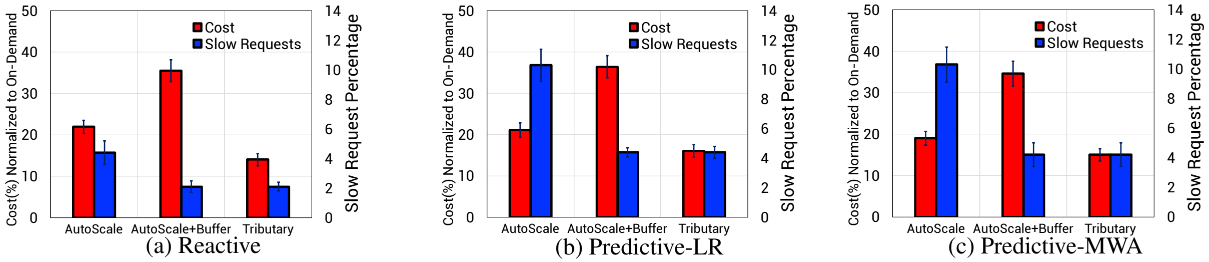
Here, we evaluate Tributary's ability to reduce cost and latency target misses against AutoScale.

AWS Autoscale. AWS AutoScale (Sec. 2.2) as offered by Amazon only supports the simplest reactive scaling policies. To provide better comparison between approaches, we implement the AWS AutoScale resource acquisition algorithm as closely as possible according to its documentation [2] and integrate it with Tributary's SvcMgr to work with its more powerful scaling policies. From here on, mentions of *AutoScale* refer to our implementation of AWS AutoScale. AutoScale is the equivalent of the AcquireMgr component of Tributary. The default AutoScale algorithm with spot instances bids for the lowest market-priced spot instance at the on-demand price upon resource requests by the scaling policy. In addition, AutoScale terminates resources as soon as the resource requirements are lowered, choosing to terminate resources that are most expensive at the moment.

Methodology and Terminology. To achieve fair comparisons across a wide range of data points, we perform cost analysis with simulations using historical spot market traces. Using traces allows us to test different approaches on the same period of market data and to get a better picture of the expected behavior of the system in a shorter amount of time. For each request arrival trace (Sec. 5.1) and resource acquisition approach, we present the average cost and percentage of *"slow" requests* over trace requests across ten randomly chosen day/time starting points between January 23, 2017 and March 23, 2017 in the *us-west-2* region. From here on, we define a *"slow" request* as a request that does not meet the latency target and the percentage of "slow" requests as the percentage of "slow" requests over all requests in a single trace. [2]

Cost Savings and Service Latency Improvements. Fig. 4 shows the cost savings and percentage of "slow" requests for the *ClarkNet* trace. The cost savings are normalized against running Tributary on on-demand resources. The results demonstrate that Tributary reduces cost and "slow" requests for all three scaling policies. Cost savings are ≈ 85% compared to on-demand resources. For the *ClarkNet* trace, Tributary reduces cost by 36%, 24% and 21% compared to to AutoScale for the *Reactive*, *Predictive-LR* and *Predictive-MWA* scaling policies, respectively. Compared to AutoScale, Tributary

[2] Prediction models were trained on data from 06/06/16 – 01/22/17.



(a) Reactive (b) Predictive-LR (c) Predictive-MWA

Figure 4: Cost savings (red) and percentage of "slow" requests (blue) for the *ClarkNet* trace.

reduces "slow" requests by 72%, 61% and 64%, respectively, for the three scaling policies.

In order to decrease the number "slow" requests, popular scaling polices are often configured to provision more resources than immediately necessary to handle unexpected increases in load. It is common to specify the resource buffer as a percentage of the expected resource requirement. For example, with a buffer of 50%, 15 resources (*e.g.*, VCPUs) would be acquired rather than the projected 10. AutoScale+Buffer shows the cost of provisioning AutoScale with a large enough buffer such that its number of "slow" requests matches that of Tributary. Tributary reduces cost by 61%, 56% and 57% compared to AutoScale+Buffer for the three scaling policies.

The cost savings for Tributary on the *Berkeley* trace relative to AutoScale are similar to those on the *ClarkNet* trace, but the reduction in percentage of "slow" requests increases. This difference in performance is due to differing characteristics of the two traces — the *ClarkNet* trace experiences more minute-to-minute volatility in request rate compared to the *Berkeley* trace. We observe similar levels of cost reductions and reduction in "slow" requests on the *WITS* and *WorldCup98* traces, results for WITS are shown in Tables 2. Compared to AutoScale+Buffer, Tributary decreased costs by 47–62% across all traces.

Scaling Policy	Cost Saving	"Slow" request Reduction
Reactive	37%	31%
Predictive-LR	33%	50%
Predictive-MWA	29%	51%

Table 2: Cost and "slow" request improvements for Tributary compared to AutoScale for the *WITS* trace

Attribution of Benefits. Tributary's superior performance arises from several factors. Much of the reduction in cost compared to AutoScale is due to Tributary's ability to get free instance hours. *Free instance hours* occur when an allocation does useful work but is preempted by AWS before the end of a preemption window. The user receives a refund for the partial hour, which means that any work done by the allocation in the preemption window comes at no cost to the user. Tributary takes the probability of getting free instance hours into account when computing the expected cost of allocations (Eq. 1), often acquiring resources that provide higher opportunities for free instance hours.

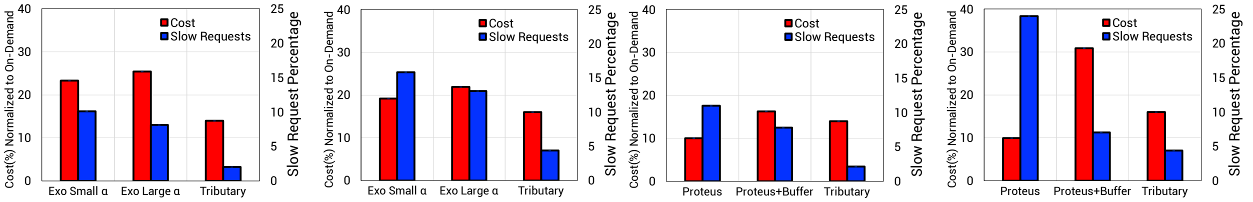
Another factor in Tributary's lower cost is its ability to remove allocations that are not likely to be preempted when demand drops. When resource demand decreases, Tributary terminates instances that are least likely to be preempted, thus lowering the expected cost of its resource footprint. The reductions in "slow" requests arise from the buffer of resources acquired by Tributary (Sec. 3.3). When acquiring instances, AcquireMgr estimates their probability of preemption. Unless all allocations have a preemption probability of zero, which never occurs for spot instances, Tributary acquires more resources than specified by the scaling policy. The primary goal of the additional resources is to ensure that, when Tributary experiences preemption events, it still has at least the specified number of resources in expectation. The additional resources also provide a secondary benefit by handling some or all of unexpected bursts of requests that exceed the load expected by the scaling policy. The cost of these additional resources is commonly offset by free instance hours; indeed, the extra resources are acquired to cope with preemptions.

5.4 Risk Mitigation

A key feature of Tributary is that it encourages instance diversification, *i.e.*, acquiring instances from mostly independent resource pools (Sec. 3.2). The default AutoScale policy is the lowest-price policy, which does not take diversification into account when acquiring instances; instead, it acquires the cheapest instance. Illustrated in Fig. 1, Tributary acquires different types of instances in different availability zones, while AutoScale acquires instances of the same type (all red). Diversifying across resource pools is important, because each has an independent spot market, avoiding highly correlated allocation preemptions within a single instance market. Acquiring too much from a single pool, as often occurs with AutoScale, creates a high risk of SLO violation when preemption events occur (*e.g.*, if the red allocation in Fig. 1c was preempted prior to minute 35).

In our experiments, we found it to be very rare for market prices to rise above on-demand prices, meaning that AutoScale rarely experiences preemption events. However, when examining past EC2 spot market traces and other availability zones, we found it to be significantly more common for the market price to rise above the on-demand price, thus preempting AutoScale instances.[3]

[3] From 01/23/17–03/20/17, the market price rose above the on-demand price 0 times for the *c4.2xlarge* instance type in *us-west-2*. From 11/1/16–01/22/17, it happened 1073 times.



(a) Reactive (b) Predictive-LR (c) Reactive (d) Predictive-LR

Figure 5: Comparing to ExoSphere and Proteus. Predictive-MWA results not shown but similar.

Since Amazon charges users the market price and not the bid price, it is possible that Amazon may once again preempt instances bidding the on-demand price with regularity—a phenomenon we recently observed in the *us-east* availability zones. Thus, AutoScale's resource acquisition approach is riskier for services with latency SLOs on spot machines.

Cost of Diversified AutoScale. In addition to the default AutoScale policy which acquires the lowest-priced instance, AWS also offers a diversified AutoScale policy that starts instances from a diverse set of resource pools [4]. Acquiring instances from different spot markets reduces preemption risks, but our experiments showed that it increases cost by 8%–12% compared to the lowest-price AutoScale policy. Compared to Tributary, which diversifies across spot markets intelligently, we found that a diversified AutoScale policy cost 68% more to achieve the same number of "slow" requests for the *reactive* scaling policy on the *ClarkNet* trace.

5.5 Pricing Model Discussion

Our experimental results are based on current AWS EC2 billing policies, as described Section 2.1. This section discusses how Tributary would function under two potential changes to the billing model: (1) elimination of preemption refunds, (2) institution of a free market.

Elimination of preemption refunds. If Amazon eliminates refunds when the market price exceeds bid price during the first hours of usage, Tributary would lose incentive to bid close to market price. Tributary's model would capture this change by setting β in Eq. 2 to zero. With higher bids, Tributary would acquire fewer resources because preemption would be less likely. The amount of resources acquired would still exceed the amount of resources required as they would still have non-zero preemption probabilities.

Although Tributary extracts significant benefit from the refunds, it still outperforms AutoScale without it. For example, in a simulation with this billing model modification, Tributary still reduces cost by 31% compared to AutoScale with sufficient buffer to match numbers of "slow" requests, for the *Clarknet* trace using the *reactive* scaling policy. As expected, Tributary continues to meet SLOs with high likelihood, as it continues to diversify its resource pool and acquire buffers of resources (albeit smaller ones) to account for preemption events.

Free market behavior. In its current design, the AWS EC2 spot markets do not behave as free markets [9]. Customers specify their bid prices for a given resource, but generally do not pay that amount. Instead, a customer is billed according to the EC2-determined spot price for that resource. It is possible, perhaps even likely as the spot market becomes widely popular, that AWS will transition toward a billing policy in which users are charged their *bid price*, instead of the *market price*, and prices move based on supply and demand rather than unknown seller policies. This change would render the commonly used strategy of bidding far above the market price (e.g., bidding the on-demand price) obsolete. Tributary's behavior would not change significantly, as it already often sets bid prices close to market prices and explicitly considers revocation risks, and we believe it would therefore outperform other approaches by even larger margins.

5.6 Comparing to State of the Art

This section compares Tributary's support for elastic services to two state-of-the-art resource managers designed for preemptible instances. Since neither system was designed for elastic services with latency SLOs, Tributary unsurprisingly performs significantly better.

Exosphere. We implemented ExoSphere's allocation strategy, described in Sec. 2.2, with the following assumptions and modifications: (i) The ExoSphere paper did not specify whether the correlation between markets is recomputed as time moves on. In order to avoid the need to constantly reconstruct ExoSphere's resource footprint, we assumed static correlation between markets. (ii) As the ExoSphere paper does not provide guidelines as to how to choose α, we experimented with a range of α from 1 to 10^9. Higher α instructs ExoSphere to be more risk averse at the expense of higher cost.

Fig. 5 shows the normalized cost and percentage of "slow" requests served for Tributary and for ExoSphere with small (1) and large (10^9) values of α. These experiments were performed on a further scaled-up version of the *ClarkNet* trace (100x of already-scaled version), since ExoSphere was designed for 100s to 1000s of instances and performs poorly at a scale of 10s.[4] In our experiments, we observed that Exosphere with a small α tends to acquire mainly the cheapest resources, inducing little diversity and increasing the number of "slow" requests in the event of preemptions. Tributary's advantage in both cost and SLO attainment results from Tributary's exploitation of spot instance characteristics (Sec. 5.3).

[4] At small scales, ExoSphere with low α had no resource diversity. With large α, it acquired too many resources, increasing its cost.

Proteus. We implemented Proteus's allocation strategy, described in Sec. 2.2, modified to acquire only spot resources (reducing cost with no significant change in SLO attainment). Fig. 5 compares Tributary and Proteus for the *ClarkNet* trace, for two different scaling policies. While Proteus achieves lower cost than Tributary, it experiences a large increase in "slow" requests. This increase is due to Proteus not diversifying its resource pool, instead only acquiring resources based on reducing average per-core cost. When told by the scaling policy to acquire additional resources, similarly to AutoScale buffers (Sec. 5.3), Proteus is unable to match Tributary's number of "slow" requests no matter how large the buffer (and, thus, how high the cost). This is once again due to the lack of diversity in the resources that Proteus acquires.

5.7 Prediction Model Evaluations

This section evaluates the accuracy of the preemption prediction models used by Tributary, which are described in Sec. 3.1. The recent Proteus system [16] used the historical median probability of preemption depending on the instance type, availability zone and the difference between the user bid price and the spot market price of the resource. Tributary improves prediction accuracy by using machine learning inference models trained with historical spot market data with engineered features. Fig. 6 shows the accuracy and F_1 scores for prediction models based on the historical median, a logistic regression classifier, a multilayer perceptron neural network (MLP NN) and a long short term memory recurrent neural network (LSTM RNN). These models were trained on spot market data from 06/06/16 – 01/22/17 and were evaluated on data from 01/23/17 – 03/20/17 for instance types *c4.large*, *c4.xlarge* and *c4.2xlarge* in *us-west-2*.

The output of the prediction models is whether the instance specified in a query will be preempted within the preemption window. Accuracy scores are calculated by the number of samples classified correctly divided by total number of samples. F_1 scores, which account for data skew, are a good accuracy measurement because the data set is skewed toward preemptions at lower *bid deltas* and non-preemptions at higher *bid deltas*. The LSTM RNN model provides the best accuracy and the best F_1 because it is able to capture the temporal nature of the AWS spot market. LSTM increases accuracy by 11% and the F_1 score by 27% compared to using the historical median. The MLP NN model performs worse than the historical median model for accuracy, but its F_1 score is higher because unlike the historical median model, the MLP model considers advanced features when predicting preemptions as described in Sec. 3.1. The increased accuracy of the LSTM RNN model translates to Tributary's effectiveness. When using the LSTM RNN model, Tributary runs at ≈37% less cost on the *ClarkNet* workload compared to Tributary using historical medians, because the historical median model overestimates the probability of preemption, causing Tributary to acquire more resources than necessary.

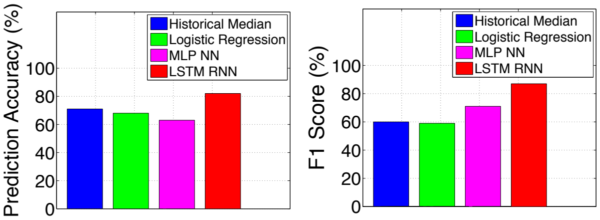


Figure 6: Accuracies and F_1 scores (accounts for data skew) for predicting preemption of AWS spot instances. The LSTM RNN outperforms prior techniques (blue bar) by 11% on the accuracy metric and 27% on the F_1 score metric.

6 Conclusion

Tributary exploits AWS spot instances to meet latency SLOs for elastic services at lower cost. By predicting preemption probabilities and acquiring diverse resource footprints, Tributary can aggressively use collections of cheap spot instances to reliably meet SLOs even in the face of bulk preemptions. Our experiments show cost savings of 81–86% relative to using non-preemptible on-demand instances and 47–62% relative to traditional high-risk use of spot instances.

Tributary exploits AWS properties, such as dynamic spot markets and preemption based thereon. We believe its approach would also work for other clouds offering preemptible resources, if they expose enough information to predict preemption probabilities, which AWS provides via the visible spot market prices. Currently, *Google Cloud Engine* [5] does not expose such a signal for its preemptible instances. For private clouds, exposing preemption logs could provide the historical view, but even better predictions can be enabled by exposing scheduler state.

FastTrack: Foreground App-Aware I/O Management for Improving User Experience of Android Smartphones

Abstract

The quality of user experience on a smartphone is directly affected by how fast a foreground app reacts to user inputs. Although existing Android smartphones properly differentiate a foreground app from background apps for most system activities, one major exception is the I/O service where I/O-priority inversions between a foreground app and background apps are commonly observed. In this paper, we investigate the I/O-priority inversion problem on Android smartphones. From our empirical study with real Android smartphones, we observed that the existing techniques for mitigating I/O-priority inversions are not applicable for smartphones where frequently inverted I/O priorities should be quickly corrected to avoid any user-perceived extra delay. We also identified that most noticeable I/O-priority inversions occur in the page cache and a flash storage device. Based on the analysis results, we propose a foreground app-aware I/O management scheme, called FastTrack, that accelerates foreground I/O requests by 1) *preempting* background I/O requests in the entire I/O stacks including the storage device and 2) *preventing* foreground app's data from being flushed from the page cache. Our experimental results using a prototype FastTrack implementation on four smartphones show that a foreground app can achieve the equivalent level of user-perceived responsiveness *regardless of the number of background apps*. Over the existing Android I/O implementation, FastTrack can reduce the average user response time by 94% when six I/O-intensive apps run as background apps.

1 Introduction

As a highly interaction-oriented device, a smartphone needs to react promptly *without a noticeable delay* to user inputs. In order to minimize a user-perceived delay, which directly affects the quality of user experience on the smartphone, Android smartphones properly differentiate a foreground (or FG) app from background (or BG) apps for most system activities. For example, when CPU cores are allocated, an FG app may be allowed to use one or more CPU cores exclusively while BG apps must share CPU cores with other apps [1, 2]. Such FG app-centric resource management becomes more important for modern Android smartphones because they run more apps at the same time thanks to aggressive multitasking support. As the number of concurrent BG apps increases, an FG app may encounter more interference from BG apps unless the FG app is managed with a higher priority over the BG apps.

Unlike FG app-aware CPU management which has been extensively investigated [3, 4, 5], I/O management on smartphones has not actively considered the quality of user experience issue in designing various I/O-related techniques. FG app-oblivious I/O management was not of a big concern for older smartphones where the number of BG apps is quite limited because of a small DRAM capacity (e.g., 512 MB) [6, 7, 8]. However, on modern high-end smartphones with a large number of CPU cores and a large DRAM capacity (e.g., 8 GB) [9, 10, 11] where the number of BG apps has significantly increased (e.g., from one in Nexus S [12] to more than 8 in Galaxy S8 [13]), FG I/O requests (or FG I/Os) are more likely to be interfered with BG I/O requests (or BG I/Os). Unless FG I/Os are treated with a higher priority over BG I/Os, FG I/Os may have to wait for the completion of a BG I/O. (That is, I/O-priority inversions occur.) In this paper, we comprehensively treat the I/O-priority inversion problem on Android smartphones including its impact on user experience, its main causes and an efficient solution.

Our work is mainly motivated by our empirical observation that I/O-priority inversions between the FG I/Os and the BG I/Os are quite common on Android smartphones. In particular, when an FG app needs a large number of I/Os (e.g., when the app starts), such I/O-priority inversions significantly degraded the response time of the FG app. For example, when five BG apps run at the same time, the app launch time of an FG app can increase by up to four times over when no BG app competes. This large increase in the app launch time of the FG app was rather surprising because the Android system is already designed to handle the FG app with a higher priority. In order to understand why the response time of a higher-priority FG app is affected by the number of BG apps, we have extensively analyzed the complete I/O path of the Android/Linux I/O stack layers on several smartphones using our custom I/O profiling tool, IOPro [14]. From our analysis study, we found that I/O-priority inversions in the page cache and the storage device were main causes of the increased response time of an FG app. We also observed that the current flush policy in the page cache, which does not distinguish whether a victim page (to be flushed) is from an FG app or a BG app, significantly impacted the FG app performance.

For frequent I/O-priority inversions on a smartphone, the existing techniques such as [15, 16, 17, 18, 19] may not be applicable because these techniques require a long latency (from the smartphone's viewpoint) to correct the inverted I/O priorities. For example, [19] depends on the priority inheritance protocol [20] to accelerate the completion of the current BG I/O before an FG I/O is started. In our experiment, the FG I/O waited up to 117 ms for the completion of the current BG I/O under the priority inheritance protocol. Obviously, this is too long for a smartphone where a delay of more than a few milliseconds is unacceptable [19]. Furthermore, the efficiency of these existing techniques, which were not specifically developed for smartphones as a target system, is limited in several aspects. For example, they do not fully exploit an important hint such as the type of apps (e.g., foreground or background) and do not take a holistic approach in optimizing the entire I/O stack layers *including the storage device*. Therefore, a different approach is necessary for resolving the I/O-priority inversion problem on smartphones. A solution should meet the fast response time requirement and should better exploit the smartphone-specific hints in a holistic I/O-path-aware fashion.

In this paper, we propose a new I/O management scheme for Android smartphones, called FastTrack (or FastT in short), which efficiently meets the above requirements on resolving I/O-priority inversions on Android smartphones. The key difference of FastTrack over the existing techniques is that FastTrack takes a more direct approach in fixing the I/O priority inversion problem by *preempting* the current background activity throughout the entire I/O stack layers. By stopping the current background activity *immediately*, FastTrack can quickly service the I/O request from an FG app. FastTrack also modifies the flush policy of the page cache to be *FG app-aware*. For example, when a victim page is selected for the next flush, FastTrack first considers pages that belong to BG apps as victim candidates.

In order to evaluate the effectiveness of the proposed scheme, we have implemented FastTrack on various Android smartphones, including Nexus 5 [21], Nexus 6 [22], Galaxy S6 [23] and Pixel [24]. Our experimental results show that FastTrack can provide the equivalent level of responsiveness to FG apps regardless of the number of BG apps. For important I/O-intensive app use cases (such as the app launch time, app switch time and app loading time)[1], compared over when no BG app runs, FastTrack can limit an increase in the average response time of an FG app within 27% even when six I/O-intensive BG apps run together. On the other hand, in the default Android implementation, the average response time can increase up to by 2,319%. Because of foreground app-centric I/O management, FastTrack is very effective in decreasing the average response time of an FG app as well. For example, when six BG apps run together, FastTrack can reduce the response time of an FG app by 94% over the default Android implementation.

The remainder of this paper is organized as follows. In Section 2, we report the key results of our empirical study on the impact of BG I/Os on user experience. Section 3 describes the root causes of the I/O-priority inversion problem on smartphones and summarizes the main requirements that must be satisfied by a solution. A detailed description of FastTrack is given in Section 4. Experimental results follow in Section 5, and related work is summarized in Section 6. Finally, Section 7 concludes with future work.

2 Impact of BG I/Os on User Experience

In this section, we empirically analyze how much FG app performance is affected by BG I/Os. We also investigate how often BG I/Os interfere with an FG app. Our empirical study is carried out under various real-life smartphone usage scenarios with 10 different smartphones.

2.1 Evaluation Study Setup

For our study, we collected 10 Android smartphones[2] (with a proper instrumentation function) from different users who are all *heavy* users (almost always carrying their smartphones with them). To avoid possible bias, we have selected the smartphones from seven different manufacturers. Each smartphone is equipped with 4 or more cores and 3 GB or larger DRAM memory which is large enough to actively support multitasking. All of the smartphones also have the latest version of Android (version 7.x) which supports enhanced multitasking features (such as a split screen).

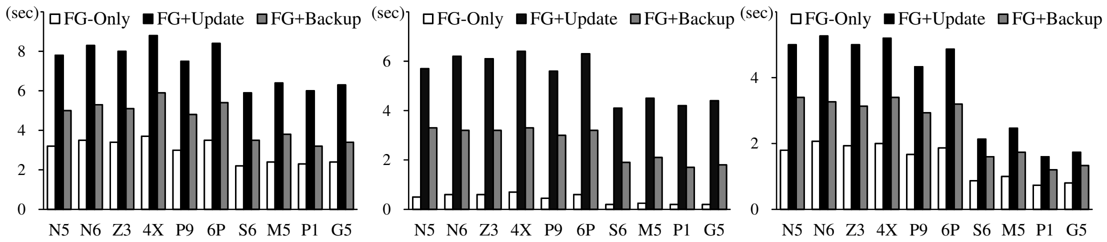
Like other active smartphone users, our study participants used Chrome, Messenger, Camera, Gallery, and Game as their main FG apps. As popular BG apps, cloud backup apps such as Dropbox [25] and OneDrive [26] were popular among the study participants. Furthermore, all the participants enabled an option for an automatic app update. The "background process limit" option was set to "standard limit", which is a default setting.

2.2 Response Time Analysis

In order to understand an impact of BG I/Os on user experience, we conducted a series of experiments on common smartphone usage cases when typical BG apps run. We have measured the user-perceived response times

[1] Since a user must wait for these use cases to complete, their response times directly affect the smartphone user experience quality.

[2] 10 phones include Nexus 5 (N5), 6 (N6), 6P (6P), Z3 (Z3), Redmi 4X (4X), P9 (P9), Galaxy S6 (S6), Mi 5 (M5), Pixel (P1), and G5 (G5).



(a) Gallery app launch time.

(b) Camera app switch time.

(c) Game app loading time.

Fig. 1: Impact of background I/Os on user experience.

of three usage cases where prompt reaction to user inputs are important – when (i) a new app is launched by a user, (ii) one app is switched to another, and (iii) a launched app is loading required contents. For BG apps, we have selected two BG workloads: `Update` and `Backup`. `Update` downloads and installs multiple apps from the Android market (e.g., as in an auto app update), and `Backup` uploads a large number of files to cloud storage services (e.g., as in Dropbox). These workloads were selected because they are known to generate substantial BG I/Os in a periodic fashion[3] Our background scenarios are automatically invoked in background when a smartphone is connected to a fast network (e.g., Wi-Fi).

Scenario A – Launching `Gallery` **App:** Launching an app requires to load a relatively large number of files, including executables, libraries, and files. While an app is being launched, a user has to wait until all the required files are loaded from a storage device. In this paper, an app launch refers to a cold start, where an app is launched without any preloaded data. It should be noted that, as the quality and complexity of mobile applications improve, the amount of data to be loaded while launching apps increases as well. In case of `Gallery` app [30], for example, 25 image files, on average, must be preloaded to complete the app's initial display.

Fig. 1(a) depicts the launch time of `Gallery` on the 10 smartphones. Here, the launch time is defined to be the time interval from when an app icon is touched by a user to when all the components are displayed on the screen. Even though there are differences depending on the hardware performance, noticeable launch time degradations are observed in all the smartphones when BG I/Os are issued simultaneously. In N6 with an eMMC storage, the launch times under two BG workloads, `FG+Update` and `FG+Backup`, increase by 2.4 times and 1.6 times, respectively, over a standalone launch (`FG-only`). Similar trends are also observed even in smartphones with faster mobile storage systems. In S6 with an UFS storage that provides higher throughput, the launch times of `FG+Update` and `FG+Backup` increase by 2.6 times and 1.7 times, respectively.

Scenario B – Switching `Camera` **App:** Switching from one app to another becomes a common feature in smartphones supporting multitasking. Before moving to a new app, a current app should be properly suspended. In the Android platform, the app switch involves the flushing of dirty pages in the page cache to persistent storage, so as to create as many free pages as possible for a new app. A user must wait for an old app to complete flushing its dirty pages before a new app is activated. Therefore, a user may experience a long unpleasant delay between app switches if BG I/Os interfere with the flushing process in the page cache.

We examine the switch time of a `Camera` app [31] when it switches to a home screen app. While the `Camera` app is recording a video for 10 minutes, we measure the time interval from when the home button is pressed to when the home screen is displayed for the next user interaction. Fig. 1(b) illustrates the switch time of `Camera` in S6 – it is less than 1 second when no BG I/Os are being issued, but it increases by 19.5 times under heavy BG I/Os. In N6, the switch time also increases by 11 times compared to when there are no BG I/Os.

Scenario C – Loading `Game` **App:** After app launching, some apps require additional file loading work before a user interacts with launched apps. One representative example is a `Game` app [32] that has to preload game contents (e.g., stage maps and rendered images) depending on a user's input after it completed the app launching process. This loading process inevitably results in response time delays from the perspective of end users.

In order to understand how much BG I/Os affect the app loading time, we measure the time interval from when the 'story mode' button on a `Game` app [32] is touched by a user to when its loading process is finished. As expected, we observed that the app loading time increases with BG I/Os in all the smartphones. We also confirm that the app loading times tend to be longer in smartphones with less memory over ones with larger memory. For example, on N5 with 2 GB DRAM, the loading time increases by 2.7 times under `Update`. The loading time, however, increases about 2 times only on P1 with 4 GB DRAM.

[3] `Update` is based on an observation that popular mobile apps (such as `Twitter`) are typically updated once every week and the average size of downloaded packages for an app update is about 110 MB [27, 28], and `Backup` is based on a report that a typical smartphone user uploads more than 200 MB of files per day to the cloud storage [29].

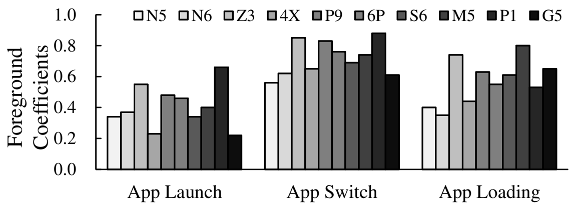


Fig. 2: FG-BG interference analysis results.

2.3 FG-BG Interference Analysis

Although we confirmed that BG I/Os can significantly degrade the quality of user experience of an FG app when they conflict with FG I/Os, if BG I/Os were unlikely to overlap with FG I/Os in practice, our response time analysis in Section 2.2 becomes less meaningful. For example, if most BG I/Os occurred while a smartphone was not actively used by a user, their actual impact on user experience would be negligible, thus making our work useless. In order to evaluate if such conflicts are really happening in real-world settings, we built a simple I/O utility[4] which can tell how much BG I/Os were issued while processing a given FG I/O *req*. If an FG I/O τ was started at t_{start} and completed at t_{finish} , our utility computes the ratio r_τ of the total amount of I/Os from τ to the total amount of I/Os in the interval $[t_{start}, t_{finish}]$. This ratio, we call the foreground coefficient C_{fg}, indicates the proportion of FG I/Os over the total I/Os in $[t_{start}, t_{finish}]$. If C_{fg} is high, it indicates that there is less interference from BG I/Os. For example, if C_{fg} is close to 1, few BG I/Os interfere with the FG I/O.

Fig. 2 shows how much BG I/Os interfere with FG apps on 10 smartphones. For each smartphone, we have collected a month's history of system call usage and computed average foreground coefficients for three use cases (explained in Section 2.2). Fig. 2 shows that a significant portion of BG I/Os can interfere with user's interaction with FG apps. For example, in the app launch scenario, FG I/Os account for only 42% of the total I/Os, which can conflict with 58% of the total I/Os that are requested from BG apps. Similarly, in the app switch scenario and the app loading scenario, FG I/Os are responsible for 77% and 53% of the total I/O requests, respectively. Although the BG I/O portion was reduced over the app launch scenario, the BG I/O portion is still large enough to affect the user experience of an FG app in a significant fashion.

3 Root Causes of User-Perceived Delay

In this section, we analyze the I/O stack of the Android platform to find root causes that are responsible for rapidly increasing user-perceived response time along with an increasing number of I/O-intensive BG apps. We first review the overall architecture of the Android I/O stack, giving a brief explanation of how apps access files in storage media. Then, we explain three major bottlenecks we found through the analysis.

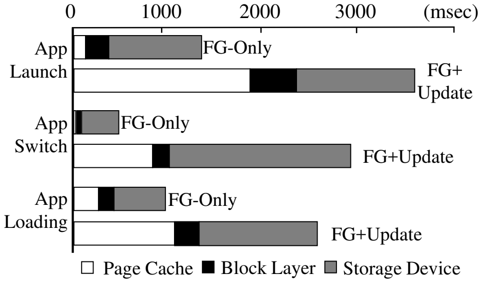

Fig. 3: A breakdown of foreground I/O execution time.

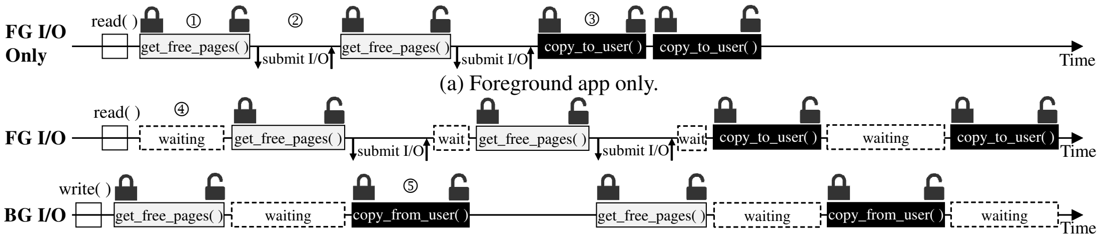
3.1 Overview of Android I/O Stack

As in typical UNIX-like OSes, Android file I/Os (i.e., reads and writes on files) created by an app are delivered to the kernel through system-call interfaces. The Linux kernel checks if corresponding file data is already cached in the page cache. If not, free pages available in the page cache are allocated to individual file I/Os. If the file I/O is for writes, user data is copied to the allocated pages in the kernel. Before sending I/O commands to an underlying block device, each file I/O is converted into a set of block I/Os with designated logical block addresses (LBAs). Block I/Os are then transferred to the block I/O layer and are put into proper I/O scheduling queues, sync or async queues, according to their types. I/O scheduling algorithms (e.g., CFQ [34]) move ready-to-submit block I/Os to a dispatch queue, which will be sent to the storage device via the eMMC [35] or UFS [36] interface. If the file I/O is for reads, data read from the storage device is stored in the allocated pages, and the data is finally copied to the user-space buffer.

In order to analyze the root causes of performance degradation by BG I/Os, we have measured the execution time of FG I/Os using IOPro. IOPro is capable of measuring the detailed elapsed times of I/O requests across all the Android I/O stacks, including a page cache, a block I/O layer, and a storage device. Fig. 3 shows a breakdown of the I/O execution time observed in the three usage scenarios used in Section 2. Because of the space limit, only the results from S6 are displayed in Fig. 3, but other smartphones also exhibit similar performance trends. When there are no BG I/Os (denoted by `FG-Only` in Fig. 3), the storage device is a major bottleneck. This is a reasonable result because the storage device is considered the slowest component in the I/O stack hierarchy.

With BG apps running heavily (`FG+Update` in Fig. 3), we observe that the execution times increased consider-

[4] Our monitoring tool is based on strace which is a popular profiling utility for analyzing system calls [33]. Strace provides PIDs of processes that generate I/Os, along with detailed information of relevant I/O system calls. Using the collected information, we can distinguish BG I/Os from FG IOs with their respective I/O traffic amounts.



(a) Foreground app only.

(b) Both foreground app and background app.

Fig. 4: Impact of lock contention on the I/O latency of the foreground app.

ably across all the layers. In particular, the times spent by the page cache layer have increased by 12 times, on average. For example, in Fig. 3, the portions of the page cache in `FG-Only` were negligible, but these rapidly increased in `FG+Update` to 32%-51% of the total execution times. While the relative portion of the time spent by the storage device has decreased, the total execution time spent by the storage device has significantly increased. For example, in the case of the app switch scenario, the execution time on the storage device has increased by 5 times. One surprising result in our study was that the impact of the block I/O layer on performance was rather negligible compared with the other two layers.

In the following three subsections, we investigate what happens inside the kernel I/O stacks when BG I/Os are heavily issued. Particularly, we focus on analyzing internal I/O activities at the page cache and the storage device layers because they are the main contributors to the increase of the execution times.

3.2 Root Cause 1: Page Allocation

From our performance bottleneck study, we found that *lock contentions in the page cache layer* are responsible for many I/O-priority inversions we have observed. As the first and major root cause of a performance degradation of an FG app under BG apps, we explain the impact of the page allocation module on user experience. When a new I/O request arrives at the kernel, free pages should be assigned first to the I/O request. When new free pages are necessary for serving the incoming I/O request, a free-page allocation module first acquires a *global lock*, *page lock*, for the exclusive access of the page cache during the page reclamation process [37] which is *non-preemptive* [38]. Acquiring free pages is mostly done quickly. However, if there are not sufficient free pages available, it takes a rather long time (e.g., more than 200 ms [19]) to create free pages by evicting dirty pages. Evicting dirty pages require extra writes to the storage device. If FG I/Os are blocked by BG apps that need the free page reclamation process, an FG app has to wait for BG I/Os to finish, thus causing an I/O-priority inversion between the FG app and the BG apps.

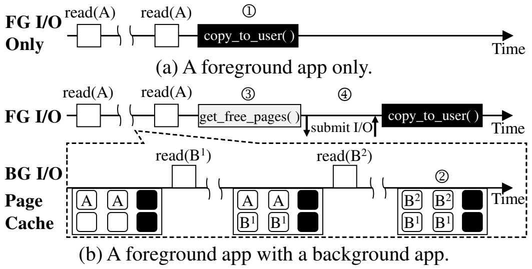
Fig. 4(a) illustrates an example where an FG app *F* reads a photo file of 256 KB size from storage media by calling a `read()` system call. We compare two different cases: 1) when *F* runs alone without any BG apps and 2) when *F* runs together with a BG app *B* that writes a large file to the storage device. Without BG apps, the FG app can quickly get free pages from the page cache (by calling `alloc_pages()` ①). Since the maximum allocation unit of free pages is limited to 128 KB [39], the kernel calls `alloc_pages()` twice, each of which gets 128 KB free pages. After calling each `alloc_pages()`, the kernel sends a read I/O command to the storage device (②), which transfers file contents from the storage to the allocated pages. Finally, data kept in the kernel pages are copied to a user-space buffer in the unit of 128 KB (by calling `copy_to_user()` ③).

Suppose that the BG app calls the `write()` system call to write data just before `read()` is invoked by the FG app. The *page lock* is grabbed by the BG app first, so the FG app has to wait until it releases the *lock* (④). This could be quite long if dirty page evictions are involved while assigning free pages to the BG app. After the *page lock* is released by the BG app, the FG app is able to acquire the lock, allocates free pages for reads, and then releases the lock. Then, it issues a read I/O command to the device. Copying data from the user space to the kernel space (`copy_from_user()`) also requires holding the same *global lock* of the page cache (⑤). As depicted in 4(b), if the BG app has already acquired the *global lock*, the FG app has to wait again for the lock to be released, which increases additional user-perceived delays.

Some might argue that the eviction of dirty pages in the middle of calling `alloc_pages()` would rarely occur. In our observation, however, when write-dominant BG apps run (e.g., `Update`), many dirty pages are created in the page cache and available free pages quickly run out. If an FG app requests I/Os in such situations, frequent evictions of dirty pages are inevitable.

3.3 Root Cause 2: Page Replacement

Our second root cause comes from a somewhat surprising source. As discussed in Section 3.2, the performance degradation of an FG app from the lock contention mostly occurs when many dirty pages are created in the page cache. When BG apps are read-dominant, such performance degradation is difficult to occur because few dirty pages may exist in the page cache. For example, in ④ of Fig. 4(a), if reclaimed pages were



(a) A foreground app only.

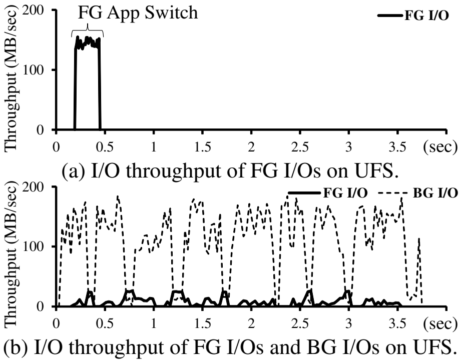
(b) A foreground app with a background app.

Fig. 5: Impact of page replacement.

clean, no writes to the storage device would be needed. Unlike our reasoning about read-dominant BG apps, our experiments revealed an interesting result that *even read-dominant BG apps can often interfere with an FG app*.

Although it was not straightforward to understand why such unexpected performance degradation occurs, we identified the page replacement policy in the page cache as the main cause. The existing Linux page replacement policy in the page cache works in an FG app-oblivious fashion. That is, the Linux kernel prefers choosing a clean page as a victim because of its cheap replacement cost regardless of whether the owner of the victim page is an FG app or a BG app. Suppose that BG apps want to read a large amount of data from the storage and they need to get more free pages by evicting existing ones from the page cache. In this situation, the Linux kernel often selects clean pages of an FG app even though those clean pages are soon to be accessed. Although choosing a clean page as a victim page is reasonable from minimizing the eviction cost, it is a bad decision for the FG app because a large page cache miss penalty can significantly increase the FG app response time.

Fig. 5 shows a concrete example of how a read-dominant BG app negatively affects an FG app. Here, the FG app *F* is assumed to read a file A twice by calling `read()`. Again, we compare two different cases: 1) when *F* solely runs and 2) when *F* runs together with a BG app which read a large file B from the storage device. Without BG apps, the FG app can quickly finish the second `read()` by reading the file A from the page cache (①). However, when the FG and BG apps run simultaneously, some pages of the file A may be evicted from the page cache (②) to create a room for the large file B. After the completion of BG reads, when the FG app tries to read the file A again, free pages should be allocated (③) and the previously-evicted pages should be read from the storage device again (④). Even worse, from our investigations on real-life app usage scenarios, we observed that many FG apps exhibit high temporal locality, repeatedly referencing the same files. For such an FG app, the existing page cache replacement policy can significantly degrade the user experience by evicting performance-critical hot pages of the FG app.



(a) I/O throughput of FG I/Os on UFS.

(b) I/O throughput of FG I/Os and BG I/Os on UFS.

Fig. 6: I/O priority inversions in flash storage device.

3.4 Root Cause 3: Device I/O Scheduling

After our bottleneck study on the page cache layer, we investigated the block layer as a next candidate for the I/O priority inversion problem. We analyzed how the block layer processes I/O requests from when the I/O requests are put into the I/O scheduler queue to when an interrupt handler receives signals notifying the completion of the requests in the storage device. Our investigation revealed that the I/O priority inversion problem occurred *in the storage device* rather than in the block layer.

Once the storage device gets I/Os from a block device driver, it processes them according to its own I/O scheduling algorithm. The storage device generally gives a higher priority to reads than writes because reads have a higher impact on user-perceived response time. For the same type of I/O requests, the storage device process them in an FIFO manner with no preference. Although this generic scheduling policy works reasonably well for equal-priority I/O requests, it causes I/O-priority inversions very frequently because the scheduling policy inside the storage device is not aware of the priority of an I/O request. For example, if FG writes and BG reads are sent to the storage device, the FG writes would be delayed until all the BG reads complete.

Fig. 6 illustrates the negative impact of a priority-unaware I/O scheduler inside a storage system on the throughput of FG I/Os. It plots the throughputs of FG I/Os and BG I/Os in the app switch scenario, where an FG app writes a large number of files, while huge files are being read in background. Note that the I/O throughputs were measured at the block device driver in order to device-level performance. Unlike the `FG-Only` case shown in Fig. 6(a), a significant degradation of the FG I/O throughput is observed in Fig. 6(b) when FG writes and BG reads are mixed inside the storage system. The app switch scenario, which was completed in 0.45 seconds without BG I/Os, took 3.55 seconds to finish. Our additional experiments showed that the I/O-priority inversion problem within the storage device occurs very frequently whenever FG writes are mixed with BG reads and its impact on an FG app is very serious.

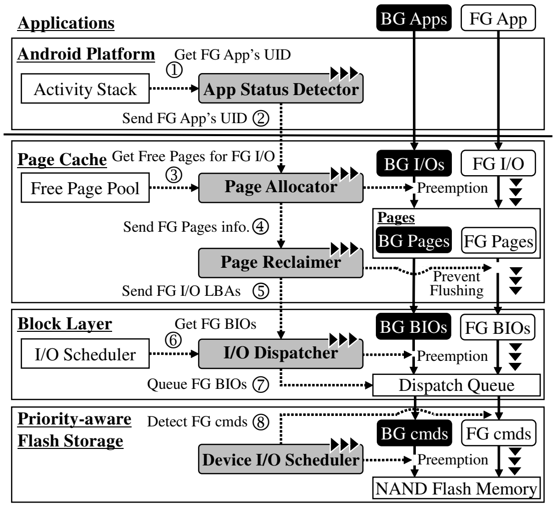


Fig. 7: An overall architecture of FastTrack.

4 Design and Implementation of FastTrack

As explained in the previous section, high-priority FG I/Os are unintentionally delayed by low-priority BG I/Os for various reasons across the entire I/O stack. One of the most commonly used solutions to resolve the I/O-priority inversion problem is to use the priority inheritance protocol that raises a priority of BG I/Os. The priority inheritance, however, is not effective in our cases – it still requires an FG app to wait for BG I/Os to finish, creating long delays to latency-sensitive smartphone users.

An ideal solution to resolve the problem is to create a *vertically-integrated fast I/O path* which is dedicated to serving FG I/Os across the entire I/O stack, including a page cache, a block layer, and a storage device. In other words, if it is possible to quickly preempt BG I/Os upon the arrival of FG I/Os and to deliver them directly to the storage device with minimal interference by I/O stack layers, it would be possible to provide the equivalent level of user-perceived responsiveness as when there is no BG I/O. Key technical challenges here are (1) how to identify FG I/Os from BG I/Os inside the kernel, (2) how to preempt BG I/Os immediately, and (3) how to prevent potential side effects that could occur when creating such a new I/O path.

Keeping these technical challenges in mind, we design the app status-aware I/O management, FastTrack, with five modules as illustrated in Fig. 7. The app status detector obtains the information of the current FG app by monitoring the activity stacks of the Android platform (①) and forwards it to the page allocator (②). Using this, the page allocator is able to identify I/O requests from the FG app, suspending the currently executing BG I/O jobs. The page allocator then grabs a global lock of the page cache, preferentially assigning free pages to FG I/Os, regardless of their arrival time (③). Until the page allocator releases the lock, BG I/Os are postponed.

If there are not enough free pages to handle I/O requests, the page reclaimer evicts kernel pages that belong to BG I/Os as victims, preventing FG pages from being flushed from the page cache (④). After acquiring all the free pages required, the page reclaimer builds up block I/Os for FG I/Os (FG BIOs) with designated LBAs, putting them into I/O scheduler's queue in the block layer (⑤). Upon the arrival of FG BIOs, the I/O dispatcher suspends servicing BG BIOs by limiting I/O queueing and then immediately delivers FG BIOs to the dispatch queue (⑥ and ⑦). When FG BIOs are converted to FG commands (FG cmds) for the storage device, the I/O dispatcher tags an FG I/O flag so that the device I/O scheduler suspends the BG I/O execution (⑧), and FG cmds can be processed immediately in the storage device.

4.1 App Status Detector

In order to identify an FG app among all the apps available in the system, the app status detector inquires of the Android activity manager holding all of the activities initiated by a user. Whenever a user inputs a command to a phone by touching a screen or an icon, the Android platform creates a new activity, which is a sort of job corresponding to user's command, and puts it into an activity stack in the Android activity manager. Since the top activity on the stack points to the current interactive app with a user (i.e., an FG app), the FG app information in the system can be easily retrieved.

All of the Android apps have its own unique ID number, called UID, which is assigned when an app was installed in the system. An UID number is different from Linux's process ID (PID). Thus, our next step is to find a list of the Linux processes connected to the FG app. A list in question can be obtained by examining all the processes in Linux's process tree. However, such an exhaustive search on the process tree takes a relatively long time. Therefore, the app status detector maintains an UID-indexed table that is updated whenever a new process or thread is created or terminated. Then, using UID as a key, the app status detector quickly retrieves a list of FG app's processes.

Whenever the top activity changes, the app status detector sends an UID of the new FG app, along with PIDs and TIDs of related Linux processes, to the Linux kernel via the `sysfs` interface. By doing this, app status detector can keep track of the currently executing FG app.

4.2 Page Allocator

The page allocator is designed to preferentially allocate kernel pages to I/O requests from an FG app by suspending outstanding BG I/Os. Fig. 8 shows how the page allocator works using the same example in Fig. 4, where the FG app generates read requests to the kernel just after the BG app issued write requests. The page allocator sees if the I/O request is from the FG app or not by

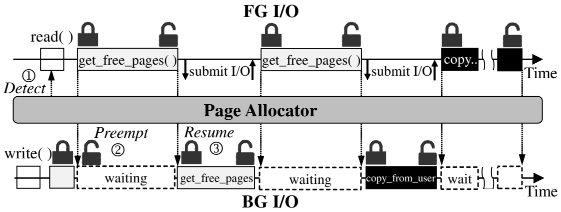

Fig. 8: Preemption of background I/Os.

comparing its UID, PIDs, and TIDs with the ones that it previously got from the app status detector (①). If it is from the FG app, the page allocator forces BG I/Os to release a global lock of the page cache just after getting a page currently being requested (②). After allocating desired pages to the FG I/Os, the page allocator resumes the preempted BG I/Os (③). At the same time, the kernel issues FG BIOs to fill up the allocated pages with data read from storage media. In a similar way, the page allocator suspends and resumes data copy operations of BG I/Os between the user and kernel space.

In order to support the prompt preemption and resumption of BG I/Os, we modified the major kernel functions relevant to the page cache, including `alloc_pages()`, `do_generic_file_read()`, and `generic_perform_write()`. These functions are divided into several execution segments. At the end of each segment, the page allocator checks if there are waiting FG I/Os. If so, the page allocator promptly suspends BG I/Os, unlocks the page-cache lock, and yields the CPU for the FG I/Os. After serving FG I/Os, the suspended BG I/Os restart at the point where they were suspended.

While conceptually simple, the implementation of the preemptive page cache raises two technical issues. Firstly, giving the highest favor to FG I/Os does not guarantee the improved response time all the time, and, in the worst case, it may result in serious response time degradation or even application deadlocks. Imagine an application that downloads files from the network and performs certain operations on the download files. The application model of Android requires an app to offload such a typical task to a built-in process that runs as a background service. In case of a file download, a network service process performs downloading files in background on behalf of a user app. If I/O requests from the network service process are preempted for FG I/Os, the execution of the FG app that initiates the file download would be delayed for a long time. Fortunately, the Android system does not allow such dependency between conventional user apps (e.g., game and camera apps) [40]. To avoid the self-harming preemption mentioned above, therefore, it is only necessary to prevent the preemption for BG I/Os from service processes. To do this, the page allocator checks if BG I/Os are issued by services or not and excludes them from the preemption if they are from service processes. This I/O filtering can be done by checking UID because the Android system assigns predefined UIDs to service processes, giving UIDs ranging from 10,000 to 19,999 to user apps [41].

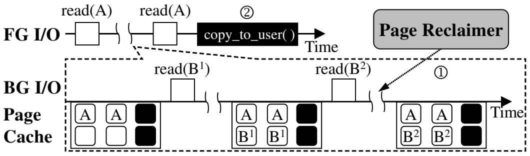

Fig. 9: Prevention of foreground page evictions.

Secondly, performing the preemption at the page cache level is not always possible. Some pieces of the kernel code must run in a special context, called an *atomic context* [42], which does not allow a CPU to go into sleep. Representative examples are interrupt handlers and critical section codes wrapped by spinlocks. The page allocator modifies the page cache functions that are also invoked by other parts of the kernel for various purposes. Thus, the page allocator should disable the preemption if it is called by a caller running in the atomic context. It is straightforward to know whether the page allocation is requested inside the atomic context. In the Linux kernel, a caller function should let the memory allocator know which type of contexts it runs now as an argument (e.g., `GFP_ATOMIC`). The page allocator refers this information and prevents the preemption if the allocation is requested inside the atomic context.

4.3 Page Reclaimer

In addition to preempting BG I/Os to accelerate page allocation for FG I/Os, the page reclaimer improves the performance of FG apps by preventing the eviction of kernel pages belonging to the FG apps.

Fig. 9 illustrates how the page reclaimer operates using the same example in Fig. 5, where the FG app attempts to read the file A twice, while the BG app is heavily reading the large file B. In Fig. 5, the second read to the file A is not hit by the page cache since it was chosen as a victim and was evicted from the page cache (② in Fig. 5). As explained earlier, this is due to the kernel's page replacement that evicts clean pages first, regardless of the status of an app. The page reclaimer prevents such a problem by adopting new replacement priorities for victim selection: *BG clean pages* (highest) $>$ *BG dirty pages* (high) $>$ *FG clean pages* (low) $>$ *FG dirty pages* (lowest). With the new policy, clean pages belonging to BG apps are preferentially evicted when there is insufficient memory. In Fig. 9, the pages labeled by B^1 are evicted for B^1, even though the pages for the file A were least recently referenced (① in Fig. 9).

Keeping FG pages in the page cache wouldn't be effective if an FG app has low temporal locality. In the worst case, it would degrade the performance of BG apps without any performance improvement on an FG app. According to the mobile app workload study [43], however, the majority of the apps have high degrees of data locality. Thus, the negative effects of the page reclaimer are expected to be minimal in smartphone usages.

4.4 I/O Dispatcher

The primary goal of FastTrack is to create a fast I/O path for FG I/Os in the entire kernel layer. To this end, it is also required to enhance the block I/O layer, together with the page cache layer. Once block I/Os are delivered to the block layer from the page cache, they are put into a sync queue or an async queue in the I/O scheduler according to their types. To accelerate FG BIOs, the I/O dispatcher looks for FG BIOs in both queues and moves them to the dispatch queue immediately.

Depending on the type of a queue, the I/O dispatcher has to take different strategies to find FG BIOs. FG BIOs can be easily found in the sync queue using the FG app's PID number delivered by the app status detector. In the case of async I/Os, however, the PID number of all async I/Os is the same as the PID of the kworker kthread which delivers async BIOs to the block layer on behalf of FG processes. Since the PID number is useless to find async FG BIOs, the I/O dispatcher uses LBAs as keys to fetch FG BIOs from the async queue.

Finally, whenever a new BIO enters the sync/async queues, the I/O dispatcher prevalidates whether it is FG BIO, then directly sends FG BIO to the dispatch queue regardless of its priority in sync/async queues.

4.5 Device I/O Scheduler

In order for FastTrack to achieve its maximum benefit, a storage device, which is at the lowest layer in the I/O stack, needs to be enhanced as well. According to [44, 45, 46], modern flash storage maintains its own internal queue, but is unaware of the status of applications issuing I/Os. To make a storage device FG I/O-aware, we modify an SCSI command set so that it carries an additional flag in a reserved opcode [47] that specifies whether I/O requests are issued by FG apps or not. This flag is used as a hint for a device-level I/O scheduler to decide the execution order of I/O requests staying in the internal I/O queue. In our current design, we assign the highest priority to FG reads, followed by FG writes and BG reads. BG writes are assigned to the lowest priority.

5 Experimental Results

In order to quantitatively evaluate the effect of FastT, we implemented the FastT modules in the Android 7.1.1 and the Linux kernel 3.10.61. Four smartphones, Nexus 5 (N5), Nexus 6 (N6), Galaxy S6 (S6) and Pixel (P1) were used for our evaluation. N5 and N6 use eMMC-based storage devices while S6 and P1 employ UFS-based storage devices. (Note that UFS supports 3 times higher throughput over eMMC.) All the smartphones were connected to the Internet through a 5-GHz Wi-Fi.

We have chosen two background usage scenarios: `Update` for a write-dominant workload and `Backup` for a read-dominant workload. The `Update` scenario updated Hearthstone game [48] downloaded from Play Store, whose size was about 1.5 GB. The `Backup` scenario uploaded 1 GB of data files to cloud storage.

While running BG apps, we executed three FG apps, `Gallery` (app launch), `Camera` (app switch), and `Game` (app loading) discussed in Section 2.2. `Gallery` was a read-dominant workload, `Camera` was a write-dominant workload, and `Game` was a mixed workload. In order to accurately measure performance, all other apps were terminated before the experiment.

5.1 Performance Analysis on Smartphones

As the response time lower limit of an FG app, we first measured user-perceived response time of the FG app when only the FG app ran without any BG apps. To understand the impact of a BG app on performance, we also measured performance when both FG and BG apps ran simultaneously on the unmodified kernel. The above two cases are denoted by FG-only and FG+BG, respectively. We compared the performances of FG-only and FG+BG with four different versions of FastT: PA, PR, ID and FastT^{-}. PA, PR, ID represents FastT with a single main component only, that is, the page allocator, the page reclaimer, and the I/O dispatcher only, respectively. FastT^{-} employs all of the main components but it uses the existing storage device I/O scheduler[5]. In all the FastT versions we tested, the app status detector was enabled by default.

Fig. 10 shows that, for six different combinations of FG and BG apps, FastT^{-} reduced the user-perceived response times by 74% over FG+BG, on average. PA exhibited significant performance improvements when BG apps were write-dominant (i.e., `Update`). `Update` required a copy of data from the user space to the kernel, which involved the allocation of free pages in the page cache. PA not only made this acquisition process preemptible, but also gave a higher priority to an FG app so that it got free pages prior to BG apps. By doing this, PA was able to prevent FG I/Os from being blocked by BG writes. Unlike PA, PR mostly contributed to reducing user-perceived response time when the read-dominant BG app (i.e., `Backup`) ran. In our observation, `Backup` required many free pages to load files from the storage before sending them to cloud storage. To create free pages, it often selected clean pages belonging to FG apps as victims, which resulted in the eviction of hot data from the page cache. PR prevented those clean pages from being evicted from the page cache, thereby reducing the

[5] Unfortunately, we cannot access the firmware inside the storage device. For a complete FastT implementation, we use an emulated storage as discussed in Section 5.2.

(d) Gallery app launch time under Backup. (e) Camera app switch time under Backup. (f) Game app loading time under Backup.

Fig. 10: Response time analysis on smartphones.

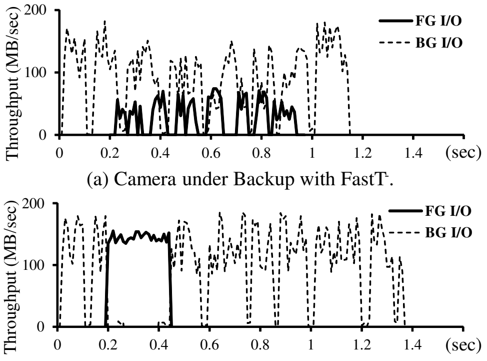
number of reads from the storage which were not necessary when only FG apps ran. ID improved the response times by 11% on average, but its impact on performance was negligible compared with PA and PR. This result confirmed our hypothesis that rescheduling I/O requests at the scheduler level was less efficient than doing it at a higher level – a page cache. As expected, by integrating the three techniques, FastT$^-$ exhibited the best performance among all the versions evaluated.

Fig. 10 also shows that FastT$^-$ works more efficiently atop a faster storage device like UFS (used in S6 and P1) than a slower one like eMMC (used in N5 and N6). In our observation, the absolute numbers of I/O latencies reduced by FastT$^-$ are almost the same, regardless of the type of underlying storage devices (i.e., UFS or eMMC). Therefore, the overall improvement ratio by FastT$^-$ becomes more significant for the fast storage, where FG apps generally exhibit shorter response times. This means that as the storage devices evolve in its speed, the effect of FastT becomes more substantial.

Even though FastT$^-$ gave FG I/Os the highest priority combined with a fast I/O path, we still observed that FastT$^-$ showed longer response times than FG-Only in all the scenarios. When we compare Fig. 11(a) and Fig. 6(a), the throughput of FG I/Os was not improved as much as FG-Only. This is because FastT$^-$ cannot resolve the I/O-priority inversion problem inside the storage device. Because of a priority-unaware I/O scheduler, for example, FG writes are always delayed by BG reads.

5.2 Performance Analysis on Emulator

Although the evaluation results in Section 5.1 showed that FastT$^-$ is quite effective on real smartphones, FastT$^-$ didn't reveal the full potential of our proposed FastT because it cannot fully control the storage device-internal I/O scheduler. In order to better understand the real effect of FastT on user experience, it is important to implement the proposed I/O device scheduler (in Section 4.5) with a complete support for the fast I/O path from the Android platform to the storage device. Since storage vendors do not allow to modify their firmware inside their storage devices, we performed evaluations using an emulated storage device with I/O traces collected from real smartphone apps.

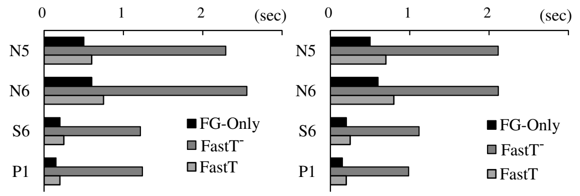


(a) Camera under Backup with FastT⁻.

(b) Camera under Backup with FastT.

Fig. 11: Storage-level snapshot of FG I/Os and BG I/Os.

We have implemented an emulation layer on top of an off-the-shelf SSD to emulate I/O latency and throughput of eMMC and UFS devices. This work is done by using a storage emulator developed for our prior studies [14]. Then, we collected the app status information, along with I/O traces, while executing scenarios described in Section 5.1 on the smartphone. The collected I/O traces were replayed on the emulated storage. Finally, we implemented the device I/O scheduler on the emulated storage which processed FG I/Os with a higher priority.



(a) Camera under Update. (b) Camera under Backup.

Fig. 12: Response time analysis on emulator.

We compared the performance of three policies: FG-only, FastT^{-}, and FastT, where FastT is FastT^{-} with the device I/O scheduler. Fig. 12 shows that FastT greatly improved the performance of Camera under both Update and Backup. In the case of Camera under Update on N6, FastT^{-} achieved the response time of 2.53 seconds, whereas FastT achieved the response time of 0.75 seconds, which is quite close to 0.6 seconds of FG-Only. For Camera under Backup, similarly, FastT achieved an equivalent response time to FG-Only. Compared with Fig. 11(a), in Fig. 11(b), we observe that FG I/Os were processed at a much higher throughput with negligible delays at the storage device level. This result shows that higher performance can be achieved if the storage device is able to handle I/O requests with the app-level priority information.

Finally, Fig. 13 shows how FastT scales when the number of BG apps increases from two to six. In addition to Update and Backup, we used four more I/O-intensive BG apps for this experiment. As shown in Fig. 13, the normalized app switch time increases from 1.1 to 1.27 only as the number of BG apps increases from 2 to 6. These results indicate that FastT can provide the equivalent level of responsiveness to an FG app regardless of the number of BG apps running with the FG app. Fig. 13 also shows that FastT is effective in improving the app switch time over the existing Android implementation (indicated by FG+BG), reducing the app switch time by 94% when 6 BG apps run.

6 Related Work

Various I/O scheduling techniques have been proposed to address the problem caused by BG I/Os [18, 19, 49, 50]. A boosting quasi-async I/O (QASIO) is one of such efforts to provide better I/O scheduling by means of the priority inheritance protocol [18]. QASIO is motivated by an observation that high-priority sync writes are often delayed by low-priority async writes. QASIO improve overall I/O responsiveness by temporarily increasing the priority of async writes over sync ones. A request-centric I/O prioritization (RCP) [19] is proposed which is also based on the priority inheritance protocol. RCP further improves QASIO by prioritizing I/O requests at the page cache layer rather than the block I/O layer.

While still effective, both QASIO and RCP have fundamental limitations in improving I/O responsiveness, in comparison to FastTrack. First, both techniques are not aware of FG I/Os and BG I/Os in smartphones, and thus, they are unable to prioritize FG I/Os that have a high impact on user-perceived response times. Second, QASIO and RCP both rely on the priority inheritance protocol. Thus, they cannot remove additional delays required for high-priority I/Os to wait until low-priority ones finish. Therefore, their effectiveness on improving user-perceived latency is limited on highly interaction-oriented devices like smartphones.

Foreground app-aware I/O management (FAIO) [49] is the first technique that accelerates FG I/Os by adopting I/O preemption in smartphones. FAIO analyzes FG app information to identify FG I/Os and preempts BG I/Os to quickly process FG I/Os. However, since FAIO uses I/O preemption only at the page cache level, it does not resolve the priority inversion problem at the storage device level. It also fails to prevent performance degradation caused by the aggressive evictions of FG data from page cache under BG I/O intensive workloads.

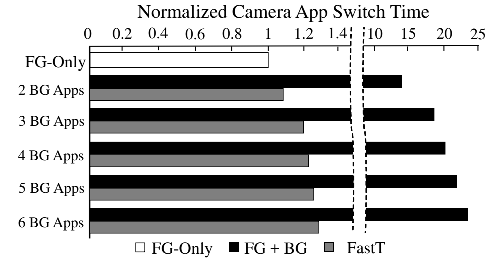


Fig. 13: Scalability of FastT over the varying BG apps.

7 Conclusions

We have presented a foreground app-aware I/O management scheme, FastTrack, which significantly improves the quality of user experience on smartphones by avoiding I/O-priority inversions between a foreground app and background apps on Android smartphones. Unlike the existing techniques, FastTrack employs a preemption-based approach for fast responsiveness of a foreground app. In order to support I/O-priority-based preemption in a holistic fashion, FastTrack reimplemented the page cache in Linux and the storage-internal I/O scheduler which previously operated in a foreground app-oblivious fashion. From a systematic analysis study, these two modules were identified as the root causes of most I/O-priority inversions. Our experimental results on real smartphones show that FastTrack is effective in improving the quality of user experience on smartphones. For example, FastTrack achieved the equivalent quality of user experience of a foreground app regardless of the number of concurrent background apps.

FastTrack can be extended in several directions. For example, we believe that our preemption-based approach can be extended to other computing environments where a strong requirement on the response time exists.

8 Acknowledgments

We would like to thank anonymous referees for valuable comments that greatly improved our paper. Abstract

Mainstream is a new video analysis system that jointly adapts concurrent applications sharing fixed edge resources to maximize aggregate result quality. Mainstream exploits partial-DNN (deep neural network) compute sharing among applications trained through transfer learning from a common base DNN model, decreasing aggregate per-frame compute time. Based on the available resources and mix of applications running on an edge node, Mainstream automatically determines at deployment time the right trade-off between using more specialized DNNs to improve per-frame accuracy, and keeping more of the unspecialized base model to increase sharing and process more frames per second. Experiments with several datasets and event detection tasks on an edge node confirm that Mainstream improves mean event detection F1-scores by up to 47% relative to a static approach of retraining only the last DNN layer and sharing all others ("Max-Sharing") and by 87X relative to the common approach of using fully independent per-application DNNs ("No-Sharing").

1 Introduction

Video cameras are ubiquitous, and their outputs are increasingly analyzed by sophisticated, online deep neural network (DNN) inference-based applications. The ever-growing capabilities of video and image analysis techniques create new possibilities for what may be gleaned from any given video stream. Consequently, most raw video streams will be processed by multiple analysis pipelines. For example, a parking lot camera might be used by three different applications: reporting open parking spots, tracking each car's parking duration for billing, and recording any fender benders.

This paper focuses on video processing on edge devices, which will be a common way to address bandwidth limitations, intermittent connectivity (e.g., in drones), and real-time requirements. Applications executing at the edge, though, face tighter bounds on resource availability than in datacenters. Naturally, optimal video application performance requires tuning for the resources available [48, 12, 51, 18, 26].

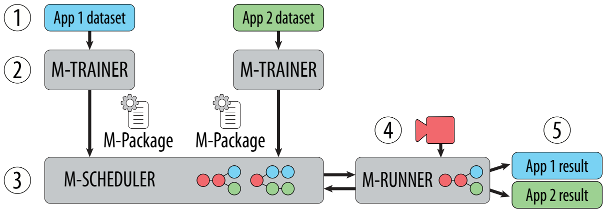

Figure 1: Mainstream Architecture. Offline, for each task, M-Trainer takes a labeled dataset and outputs an M-Package. M-Scheduler takes independently generated M-Packages, and chooses the task-specific degree of specialization and frame rate. M-Scheduler deploys the unified multi-task model to M-Runner, performing inference on the edge.

Unfortunately, what resources will be available to the application at deployment time is often unknown to the developer. Further, resource availability changes as additional applications arrive and depart. Instead, individual application developers typically develop their models in isolation, assuming either infinite resources or a predetermined resource allotment. When a number of separately tuned models are run concurrently, resource competition forces the video stream to be analyzed at a lower frame rate—leading to unsatisfactory results for the running applications, as frames are dropped and events in those frames are missed. However, due to the popularity of *transfer learning* (Sec. 2) [40, 47, 37, 43], contention can be reduced by eliminating redundant computation between concurrent applications [18].

Mainstream is a new system for video processing that addresses resource contention by dynamically tuning degrees of work sharing among concurrent applications. Specifically, it focuses on sharing portions of DNN inference, which consumes the majority of video processing cycles. Mainstream exploits the potential "shared stem" of computation that results from application developers' use of the standard DNN training approach of transfer learning. In transfer learning, training begins with an existing, *pre-trained* DNN, which is then re-trained for a different task. Typically, only a subset of the pre-trained DNN is specialized; when different applications start with the same pre-trained DNN, Mainstream identifies the common layers and executes them only once per frame.

A critical challenge of exploiting shared stems well is determining how much to share. Application developers usually specialize as much of the pre-trained DNN as is necessary to achieve high model accuracy. More specialization, however, means that less of the pre-trained DNN can be shared. Thus, there is an explicit trade-off between the benefits of greater per-frame accuracy (via more-specialized DNNs) and processing more frames of the input video stream (via more sharing of less-specialized DNNs). The right choice depends on the edge device resources, the number of concurrent applications, and their individual characteristics.

Deployment time model selection. Mainstream moves the final DNN model selection step from application development time to deployment time, when the hardware resources and concurrent application mix are known. By doing so, Mainstream has the necessary information to select the right amount of DNN specialization (and thus sharing) for each application. As applications come and go, Mainstream can dynamically modify its choices. Previous systems like VideoStorm [48] select models by considering each application independently. *The specialization-vs-sharing trade-off, however, can only be optimized when considering applications jointly.* Joint optimization produces a combinatorial set of options, which Mainstream navigates using application metadata and domain-specific models; the system uses this information to estimate the effects of DNN specialization and frame sampling rate on application performance. Unlike black-box approaches, Mainstream can jointly optimize for stem-sharing without needing to profile each combination.

Mainstream consists of three main parts (Fig. 1). The *M-Trainer* toolkit helps application developers manage their training process to produce the information needed to allow tuning the degree of specialization at deployment time. Current standard practice is for developers to experiment with different model types, hyperparameters, and degrees of re-training to find the best choice for an assumed resource allocation, discarding the trained DNN models not chosen. M-Trainer instead keeps "less optimal" *candidate* DNN models, together with associated training-time information (e.g., per-frame accuracy, event detection window). The *M-Scheduler* uses this information, together with a profile of per-layer runtime on the target edge device, to determine the best candidate for each application—including the degrees of specialization and, thus, sharing. It efficiently searches the option space to maximize application quality (e.g., average F1 score among the applications). The *M-Runner* runtime system runs the selected DNNs, sharing the identical unspecialized layers.

Experiments with several datasets and event detection tasks on an edge node confirm the importance of making deployment-time decisions and the effectiveness of Mainstream's approach. Results show that dynamic selection of shared stems can improve F1-scores by up to 87X relative to the common approach of using fully-independent per-application DNNs (No-Sharing) and up to 47% compared to a static approach of retraining only the last DNN layer and sharing all others (Max-Sharing). Across a range of concurrent applications, Mainstream adaptively selects a balance between per-frame accuracy and frame sampling rate that consistently provides superior performance over such static approaches.

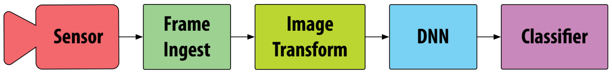

Figure 2: Example computation pipeline for event detection.

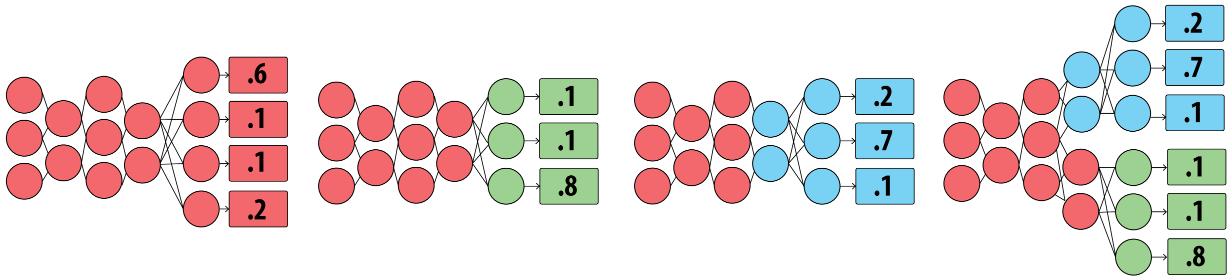
Contributions. This paper makes three main contributions. First, it highlights the critical importance of reducing aggregate per-frame CPU work of multiple independently developed video processing applications via stem-sharing; No-Sharing is unable to support even three concurrent applications on our edge node deployment. Second, it identifies the goodness trade-off between per-frame quality and the frame sampling rate dictated by the degree of DNN specialization (and thus the amount of sharing). Third, it describes and demonstrates the efficacy of the Mainstream approach for automatically deploying the right degree of specialization for each submitted application's DNN.

2 Background

DNNs are a powerful tool used in computer vision tasks such as human action recognition [43], object detection [15], scene geometry estimation [14], face recognition [45], etc. Fig. 2 shows a typical computation pipeline for an image classification application. Although frame ingest and image preprocessing are necessary stages of computation, they are low cost and easily shared between concurrent applications. DNNs, on the other hand, are typically unique to each application and computationally expensive: in one image classification application we run, the DNN inference incurs 25X more latency than the preprocessing steps.

DNNs and transfer learning. A machine learning (ML) *model* is a parameterized function that performs a task. *Training* is the process of learning parameter values (called weights) such that the model will approximate the desired function with some measure of accuracy. For example, when training an image classifier, one might examine labeled input images and use gradient descent to find a set of weights that minimizes a loss function over the labels. Using the trained model to find the function's



(a) Base DNN model **(b)** App. #1's DNN model **(c)** App. #2's DNN model **(d)** As executed in Mainstream

Figure 3: Fig. 3a depicts a base DNN trained from scratch for its task. Fig. 3b and Fig. 3c show two new task DNNs, fine-tuned against the base DNN. App. #1 freezes more layers during training than App. #2. Fig. 3d shows how Mainstream runs the applications concurrently. Layers frozen by both App. #1 and App. #2 can be shared.

Architecture	Number of Layers	ImageNet Top-1 Accuracy (%)
InceptionV3	314	78.0
MobileNets-224	84	70.7
ResNet-50	177	75.6

Table 1: Top-1 accuracy of three neural networks architectures trained on the ImageNet dataset.

output given a new, unlabeled input is called *inference*.

DNNs are a class of ML models that usually have a large input space, such as the pixels of an image. A DNN can be represented by a graph where nodes are organized into *layers*; each node computes a function of its inputs, which are outputs from the previous layer.

The "deep" in DNNs refers to their many layers. Increasingly, successful applications of DNNs have largely been the result of building models with more layers that take larger vectors of inputs [42, 29, 19, 44]. The success of these models has hinged critically upon the arrival of very large, labeled datasets for training [13, 32, 3].

Training these large models is notoriously hard. One often lacks sufficient labeled data or computational resources to train such a model. *Transfer learning* is an alternative to training a model from scratch. Here, a model that has already been trained on a similar task (a *base DNN* as in Fig. 3a), is used as an initialization point or feature extractor for the new *target DNN*. During training, a subset of the old parameters are *frozen* and do not change. The remaining free parameters are then retrained on the new task with a new training dataset (Fig. 3b and Fig. 3c). This process *fine-tunes* these parameters to achieve a result comparable to end-to-end training on the entire DNN, but does so with much less data and at a much lower computational cost. In practice, few practitioners train networks from scratch, let alone develop novel network architectures. Transfer learning via one of a few popular neural networks is standard practice.

DNNs for image classification and event detection. Although we believe that Mainstream's approach is generally applicable to video stream analysis, in this paper, we focus on applications that use image-classification DNNs to perform event detection.

Image classification aims to assign one label from a set of categories or *classes* to each image. For example, a 10-class classifier takes an input image and returns a 10-item vector of probabilities representing the likelihood that the image belongs to each class. *Top-N accuracy* is the probability that the correct label is among the top-N highest probability output labels. So, Top-1 accuracy indicates the fraction of images that the model classifies correctly. We refer to this metric as the *per-frame accuracy* in the context of video classification. Popular neural network architectures for image classification include ResNet [19], InceptionV3 [44], and MobileNets [20]. Table 1 describes these three neural networks and their Top-1 accuracy achieved on the ImageNet dataset [13]. Networks trained on ImageNet are popular base-DNNs for image classification tasks.

We define an event as a contiguous group of frames containing some visible phenomenon that we are trying to identify: e.g., a cyclist passing by, or a puff of smoke being emitted. One way of doing event detection is to perform image classification across a sequence of frames. An event is detected if at least one of the contiguous frames is sampled, analyzed, and correctly labeled. Previous works [31] have also used this existence metric to measure recall and precision of range-based queries. (Event detection is not to be confused with object detection, where the goal is to locate an object in a single frame. Indeed, object detection is another way of performing event detection.) We evaluate event classification applications by measuring the *event F1-score*, the harmonic mean between *event recall* and *event precision*. The event recall reports the proportion of ground truth events identified. The event precision reports the proportion of classified events that are true positives. Note that these metrics are relative to the detection of events across multiple frames and are distinct from per-frame metrics (e.g., Top-1 accuracy).

3 Mainstream Approach: What and Why

Sharing computation between DNNs. When supporting multiple inference applications on a single infrastructure, the common approach is to execute every application's DNN model independently. We refer to this as a "No Sharing" approach. To avoid redundant work, Mainstream instead computes results for DNN layers common to multiple concurrent applications just once and distributes the outputs of shared stems to the specialized layers of all sharing applications. This is analogous to common subexpression elimination used in other domains, e.g., optimizing compilers or database query planners.

Fig. 3 illustrates how compute sharing can be leveraged when two DNNs are fine-tuned from a common pre-trained model and have some unspecialized layers in common. Compute sharing can significantly affect per-frame computation cost and improve throughput for a given CPU resource. Fig. 4a quantifies this effect. It shows the throughput achieved by Mainstream running up to eight concurrent InceptionV3-based event detection pipelines, as a function of how many DNN layers they have in common (i.e., their common degree of specialization). With no sharing (the left-most points), adding a second application halves throughput, which continues to degrade geometrically as more applications are added. Moving to the right, throughput improves as more layers are shared. When all but the last layer are shared, additional applications can be run at very low marginal cost.

On the other hand, there are costs to enabling sharing by leaving many layers unspecialized. In particular, the per-frame accuracy of a model may be lower when only a few layers are specialized. Fig. 4b shows the effect of specialization on per-frame accuracy for several combinations of DNN architectures and classification tasks. As expected, accuracy decreases slowly as less-specialized networks are employed (and hence more sharing is enabled)— with a large decrease occurring only when the fraction of the network specialized is very small. This characteristic enables Mainstream to share large portions of the network with low accuracy loss.

Adaptive management of the sharing opportunity. Since transfer learning is so commonly used by ML developers, and base models are shared within organizations and on the Internet, there may be many opportunities to exploit inter-DNN redundancy in the unspecialized layers. Most developers either use a popular default of specializing only the last layer (which is great for sharing potential, at the potential cost of model accuracy) or determine the degree of specialization based on the amount of training data available, since retraining too many layers without sufficient training data leads to over-fitting. Notably, each developer decides independently.

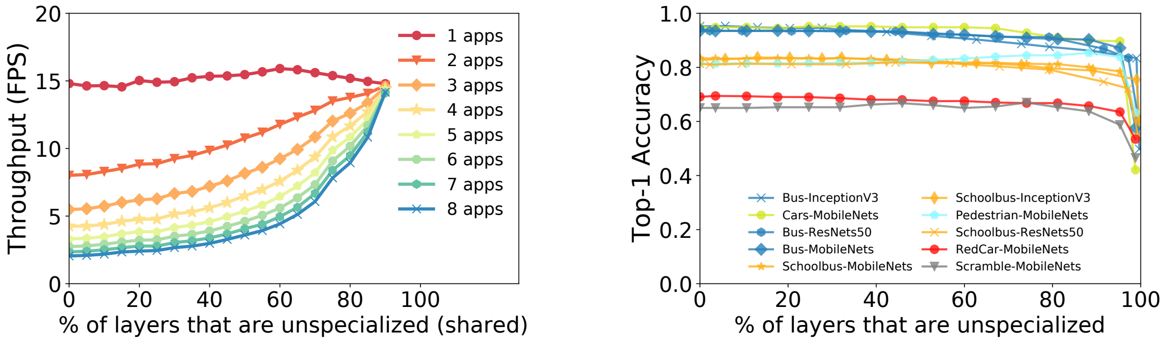
The problem with this approach is that the impact of sharing computation on application quality depends on factors only known at deployment time: the set of concurrent applications and the resources of the edge node on which they are run. Hence, Mainstream defers the decision regarding how much specialization to employ from application development time to deployment time.

Impact of sampling rate for event detection. Given the trade-off between per-frame accuracy and frame processing throughput, picking the right degree of specialization is challenging. Consider an application for monitoring environmental pollution from trains, which is being built using a train detector we deployed. When the application detects a train coming into view, it triggers the capture of high fidelity frames of the train's smoke stack (for subsequent pollution analysis).

Increasing specialization to improve per-frame accuracy increases the probability of correctly classifying frames containing trains— but reduces shared computation. This, in turn, leads to less frequent sampling, which removes opportunities to analyze frames containing a particular view of a train. A higher frame rate increases the probability that an event will be observed in more frames, creating more opportunities for detection. So, the question becomes: should one sample more frames using a less accurate model or sample fewer frames using a more accurate model?

Analytical model for event detection. The Mainstream scheduler (Sec. 6) navigates this "accuracy vs. sampling rate" space by evaluating various candidate *{specialization, frame rate}* tuples. To do so, however, the scheduler must be able to interpret the benefit at the application (not per-frame) level. Hence, we propose an analytical model (sketched in Equations 1-4, below) that approximates the *event* F1-score for a given DNN, given estimates of (a) event length, (b) event frequency, (c) the correlation between frames (discussed below), (d) per-frame DNN accuracy, and (e) DNN analysis frame rate. The frame rate (e) comes directly from the scheduler's proposed tuple; similarly, the accuracy (d) associated with a given specialization proposal will be available to the scheduler (see Sec. 5). Values for event length (a), frequency (b), and correlation (c) can either be measured using representative video samples, or they can be estimated by the developer.

We are able to predict the application's F1-score by estimating the expected number of frames per event that we will have the opportunity to analyze and computing the probability that analyzing the set of frames will result in a detection. The expected number of frames analyzed per event is dependent on the event length and frame rate. The per-frame Top-1 accuracy represents the probability that



(a) Throughput vs. Sharing

(b) Per-frame accuracy vs. (Potential) sharing

Figure 4: Conflicting consequences of DNN compute sharing. (a) shows the frame processing rate for 1–8 concurrent event detection applications as a function of the fraction of the InceptionV3 DNN they share, from No-Sharing on the left to sharing all but the last layer (Max-Sharing) on the right. The experiments are run on the hardware described in Section 7. (b) shows Top-1 accuracy as a function of the fraction of unspecialized layers for three popular DNN architectures (ResNet-50 [19], InceptionV3 [44], and MobileNets-224 [20]) using six of the datasets described in Table 2. We trained each classifier using all three network architectures but omitted some curves for brevity. The horizontal axis starts from fully specialized DNNs on the left to only the last layer being specialized on the right; recall that potential computation sharing is limited to the unspecialized layers.

we will classify any individual frame correctly. However, this does not factor in the fact that sequential frames of an event may be correlated in some way. We therefore introduce and estimate the *inter-frame correlation*, which measures the marginal benefit of analyzing more frames of a single event.

The inter-frame correlation, *corr*, is based on conditional probabilities. For frames corresponding to an event, if P(X_i) and P($\neg X_i$) are the probabilities of detecting or not detecting the event in frame i, respectively, then $P(\neg X_2 \mid \neg X_1)$ is the probability of not detecting the event in frame X_2, given that we did not detect it in frame X_1. This conditional probability can be measured empirically from training data. Relying on the Kolmogorov definition, we can calculate the probability the event is detected in at least one of the two frames as $1 - P(\neg X_2 \mid \neg X_1) * P(\neg X_1)$. This logic can be extended to approximate the probability of detecting the event in N tries and to estimate recall.

To estimate recall, we calculate the probability that our DNN will correctly classify at least one frame of an event using the following steps:

$$N = \begin{cases} \left\lceil \frac{d}{stride} \right\rceil & \text{w.p. } \frac{d-(stride\%d)}{stride} \\ \left\lfloor \frac{d}{stride} \right\rfloor & else \end{cases} \tag{1}$$

$$P_{miss\_1} = 1 - accuracy_{per-frame} \tag{2}$$

$$P_{miss\_N} = corr^{N-1} * P_{miss\_1} \tag{3}$$

$$recall = 1 - P_{miss\_N} \tag{4}$$

We use Eq. 1 to calculate N, the expected number of frames of the event that the model will process. Here, d is the event length, and *stride* is the inverse of the frame rate. Equation 3 estimates the probability the DNN misclassifies all N analyzed frames. Recall is the complement: the probability that we correctly classify at least one frame of the event.

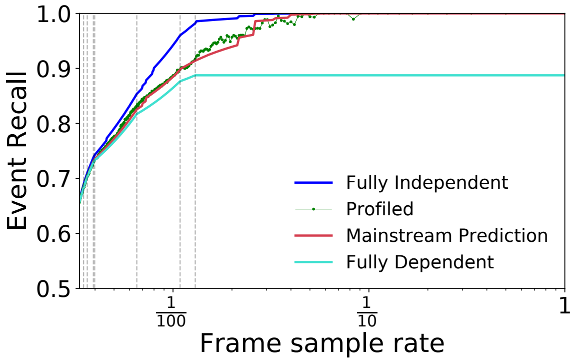


Figure 5: Effect of sample-rate on recall, for different inter-frame correlations. The dotted vertical lines represent each train in the dataset, denoting $\frac{1}{trainlength}$, which is the sample rate required to ensure that one frame of that train is analyzed. The "Profiled" line is measured directly from the TRAIN video dataset, and the other three are approximations based on different inter-frame correlations (uncorrelated, fully correlated, and the empirical correlation observed in the TRAIN dataset).

To estimate the false positive rate, we repeat this calculation, except that d is the number of frames between events (derived from the event frequency), and P_{miss_1} is the probability of *true* negatives. The true positive rate, the false positive rate, and the event frequency are used to calculate the precision. The F1-score is the harmonic mean between precision and recall.

To evaluate our model, we profile an application and measure the actual recall observed when running the event detector application (e.g., train detection) on the video stream at different sampling rates (Fig. 5). This was measured by averaging the recall achieved from 10,000 trials of sampling at each sample rate. The result is plotted by the "Profiled" line. Our analytical model ("Mainstream Prediction") is sufficiently accurate to describe the complex relationship between frame sample rate and application recall. Mainstream uses this analytical model to efficiently optimize for the trade-off between per-frame accuracy and frame rate.

We use Mainstream for event detection but believe its approach can be generally applied to DNN-based tasks where application quality depends not only on its model, but also on its input sampling rate (e.g., object tracking, action recognition.)

4 Mainstream Architecture

We have developed Mainstream, a training and runtime system for DNN-based live analytics of camera streams, which (a) enables efficient sharing of computation between detection applications, (b) maximizes event F1-score across all tasks, and (c) allows each task to be independently developed, trained, and deployed. Fig. 1 shows the architecture of Mainstream, which consists of three components: M-Trainer, M-Scheduler, and M-Runner.

To deploy a new application to Mainstream, the user provides a corresponding labeled training dataset to their local instance of M-Trainer (Step 1). M-Trainer uses the dataset to train a number of potential models, with varying numbers of specialized layers. This *Model Set* and associated metadata are then assembled into an "M-Package" (Step 2). Note that these are offline steps, performed just once per application prior to deployment, independent of all other tasks. At runtime, M-Scheduler uses the M-Packages of all currently-deployed applications to determine, for each application, the degree of DNN sharing and sampling rate such that, across all applications, the event F1-score is maximized, subject to the resource limits of the edge platform (Step 3). M-Scheduler runs in the datacenter, and is executed once for each scheduling event (e.g., a change in the deployed set of applications, or in available hardware resources). M-Runner then executes the selected model configuration on edge devices (Step 4) and returns app-specific results in real-time (Step 5).

M-Runner is a relatively straightforward execution system for running visual processing pipelines. It accepts a DAG, where each node represents a unit of independent computation, and connections represent data flow. Fig. 2 illustrates the logical DAG for an image classification application. Most of the computation is expected in the "DNN" process, which evaluates the merged DNN of all concurrent tasks. This combined DNN, as illustrated in Fig. 3d, represents the set of models selected by M-Scheduler across all tasks. This DNN is structured as a tree, with sets of layers branching from the shared stem. M-Runner executes the shared stem once per frame, reducing the total processing costs of the deployed tasks.

We next describe how M-Trainer independently trains model candidates for potential sharing (Sec. 5) and how M-Scheduler dynamically chooses among them (Sec. 6).

5 Distributed Sharing-Aware Training

M-Trainer produces a set of models for each task so that they can be combined dynamically at runtime to maximize collective performance. Application developers use M-Trainer independently at different times and locations.

One approach to sharing computation between applications would be to jointly train them using a multi-task network. This, however, requires centralized training of applications. MCDNN [18] proposed fine-tuning models independently and sharing the unspecialized DNN layers. This static approach prevents M-Scheduler from dynamically tailoring stem-sharing to the available resources. In contrast, M-Trainer generates a *set of models* that vary in the number of specialized layers. These models compose an application-specific *Model Set*. The generation of Model Sets allows for the late binding of the degree of specialization to deployment time, when the platform characteristics and co-deployed applications are known.

To construct a Model Set, M-Trainer first analyzes the structure of the base DNN to identify *branchpoints*, the potential boundaries between frozen and specialized layers. Using the app-specific training data provided by the developer, M-Trainer generates a set of fine-tuned DNN models, one per branchpoint, where layers up to the branchpoint are frozen, and the rest are specialized. Only the models at the Pareto-optimal frontier with respect to number of layers specialized and estimated accuracy are actually included in the M-Package. This eliminates from consideration models that reduce accuracy, while requiring more specialization. For example, an overfitted model, caused by specializing too many layers with insufficient training data, will not be included.

Model Sets are bundled together with application metadata into an *M-Package*. This metadata includes the measured per-frame accuracy of each model (we use a portion of the data as the validation dataset.) The expected minimum event duration, event frequency, and inter-frame correlation are optionally measured from the training data and included in the M-Package, or directly provided by the application developer.

The construction of the M-Package is an offline operation, which is run just once per application. For each application, M-Trainer must train multiple models. Although training a model from scratch can be very resource intensive, fine-tuning is much quicker. M-Trainer creates Model Sets with 15 model options in 8 hours on a single GPU (Sect. 7). Note that the computation for generating all of the models is easily parallelized in a datacenter setting, and may not be significantly higher than traditional fine-tuning. For example, to find the right number of layers to specialize in order to maximize accuracy, one may need to generate these models anyway. The key difference here is that intermediate runs are not discarded, and the final selection is made at run time by M-Scheduler.

As each application's models are independently trained and analyzed, no coordination or sharing of training data is needed between developers of different tasks. The resulting M-Package, however, contains enough information that M-Scheduler, at run time, can optimize across the independently-developed tasks.

6 Dynamic Sharing-Aware Scheduling

At each *scheduling event* (typically, an application submission or termination), M-Scheduler uses the M-Packages created by the various per-application M-Trainers to produce a new overall schedule that optimizes some global objective function, subject to resource constraints (currently, M-Scheduler maximizes average event F1-score across applications). The *schedule* consists of a DNN model selection (indicating the degree of sharing) and target frame-rate for every running application.[1] The final schedule is a tree-like model with applications splitting from a shared stem at potentially different branch points, with each application able to run at its own frame rate.

M-Scheduler optimization algorithm. With N applications to schedule, S possible specialization settings per application, and R frame-rate settings per application, the number of possible schedules is $(S \cdot R)^N$. Although this space is large (e.g., $N \approx 10$, $R \approx 10$, and $S \approx 10$ in our experiments), M-Scheduler can efficiently determine a good schedule using a greedy heuristic (Algo. 1). We compare the schedules generated by our greedy scheduler to those of an exhaustive scheduler in >4,800 workloads each consisting of up to 10 applications, and find that the greedy schedules are on average within 0.89% of optimal.

Essentially, at each step of our iterative algorithm, the scheduler considers making a *move* which improves the application quality of a single application by tweaking its frame rate and/or model specialization. The algorithm greedily selects the move that yields the best ratio of *benefit* to *cost*, defined below. Naturally, before this iterative refinement, the schedule is initialized to the lowest cost configuration— Max-Sharing with minimum frame rate. At any iteration step, the number of possible moves is bounded by $S \cdot R \cdot N$. The total number of moves per invocation of the scheduler is similarly bounded by $S \cdot R \cdot N$, but in practice is much fewer as the set of potential moves that fit within the computational budget is exhausted.

Algorithm 1 Scheduler optimization algorithm

```
function GetNextMove(schedule)
    ▷ Finds change to schedule with the highest $\frac{benefit}{cost}$
function Schedule(budget)
    sched ← GetSchedule(max_sharing, min_fps)
    while True do
        next_move ← GetNextMove(sched)
        cost ← cost + GetCost(next_move)
        if cost < budget then
            sched ← UpdateSchedule(next_move)
        else return sched
```

Measuring the Benefit of a Move. The benefit associated with a move captures the improvement in F1-score for the application associated with that move. This value is calculated using the analytical model presented in Sect. 3 and the application metadata in the M-Package.

Measuring the Cost of a Move. The cost value considered represents the computational resources (e.g., CPU-seconds per second) consumed by a given schedule arrangement and depends on the number of shared subgraphs, the number of task-specific subgraphs, and the intended throughput (frame-rate) of each subgraph. The relative cost of a schedule is the sum of the execution time of each model layer, multiplied by the desired throughput. Consider for example a schedule with two applications, both executing at F FPS. Assume they share a compute stem A, and then branch to specialized subgraphs B_1 and B_2. If C_A represents the execution cost (in CPU-seconds per frame, say) of A, and C_B the execution cost of B_1 and B_2, then the total cost of the schedule is $F \cdot C_A + 2F \cdot C_B$. Adding a third application based on the same network, using the same branchpoint and frame rate will add another factor of $F \cdot C_B$ to the schedule cost.

To most accurately model the compute costs (e.g., C_A and C_B), a forward pass execution of the base DNN should be executed and measured once on the target hardware. Note that as cost is relatively insensitive to the assigned model weights, each base DNN need only run one time (ever) per target hardware, not once per trained application.

Max-Min Fairness Among Applications. Although stem-sharing improves overall system efficiency, maximizing a global objective may lead to an inequitable allocation of resources for individual applications. Thus, M-Scheduler can also be run in max-min fairness mode, which maximizes the minimum benefit among applications, instead of the average. Max-min fairness is scheduled by searching the space using dynamic programming.

[1] Here, we assume that some admission control policy (outside the scope of this work) has been applied to ensure that some schedule is feasible for the set of running applications.

X-Voting To Improve Precision. Mainstream uses *voting* across frames to improve precision, and consequentially F1-score. With X-voting, Mainstream requires X consecutive positives to identify an event. While X-voting decreases false positives, it is not guaranteed to increase precision. For X-voting to improve precision, it must decrease false positives at a higher rate than true positives. The ideal X-voting configuration again depends on the applications and the resources available. A higher *X* incurs fewer false positives, but requires more cost to sustain high recall (either by increasing FPS or increasing specialization). We evaluate the effect of various X-voting configurations in Sect. 8.

7 Experimental Setup

To evaluate our system, we implement seven different event detection applications. We refer to the set of applications as 7-Hybrid. These are listed in Table 2, along with the datasets we used to train and test them. A pedestrian-detection application (Pedestrian) is trained based on the fully-labeled, publicly-available Urban Tracking video dataset [25]. Our application to classify car models (Car) uses the Stanford Cars image dataset [28]. Train detection (Train) is based on video of nearby train tracks that we have captured in our camera deployment, and have hand labeled. The remaining classifiers are trained on a video of a nearby intersection, also captured in our camera deployment. We have obtained the necessary permissions and plan to make our Trains and Intersection video dataset available publicly. We reserve a portion of these datasets to create synthetic video workloads for testing.

We use M-Trainer to produce a task-specific M-Package for each application. Model candidates are fine-tuned using the MobileNets-224 model pretrained on ImageNet as a base DNN (implemented in Keras [8] using TensorFlow [2]). Each M-Package contains several models with different degrees of fine-tuning as described in Section 5. We evaluate Mainstream using the M-Packages and hold-out validation sets from our datasets. Our experiments use the applications in Table 2.

Hardware. Training is performed on nodes equipped with Intel® Xeon® E5-2698Bv3 processors (2.0 GHz, 16 cores) and an Nvidia Titan X GPU. All end-to-end experiments use an Intel® NUC with an Intel® Core™ i7-6770HQ processor and 32 GiB DRAM, which is intended to represent an edge processing device. The Train and Intersection videos were captured using an Allied Vision Manta G-1236 GigE Vision camera.

8 Evaluation

We evaluate our system in the context of independent DNN-based video processing applications sharing a fixed-resource edge computer. In our evaluation, we show that Mainstream's dynamic approach outperforms static solutions in all of our experimental settings, across various application workloads, computational budgets, and numbers of concurrent applications. Mainstream's X-voting is capable of improving F1-score but, like model specialization, must also be dynamically configured to the resources available. In addition to our benchmarked applications, we show an end-to-end Mainstream deployment of a train detection application used for environmental pollution monitoring.

8.1 Mainstream Improves App Quality

Our goal in event detection is to maximize per-*event* F1-score. We compare the F1-score achieved by Mainstream with two baselines: No-Sharing and Max-Sharing. *No-Sharing* is the default behavior for a multi-tenant environment and is the approach taken by systems like TensorFlow Serving [1] and Clipper [12]. No-Sharing maximizes classification accuracy at the cost of a reduced sampling rate and requires no coordination between tenants. *Max-Sharing* is the sharing approach used by MCDNN [18]. It uses partial-DNN sharing by fine-tuning the final layer of concurrent DNNs. In many cases, Max-Sharing provides better F1-score relative to No-Sharing when a non-trivial number of applications share the infrastructure; it sacrifices classification accuracy to maximize the number of frames processed. We show, however, that Max-Sharing is less effective than making deliberate runtime decisions about how much sharing to use.

In order to observe the effects of increasingly constrained resources without a large number of distinct applications, we generate additional applications by augmenting our application set. Each of the seven classification tasks in Table 2 has a corresponding "accuracy-tradeoff curve", which represents the relationship between per-frame accuracy and the shared stem size (Fig. 4b). For each application in our experiments, we randomly choose one of the seven classifiers (and its corresponding accuracy-tradeoff curve) and parameterize it with a different event length, event frequency and inter-frame correlation. To capture the effects of diverse application characteristics, the parameters are uniformly sampled from a range of possible values. Each workload consists of up to 30 concurrent applications. In most experiments, we show the behavior averaged across 100 workloads. Our video capture rate for all experiments is 10 FPS.

Mainstream outperforms static approaches. M-Scheduler maximizes per-event F1-score by varying the sampling rate and amount of sharing. Each additional application introduces more resource contention, forcing the system to pick a different balance between accuracy and sampling rate to achieve the best average F1-score.

Detection Task	Dataset Description	Number of Images	Avg Event Length	Min Event Length	Event Frequency
Pedestrians	Urban Tracker atrium video	4538	59	2	0.63
Bus	Intersection near CMU video	4762	1039	141	0.27
Red Car	Intersection near CMU video	9172	228	46	0.08
Scramble	Intersection near CMU video	1500	412	382	0.16
Schoolbus	Intersection near CMU video	2600	854	92	0.03
Trains	Train tracks near CMU video	3066	132	20	0.01
Cars	Images of 23 car models	3042	—	—	—

Table 2: Labeled datasets used to train classifiers for event detection applications. Average and minimum event lengths are reported in number of frames. Event length and event frequency only apply to video datasets and not Cars.

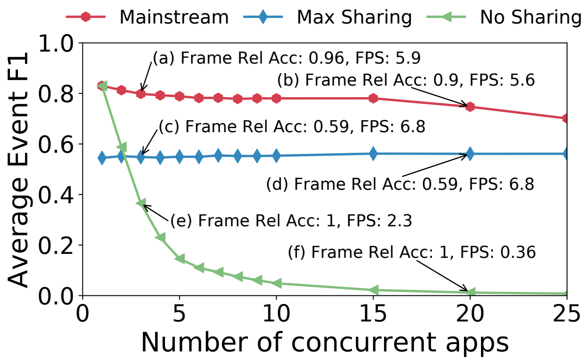

Figure 6: Mainstream improves F1-scores vs. No-Sharing between applications or conservatively sharing all layers but the last one. "Frame Rel Acc" is the relative image-level accuracy of the model deployed, compared to the best performing model candidate. "FPS" is the average observed throughput of the deployed applications.

Fig. 6 compares Mainstream with our baseline strategies. Mainstream delivers as much as a 87X higher per-event F1-score than No-Sharing and as much as a 47% higher score vs Max-Sharing. Fig. 6 reports F1-scores averaged across 100 workloads. The relationship between the three schedulers holds when examining individual workloads. No-Sharing exhibits low recall because of its low throughput—the system has fewer opportunities to detect the event. Max-Sharing has high throughput but a worse precision because the underlying model accuracy is lower—it evaluates many frames but does so inaccurately. Mainstream outperforms by striking a balance, sometimes choosing a more accurate model, and sometimes choosing to run at a higher throughput.

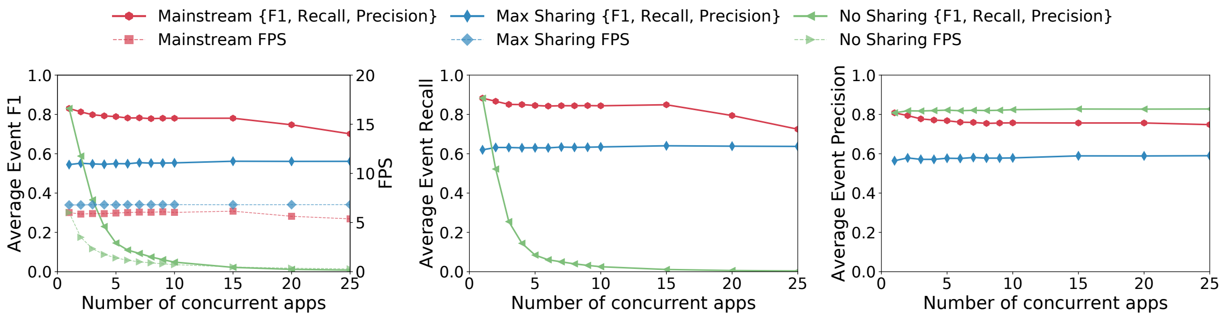
Mainstream dynamically balances precision and recall. Fig. 7 delves into the system effects of Mainstream more deeply. F1-score, recall, and precision are plotted. The average application frame rate is plotted, showing how Mainstream dynamically tailors resource usage to the workload. (Not shown is the varying model accuracy.) Optimizing for precision requires careful tuning of the application frame rate. While higher FPS always leads to higher recall, it does not always lead to higher precision. (A high frame rate may only increase false positives without increasing expected true positives.) For instance, No-Sharing's low frame rate and high per-frame accuracy allows it to have the highest precision of the three approaches. When given just a few applications, Mainstream runs specialized models, while throttling the stream rate to avoid unnecessary false positives. As resources become scarce, many applications begin to share more of the network.

Mainstream improves upon Max-Sharing even under tight resource constraints. Fig. 8 shows the effect of Mainstream, Max-Sharing, and No-Sharing on a range of computational budgets. We average the event F1-scores across 100 workloads, each with 3 applications. The right-most points represent the scenario of running on computational resources equivalent to an Intel$^{\circledR}$ NUC. With a small workload of three applications, No-Sharing performs better than Max-Sharing, as it is able to run expensive models at a high enough frame rate. As we decrease the available budget, Max-Sharing's conservative sharing approach allows it to be more scalable than No-Sharing. However, even after the computational budget is reduced by 83%, Mainstream still improves application performance, compared to the overly conservative Max-Sharing approach.

8.2 Tuned X-Voting improves F1-score

Applications that suffer from low per-frame precision will generate many false positives. An X-voting approach can greatly decrease the incidence of false positives, as X consecutive classifications are needed in order to report a detection. Too large a value of X can hurt recall, causing real events to go unreported. By using X-voting and optimizing the parameter X, Mainstream can improve the overall average event F1-score.

Fig. 9 shows the effects of X-voting on F1-scores as X and the number of applications are varied, while total resources are kept fixed. With just a few concurrent applications, running at high frame rates, 7-voting and 5-voting yield the highest F1-scores. With more resource



(a) F1-score

(b) Recall

(c) Precision

Figure 7: The average event F1-score (Fig. 7a), recall (Fig. 7b) and precision (Fig. 7c) across 100 deployed workloads are shown (solid lines) alongside the average frame-rate across applications (dotted lines). Mainstream dynamically balances recall and precision to maximize aggregate F1-score. With high numbers of concurrent applications, Mainstream sacrifices small amounts of both specialization and frame-rate.

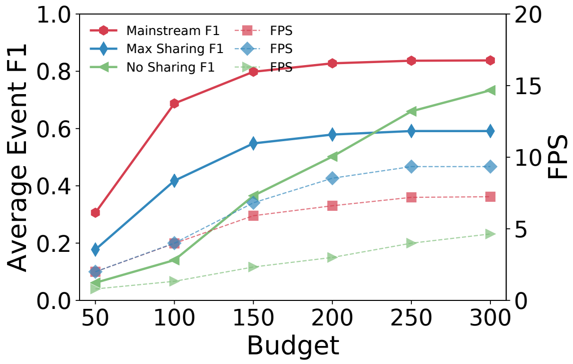


Figure 8: Mainstream improves F1-score of workloads under varying computational budgets. The rightmost points on the X axis represent the resources available on an Intel® NUC. Even under heavy resource constraints, there is available capacity for Mainstream to perform optimizations.

contention, and lower throughput, 3-voting becomes the best choice as the cost of dropping true positives outweighs the benefit of reducing false positives for higher values of X. When resources become too constrained, this approach is less viable, e.g., 1-voting becomes the best approach at 25 concurrent apps. Fig. 9 also shows the Pareto frontier of F1-scores achievable across all values of X for a given number of concurrent applications.

8.3 Mainstream Deployment

We deployed our environmental pollution monitor application and nine other concurrent applications using both Mainstream and a conventional No-Sharing approach for one week on the hardware setup described in Section 7. Fig. 10 shows the trace of both approaches on a *single* train event sequence, indicating the frames analyzed. A hit represents a correct classification of the train, a miss represents an incorrect classification. We see that Mainstream's deployment samples the stream more frequently, yielding many more hits (and misses) than No-Sharing;

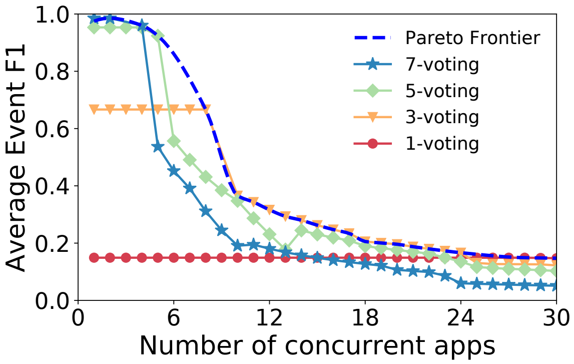

Figure 9: X-voting increases precision and helps Mainstream achieve a higher F1-score, but only if frame rate is high enough to avoid hurting recall. Thus, the effects vary by the level of resource contention. The Pareto frontier shows the F1-scores achievable given the dynamic selection of an optimal X-voting scheme for the resource scenario.

the result, though, is that Mainstream detects the train event earlier and more confidently.

We control the false positive rate with 2-voting, requiring Mainstream to have two positive samples before an event is classified. The false positive rate of the Train video drops from 0.028 to 0.00056. No-Sharing and Mainstream achieve a 0 and a 0.00056 false positive rate, respectively. In the analyzed deployment in Fig 10, we see that Mainstream still detects the train easily and quickly.

9 Additional Related Work

Several recent systems have attempted to tackle the problem of optimizing execution of visual computing pipelines.

VideoStorm [48] is a video analytics system for large-scale clusters and workloads. It analyzes resource use and application-goal-based metrics as a function of tunable parameters of the analytics pipelines, building models for each application independently. It uses these models

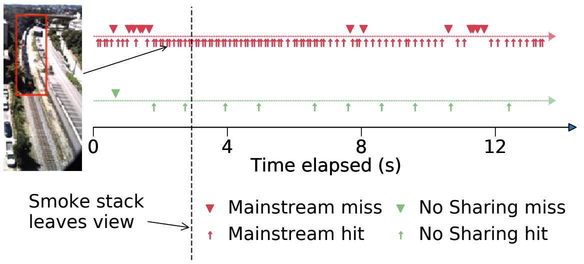

Figure 10: Timeline of Mainstream running a train detector app with 9 concurrent applications. Our goal is to detect the train as early as possible, before the smoke stack is out of view (end of window represented by the dotted line). Mainstream detects the train earlier and more confidently than No-Sharing.

to allocate resources and select parameters for deployed applications on a target platform, in order to maximize application quality metrics. VideoStorm takes a black-box view of the applications, and assumes that quality and resource consumption of co-deployed applications are independently determined. Therefore, it cannot take into account computation sharing, or optimize the sharing vs. degree of specialization tradeoff. In contrast, Mainstream takes a white-box approach to modeling application quality, and can explicitly tune computation sharing to improve application quality metrics. Compared to VideoStorm, Mainstream sacrifices some generality to solve the joint optimization problem.

MCDNN [18] introduces a static approach to sharing DNN computation, in which each application developer independently determines their amount of model specialization. MCDNN opportunistically shares any identical unspecialized layers between applications. In contrast, Mainstream's training and scheduling components allow late binding and jointly-optimized selection of the degrees of specialization at run time, when resource availability and co-deployed tasks are known.

Inference serving systems. Mainstream is an inference serving system for running neural networks on resource-constrained nodes. Other inference serving systems include Clipper [12], NoScope [26], and TensorFlow Serving [1]. Like Mainstream, these systems optimize for latency and throughput gains. Clipper caches results from multiple models, dynamically chooses from the results, and optimizes the batch size. NoScope replaces expensive neural networks for object detection with cheaper difference detectors and specialized models. TensorFlow Serving increases throughput with batching and hardware acceleration. LASER [4] and Velox [11] are inference serving systems for non-DNN models. LASER deploys linear models while Velox deploys personalized prediction algorithms using Apache Spark.

Unlike Mainstream, these inference serving systems do not share computation between independently trained models. They also target cluster environments. Mainstream targets edge devices with limited resources, where achieving the right degree of DNN computation sharing is particularly important, though such sharing would also be valuable in large data centers.

Reducing DNN inference time. Approaches to reducing DNN inference time for vision applications can be broadly classified into those that reduce model precision [16, 50, 10, 9, 7, 23, 39], use efficient network architectures [20, 24], use anytime prediction methods [22, 21], or employ model compression and sparsification [17, 33, 46]. All of these methods are orthogonal to Mainstream's adaptive DNN computation sharing technique, but share its goal of selecting the right trade-off between per-frame quality and frame throughput.

Multi-task networks. Multi-task learning [6, 49, 5, 36, 35, 34, 27, 38] is a ML approach in which a single model is trained to perform multiple tasks. Using multiple tasks to train a single model helps achieve better accuracy because of better generalization and complementary information [6, 41]. In the context of DNNs, a multi-task network can have a varying number of shared layers across tasks and task-specific layers [36, 35]. Multi-task learning assumes that all of the tasks are known *a priori*, and that training data for all of the tasks is available for use in a single training process. In contrast, Mainstream allows each task to be developed, trained, and deployed independently, and avoids the need to share or expose proprietary or privacy-sensitive training data between task developers. Note that one can run a multi-task network as a single large application in Mainstream.

10 Conclusion

Mainstream adaptively orchestrates DNN stem-sharing among concurrent video processing applications sharing the limited resources on an edge device, resulting in much higher aggregate application quality. Experiments with several event detection tasks confirm that Mainstream significantly increases overall event F1-score relative to current approaches over a range of concurrency levels.

Abstract

Many video streaming applications require low-latency processing on resource-constrained devices. To meet the latency and resource constraints, developers must often approximate filter computations. A key challenge to successfully tuning approximations is finding the optimal configuration, which may change across and within the input videos because it is content-dependent. Searching through the entire search space for every frame in the video stream is infeasible, while tuning the pipeline offline, on a set of training videos, yields suboptimal results.

We present VIDEOCHEF, a system for approximate optimization of video pipelines. VIDEOCHEF finds the optimal configurations of approximate filters at runtime, by leveraging the previously proposed concept of canary inputs—using small inputs to tune the accuracy of the computations and transferring the approximate configurations to full inputs. VIDEOCHEF is the first system to show that canary inputs can be used for complex streaming applications. The two key innovations of VIDEOCHEF are (1) an accurate error mapping from the approximate processing with downsampled inputs to that with full inputs and (2) a directed search that balances the cost of each search step with the estimated reduction in the run time.

We evaluate our approach on 106 videos obtained from YouTube, on a set of 9 video processing pipelines with a total of 10 distinct filters. Our results show significant performance improvement over the baseline and the previous approach that uses canary inputs. We also perform a user study that shows that the videos produced by VIDEOCHEF are often acceptable to human subjects.

1 Introduction

Video processing has brought many emerging applications such as augmented reality, virtual reality, and motion tracking. These applications implement complex video pipelines for video editing, scene understanding, object recognition and object classification [14, 49]. They often consume significant computational resources, but also require short response time and low energy consumption. Often, the applications need to run on the local machines instead of the cloud, due to latency [14], bandwidth [50], or privacy constraints [46].

To enable low-latency and low-energy video processing, we leverage the the fact that most stages in the video pipeline are inherently *approximate* because human perception is tolerant to modest differences in images and many end goals of video processing require only estimates (*e.g.*, detecting object movement or counting the number of objects in a scene [5]). Many *domain-specific* algorithms have exposed algorithmic knobs, that can e.g., subsample the input images or replace expensive computations with lower-accuracy but faster alternatives [45, 41, 13, 26]. To complement domain-specific approximations, researchers have proposed various generic *system-level techniques* that expose additional knobs for optimizing performance and energy of applications while trading-off accuracy of the results. The techniques span compilers [39, 30, 42, 7, 36, 27], systems [3, 15, 18, 17, 31], and architectures [32, 29, 37, 36, 8].

Content-dependent Approximation. A fundamental challenge of uncovering the full power of both generic and domain specific approximations is finding the configurations of these approximations that provide maximum savings, while providing acceptable results for *each given input*. This challenge has two main parts.

First, the optimal approximation setting is dependent on the *content of the video*, not just on the algorithms being used in the processing pipeline. Often individual videos, or parts of the same video should have different approximation settings, requiring the program to make the decisions at runtime. Second, the optimization needs to explore a large number of approximate configurations before selecting the optimal one for the given input, requiring the optimizer to construct off-line models. Systems like Green [3] and Paraprox [36] dynamically adapt the computation using runtime checks of the intermediate results, while Capri [43] selects approximation level from the input features at the program start. However, the systems rely on extensive off-line training to map the approximation levels to accuracy and performance.

To relax the dependency on off-line training, Laurenzano *et al.* [25] propose Input Responsive Approximation (IRA) for runtime recalibration with no offline training. IRA creates *canary inputs*, smaller representations of the full inputs (obtained via subsampling), and then reruns the computation on the canary input with different approximation settings, until it finds the most efficient setting that maintains the accuracy requirement (on the canary). While the concept is promising, the application of IRA to video processing pipelines is limited:

- IRA has been applied to individual computational kernels (in contrast to full pipelines). It is unclear how to capture the interactions between the stages of the pipeline, how often to calibrate, and what are the optimal canary sizes.
- IRA uses the approximation settings derived from the canary input to the full input, assuming that the errors for the full and correlated inputs will be *identical*. However, this assumption is often incorrect (98% of cases, Figure 2) and leads to missed speedup opportunities.
- IRA's greedy search may introduce additional overheads and may not find good approximation settings efficiently because it has no notion of what are the appropriate points in the stream to search.

Our Solution: VIDEOCHEF. We present VIDEOCHEF, a fast and efficient processing pipeline for streaming videos. VIDEOCHEF can optimize the performance subject to accuracy constraints for the system-level and domain-specific approximations of all kernels in the video processing pipeline. Figure 1 presents VIDEOCHEF's end-to-end workflow:

- Like IRA, VIDEOCHEF uses small-sized canary input to guide the on-line search for approximation setting. However, unlike IRA, VIDEOCHEF is tailored for optimization of the whole video processing pipelines, not just individual kernels.
- In contrast to IRA, VIDEOCHEF presents a finely tunable prediction model for mapping the error from the canary input to that with the original input. This prediction model is trained offline and hence does not generate any additional runtime overhead. At the same time, it is much more lightweight than the full off-line training employed by other approaches.
- At runtime, VIDEOCHEF performs an efficient search through the space of approximation settings and ensures that the cost of the search does *not* overwhelm the benefit of approximating the computation.

***Figure 1:** End-to-end flow of approximate video processing with* **VIDEOCHEF.** *The video processing pipeline comprises multiple filters, which can be approximated to save computation at the expense of tolerable video quality. The offline and the online components of* **VIDEOCHEF** *work together to determine the best approximation setting for each approximable filter block.*

We evaluate VIDEOCHEF with three error models and two search strategies, applied to a corpus of 106 YouTube videos from 8 content categories, which span the range of video features (e.g., color and motion). We analyze 10 filters arranged in 9 pipelines of size 3. We find that VIDEOCHEF is able to reach within 20% of the theoretical best performance possible and outperforms IRA's performance by 14.6% averaged across all videos and saves on an average 39.1% over the exact computation given a relatively restrict quality requirement. While given a more loose quality requirement, VIDEOCHEF is able to reach within 26.6% of the theoretical best and also achieve higher performance gain – 53.4% and 61.5% over IRA and exact computation, respectively.

While we have framed this discussion in terms of video processing, the novel contributions outlined below apply to other low-latency streaming applications, with the fundamental requirement that the characteristics change to some extent from one segment of the stream to another, for instance, online video gaming, augmented reality and virtual reality applications.

Contributions. We make the following contributions:

1. We present VIDEOCHEF, a system for performance and accuracy optimization of video streaming pipelines. It consists of off-line and on-line components, that together adapt the application's approximation level to the desired output quality.
2. We build a predictive model to accurately estimate the quality degradation in the full output from the error generated when using the canary input. This enables more aggressive approximation setting the approximation algorithm that has tunable knobs.
3. We propose an efficient and incremental search technique for the optimal approximation setting that

takes hints from the video encoding parameters to reduce the overhead of the search process.

4. We demonstrate the benefits of VIDEOCHEF through (1) quantitative evaluation on various real-world video contents and filters and (2) a user study.

2 Background and Motivation

Error Metric: At a high-level, a video is composed of a sequence of image frames. To quantify the error in the output or the processed video due to approximation, we measure the Peak Signal-to-Noise Ratio (PSNR) of the output video. PSNR is the average of the PSNRs of the individual frames in the output video. Suppose that a video consists of K frames where each frame has $M \times N$ pixels. Let $Y_k(i,j)$ be the value of the pixel at (i,j) position on the k-th frame of the processed video without any use of approximation, and $Z_k(i,j)$ be the value of the pixel when approximation was applied. Then, the PSNR of the approximate output is computed as follows:

$$PSNR = \frac{1}{K}\sum_{k=0}^{K-1} 20 \times log_{10}\frac{MaxValue}{\sqrt{MSE(Z_k,Y_k)}}, \qquad (1)$$

where $MaxValue$ is the maximum possible pixel value present in the frame, and $MSE(Z_k,Y_k)$ is the mean square error between Z_k and Y_k, i.e., $\sum_i\sum_j(Z_k(i,j)-Y_k(i,j))^2$, as a result of approximation. Thus, lower the PSNR, the higher the error in the output video.

Isn't the problem solved by IRA and Capri? IRA (Input Responsive Approximation) [25] and Capri [43] attempted to address the problem of selecting optimal approximation level for individual inputs.

IRA [25] solely relies on canary inputs to search for best approximation settings. Thus, it implicitly assumes that the magnitude of error corresponding to a particular approximation setting on the *canary inputs* is identical to the error with the same approximation settings on the *full-sized inputs*. But, Figure 2 shows our experiment with 424 real images and 216 different approximation settings. We found that for the same approximation settings, the PSNR of the full-sized inputs can be significantly different from the PSNR of the canary inputs. Most of the points (about 98%) are above the diagonal, indicating that the error on the full input is lower than that with the canary input for the same approximation level.

We attribute the difference in the approximation to the higher variations between neighboring pixel values for canary inputs. Therefore, for the same approximation settings, the approximate processing on canary inputs gives lower PSNR. We found that on an average, the PSNR of a full-sized output is 5.36 dB higher than the PSNR of canary output. Therefore, IRA misses an opportunity for more aggressive optimization that can fit within the user-specified quality threshold.

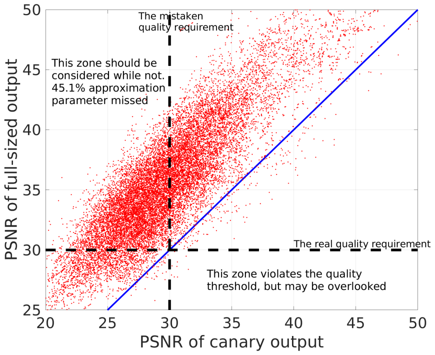

Figure 2: The PSNR of full-sized output versus the PSNR of canary output, for the I-frames of 106 videos on one of our application Boxblur-Vignette-Dilation video filter pipeline. The PSNR of full output is higher for over 98% approximation settings and 45.1% of the approximation settings lie in such a zone that is ignored by IRA approach but actually satisfies the quality requirement.

Capri [43] rigorously addresses the problem of selecting the best approximation settings to minimize the computational cost, while meeting the error bound. But Capri also fails in the video processing setting because it does not recalibrate itself with the stream and thus cannot change its approximation settings when the characteristics of the stream change. Further, it (1) relies on prior enumeration of all possible inputs, which is impossible in this target domain, and (2) performs the selection of approximation settings completely offline, which reduces the cost of the optimization but makes it non-responsive to changes in the input data.

3 Solution Overview

Figure 1 shows the end-to-end workflow of streaming video processing, with approximation.

Approximation. Under normal processing, a video decoder converts the video into its constituent frames. Then a sequence of "filters" (synonymously, processing steps or pipeline stages) is applied to each frame. Examples include blurring filter (*e.g.*, at the TSA airport checkpoint scanners) and edge detection filter (*e.g.*, for counting people in a scene). Finally, the transformed frames are optionally put together by a video encoder. To make such processing fast and resource efficient, VIDEOCHEF intelligently uses selective approximation (Section 3.1) during the computation of the filters. The user sets the quality constraint on the output video quality. An example specification is that the PSNR of the output video should be above 30 dB.

Accuracy Calibration with Canary Inputs. For each representative frame (called "key frame" here), VIDEOCHEF determines a *canary input* (Section 3.2), which summarizes the full frame such that the dissimilarity between the full and the canary frame remains below a threshold. With the canary input, VIDEOCHEF occasionally recalibrates the approximation levels of the filters. It determines when to call the search algorithm using domain specific knowledge about the frames and scenes (Section 3.3). For this, we extract hints from the video decoder which lets VIDEOCHEF determine the key frames. This amortizes the cost of the search across many frames of the video, with 80-120 frames being a typical range for MPEG-4 videos. In the absence of such a video decoder, we have a variant, which triggers the search upon a scene change detection.

Online Search for Optimal Tradeoffs. VIDEOCHEF searches for the approximation setting of each filter that gives the lowest execution time subject to a threshold for the output quality (Section 3.4). Since the search for approximation is done with the *canary input*, the error of approximate computation is different from the error of the computation on the full input. VIDEOCHEF introduces a method to accurately map between these two errors (Section 3.5). In performing this estimation, we consider multiple variants of VIDEOCHEF, depending on what features are available to the predictor, such as, some categorization of the video frame according to its image properties. Through this procedure, we aim to maximally leverage the approximation potential in the application and give flexible approximation choices.

3.1 Approximation techniques

The computations involved in filtering operations can be approximated by VIDEOCHEF in various ways as long as each of the underlying approximation techniques exposes knobs that can be tuned to control the approximation levels (ALs). For example, in the three popular program transformation-based approximation techniques, the variable `approx_level` is a tuning knob that controls the levels of approximation. A higher value implies more aggressive approximation, leading most often to higher speedup but also higher error. These transformations are performed automatically by a compiler (LLVM in our case).

Loop perforation: In loop perforation [42, 30], the computation is reduced by skipping some iterations, as shown below.

```
for (i = 0; i < n; i = i + approx_level)
  result = compute_result();
```

Loop truncation: In loop truncation [42, 30], the last few iterations of the computation are dropped as shown in the following example:

```
for (i = 0; i < (n - approx_level); i++)
  result = compute_result();
```

Loop memoization: In this technique [7, 36], for some iterations in a loop we compute the result and cache it. For other iterations we use the previously cached results.

```
for (i = 0; i < n; i++)
  if (i % approx_level == 0)
     cached_result = result = compute_result();
  else result = cached_result;
```

3.2 Canary Inputs

To reduce the search overhead for finding the best approximation level within each frame of the video, we generate canary inputs for the frame following the work in [25]. A good canary input should meet two requirements: (1) it should be *close enough* to the original input so that the AL found by the canary is the same as the AL computed from the original; (2) it should be small enough that the search process using the canary input is efficient. We first define the dissimilarity metric to compare the canary sample video and the full-sized video and then show how to choose the appropriate canary input.

Metrics of Dissimilarity. We define two metrics of dissimilarity. Let a full-sized video have K frames and $M \times N$ pixels in each frame, and each pixel has the property $X(i,j)$. A canary video has K frames with $m \times n$ pixels, and the same property $Y(i,j)$. The property could be one component in the YUV colorspace of an image, where the Y component determines the brightness of the color (known as "luminance") while the U and V components determine the color itself (known as "chroma") and each ranges from 0 to 255. The "dissimilarity metric for mean" (SMM), is defined as follows (following [25]):

$$mFull = \frac{1}{M \times N \times K} \sum_{i=0}^{K-1} \sum_{i=0}^{M-1} \sum_{j=0}^{N-1} X(i,j) \tag{2}$$

$$mSmall = \frac{1}{m \times n \times K} \sum_{i=0}^{K-1} \sum_{i=0}^{m-1} \sum_{j=0}^{n-1} Y(i,j) \tag{3}$$

$$SMM = \frac{|mSmall - mFull|}{mFull} \tag{4}$$

When a pixel has a vector of values, such as the YUV colorspace which has 3 values for the 3 components, then the SMM metric is combined across the different elements of the vector. The combination could be a simple average or a weighted average; we use the latter due to the higher weight of the Y-channel in the YUV colorspace. Similarly, we define the "dissimilarity metric of standard deviation" (SMSD) to capture the dissimilarity in the Standard Deviation between the full input and the canary input.

Generating Candidate Canary Videos. Given a frame of the video from which to generate the canary video, we resize the frame to a fraction $1/N$ of its original size to create the canary video. Typical sizes that we find useful in our target domain are $1/16$, $1/32$, $1/64$, $1/128$, $1/256$ of the original size. Since the frame is a 2-D matrix of pixels, to resize it to $1/N$ of its original size, we shrink the width and height each to $1/\sqrt{N}$ of the full size by sub-sampling 1 pixel out of every $\sqrt{N}$ pixels.

Reducing an input size causes at least proportional reduction in the amount of work inside the filter. Many filters that are finding increasing use are super-linear, where the benefit of using a small canary frame is even more significant. Two popular examples are determining optical flow to measure motion [4] and morphological filter [10], where the value of each pixel in the output image is based on a comparison of the corresponding pixel in the input image with its neighbors. We compute the similarity between the full-sized video frame and the canary video frame according to the metrics SMM and SMSD. We set the maximum dissimilarity metric we can tolerate as a threshold parameter—we find 10% is a practically useful threshold for both SMM and SMSD. Among all the qualified canary inputs, we select the smallest one as our final choice.

3.3 Identifying Key Video Frames

Searching for the best AL for each approximable program block is computationally expensive. Conceptually, we would want to repeat the search when the characteristic of the video changes significantly so that the optimal approximation setting is expected to be different. In practical terms, we want to perform such change point detection without having to parse the content of the video. Video encoders already provide hints when the content of the scene has changed significantly.

We make the observation that videos have temporal locality, and many frames in the *same group* will have the same approximation setting. Therefore, we can perform a single search once per a single group of frames. We leverage domain-specific knowledge about videos to automatically select the group boundaries in two ways:

Scene Change Detector. Our first observation is to recalibrate the approximation at the beginning of different scenes. This approach is general and works for any video format. There are mainly 2 classes of scene change detectors, namely, pixel-based and histogram-based. The pixel-based methods are highly sensitive to camera and object motion. Histogram-based methods are good for detecting abrupt scene changes. To keep our overhead low (since the detection algorithm runs on every frame), we limit ourselves to detecting only abrupt scene changes and use canary frames for this detection.

We implement a histogram-based scene change detector using only the Y-channel of the canary frames [20]. We experimentally found the Y-channel information was sufficient to detect abrupt scene changes and we were more concerned about overhead of scene change detector than its accuracy. The algorithm detects a scene change whenever the sum of the absolute difference across all the bins of histograms of two consecutive frames is greater than some predefined threshold (20% of the total pixels in our evaluation). Our experiments show that the optimal configuration (found through offline brute-force search) changes dramatically at scene change boundaries but stay relatively stable within a group of frames.

I-frame Selection for MPEG videos. The second solution takes advantage of I-frames, present in the popular H.264 encoder (which the MPEG-4 and many other video formats follow). It defines three main types of frames: $I-$, $P-$, and $B-frames$ [21]. An I-frame uses intra-prediction meaning the predicted pixels within this frame are formed using only samples from the same frame. The P- and the B-frames use inter-prediction meaning the predicted pixel within this frame depends on samples from the same frame *as well as* samples from other frames around it (the distinction between P- and B-frames is not relevant for our discussion).

When to insert an I-frame (also called a "reference frame") depends on the exact coding scheme being used, but in all such coding schemes that we are aware of, a big difference in the frame triggers the insertion of a new I-frame, since inter-coding will give almost as long a code as intra-coding. Further, because an I-frame does not have dependencies on other frames, this makes it easier to reconstruct and perform the (exact or approximate) computation. We see empirically that for a wide range of videos used in our evaluation, the average spacing between adjacent I-frames is 137 frames. Although specific to only some video formats, it results in a low sampling rate and consequently the low search overhead, while triggering search at a suitable granularity.

3.4 Search with Canary Inputs

An approximable program block exposes one or more approximation knobs. The `approx_level` variable mentioned with the loop-based approximation techniques in Section 3.1 is an example of such a knob. In our notation, we use AL 1 to denote the exact computation. The higher the AL is, the less accurate the computation is and the higher the speedup is. Now for a pipeline of cascaded filters, each having one or more approximation knobs we have a *vector* of approximation settings per frame. We define a *setting* in the processing pipeline as the combination of ALs for each of the approximable program blocks in the video processing pipeline. For example, with an *n*-stage processing pipeline and each stage being approximable and having exactly one approximation knob, the setting will be $\vec{A} = \{a_1, a_2, \cdots, a_n\}$, where a_i denotes the AL of knob i.

To find the best approximation setting, we follow a searching algorithm outlined as follows:

1. **Start searching** at a particular setting, typically $(1, 1, \cdots, 1)$, corresponding to no approximation.
2. **Select a group of candidate settings** by the Candidate Selection Algorithm. The selection algorithm simply selects the next set of settings to try out in the search process. The greedy algorithm works as follows: given the current setting $\vec{A^{(0)}}$, we assume that we can reach the best AL by looking at each step 1 AL further in each approximable block. So the candidates

are $\{\vec{A^{(i)}}\}$, with $i = 1 \cdots n$, for n approximable blocks and $\vec{A^{(j)}} = \{a_1^{(0)}, \cdots a_{j-1}^{(0)}, a_j^{(0)} + 1, a_{j+1}^{(0)}, \cdots, a_n^{(0)}\}$.

3. **Decide whether to continue search**, i.e., whether it is worthwhile to try any of these candidate settings. We use the Approximation Payoff Estimation Algorithm (Section 3.4.1). If not, return the current setting. This algorithm estimates whether the saving due to the more aggressive approximation can compensate for the time of the additional search step.
4. **Try each worthwhile candidate setting** from the set computed by the previous step. Use the ALs in candidate settings to run approximate computation on canary video and compute the error metric for each candidate setting. Then map the error metric to that with the full sized outputs.
5. **Check for exit or iterate** – if error metrics of all the full video outputs exceed the error boundary, return the current setting. Otherwise, the candidate setting which gives the lowest error becomes the next setting, go to (2) and iterate.

3.4.1 Approximation Payoff Estimation Algorithm

The goal of this algorithm is to estimate the benefit of executing the application with the new AL searched for versus the cost of searching with the new AL, all for the key frame under question. Let the current setting be represented by $\vec{A^{(0)}} = \{a_1^{(0)}, a_2^{(0)}, \cdots, a_n^{(0)}\}$. Recollect that this is the set of ALs for each of the approximable blocks in the application. Let the execution time of the application at setting $\vec{A^{(i)}}$ and with canary downsampling C_d be given by $g(A^{(i)}, C_d)$, where $C_d = 1$ denotes the execution time with the full input.

This algorithm works in a breadth-first fashion and attempts to prune some of the paths where exploring higher degrees of approximation for a particular knob cannot speedup the execution further and may lead to slowdown due to associated overheads. From the current setting of $\vec{A^{(0)}}$, let the next possible settings of exploration be $\vec{A^{(1)}}, \vec{A^{(2)}}, \cdots, \vec{A^{(N)}}$. For example, with greedy search, with n approximable blocks, there will be n possible next settings. The maximum possible benefit by exploring all the candidate next settings is calculated as:

$$B = \max_{i=1}^{N}[g(A^{(0)}, 1) - g(A^{(i)}, 1)] \tag{5}$$

This benefit B simply means the maximum reduction in execution time across all the possible candidate settings, when run with the full input. However, to realize this gain, we have to pay the cost of searching, which can be expressed in terms of the overhead as follows:

$$O = \sum_{i=1}^{N} g(A^{(i)}, C_d) \tag{6}$$

This overhead O is simply the cost of executing the application with the next step ALs, but with the canary input (and hence the downsampling ratio C_d). The decision for VIDEOCHEF becomes simple: if $B > O$, then continue the search, else stop and return the current setting.

3.5 Error mapping model

We have to develop an error mapping model to characterize the relation between error in the canary output and error in the full output, for the same approximation levels. This is important because we have seen empirically (Figure 2) that the canary errors are higher than full frame errors for most points. We propose three different mapping models to use according to different amounts of knowledge in the model.

3.5.1 Model-C

Suppose we know the error metric of a canary output C. The error metric of a full-sized output F is estimated by a quadratic regression model as follows,

$$F = w_0 + w_1 \times C + w_2 \times C^2 \tag{7}$$

Offline, we calculate the ground truth of the pairs (C, F) for every possible AL $\vec{A}$ and for all the videos in the training set. In practice, we find that sub-sampling the space of possible ALs still provides accurate enough training, with a sub-sampling rate of 10% being adequate. Let us say that the error bound specified by the user is E_B. Then clearly we want $F < E_B$. However, due to the possible inaccuracy of the error mapping model, we want to explore a larger space so that we are not missing out on opportunities for approximating. Therefore, while training the model, Model-C, we explore all the points where $F \le E_B + \Delta$, where Δ is a user configurable parameter for how far outside the tolerable region we want to explore in the model. Then we solve the unknown coefficients w_0, w_1, and w_2 in the model. We find empirically that for a large set of videos, this model reaches its limits with the quadratic regression function.

3.5.2 Model-CA

Now, suppose VIDEOCHEF has additional knowledge of what ALs were in effect. Given the error metric of a canary output C, which is computed approximately with ALs $\vec{A} = \{a_1, a_2, \cdots, a_n\}$, we construct the input vector $\vec{I} = (1, C, \vec{A})$. The first element of this vector is the constant 1 and allows for a constant term in our equation for F. Then the error metric of a full-sized output F is estimated by a regression model as follows,

$$F = \vec{I} \cdot w \tag{8}$$

where w is a $(n+2) \times 1$ coefficient vector. The goal of the training is to estimate the matrix w. The elements of the matrix w provide the weights to multiply the different input components—the error in canary output (C), and the different ALs. We use similar training method offline as for Model-C.

3.5.3 Model-CAD

Many of approximation techniques on image processing reduce computation load by skipping a fraction of rows of images. Thus, the difference over rows is often related with approximation quality. Inspired by this characteristic, we consider a new feature vector $\vec{D} = (d_1, d_2, d_3)$, where each of d_k's represents a feature extracted from one of Y, U, and V channels of an image. The feature d_k is referred to as a row-difference feature and is defined as the mean of absolute difference in pixel values of the same column between consecutive rows in each channel. Averaging over rows and columns, we use only one representative number as d_k for each channel.

Considering an input vector $\vec{I} = (1, C, \vec{A}, \vec{D})$, the error metric of a full-sized output F is estimated by a linear regression model as:

$$F = \vec{I} \cdot w, \tag{9}$$

where w is a $(n+5) \times 1$ coefficient vector. In the experiment results, we will see that Model-CAD outperforms the other models.

3.5.4 Non-linear models.

We have also tested complex non-linear models to predict F, using artificial neural networks with all pixel information as input. However, considering the run-time complexity [23], we could not observe any significant benefit of the non-linear models over the linear models mentioned earlier. Thus, we do not report their results in the evaluation.

4 Implementation and Dataset

We use loop perforation and memoization [42, 30] to approximately filter the frames in the video. The implementation of VIDEOCHEF is comprised of an offline and an online component. The offline component uses a set of training videos (50% of videos described under the dataset below) and creates models for the error mapping and for the cost and the benefit of each step of the search. This last model is actually implemented as a lookup table, due to the space being only piece-wise continuous. During runtime, VIDEOCHEF queries these models, using linear interpolation if needed, and performs an efficient search to identify the optimal ALs and runs each of the three filters in any pipeline with their optimal values.

VIDEOCHEF API. Our compiler pass identifies the approximable blocks using program annotations and then performs the relevant transformations to insert the approximation knobs to be tuned (such as `approx_level` in Sec. 3.1). We have provided support for similar annotations in other domain specific languages that we have built in the past and that helps to reduce the programmer burden [28]. The user can then use the following API calls to enable VIDEOCHEF in the video pipeline:

- *setCalibrationFrequency(f=”I-frame”)* : This will set how frequently VIDEOCHEF will search for the best approximation settings. The default value is VIDEOCHEF will trigger a search for every I-frame. If *f*=”*x*”, then VIDEOCHEF will search every *x*-th frame.
- *setQualityThreshold(b=”30”)* : This will set the (lower) PSNR threshold that the approximated pipeline must deliver. Default is 30 dB. VIDEOCHEF exposes to the user approximate versions of many filters from the FFmpeg library, with names like *deflate_approx*. The developer of VIDEOCHEF can register a callback with the video decoder using the call *void notifyIFrame(void *)*.

Video Dataset. We used 106 YouTube MPEG-4 videos for our evaluation. We used `libvideo`, a lightweight .NET library [24], to download the videos. The videos were collected from 8 different categories to cover a spectrum of different motion and color artifacts in the frames: Lectures, Ads, Car Races, Entertainment, Movie trailers, Nature, News, and Sports. At the first step, a single seed video was downloaded from each category, then we downloaded all YouTube's recommendations to the seed video, which turned out to belong to the same category as that of the seed video. Once the set of videos was collected, we randomly sub-sampled a 20 second clip from each video, being motivated by a desire to bound the experiment time. For each category, we collected approximately 25 videos and filtered out those with low resolution (since the quality threshold was likely already breached with the original video).

5 Evaluation

We describe our benchmarks first and then the four experiments to evaluate the macro properties of VIDEOCHEF and then its various components.

Benchmarks. We construct our benchmark by including different video processing pipelines. Each video processing pipeline consists of 3 consecutive filters, which are selected from a pool of 10 video filters from the FFmpeg library. These filters are modified to support approximation with tuning knobs. To execute on these filter pipelines, one needs to provide a video input and a quality threshold. Finally, the output is also a video, together with a quality metric with respect to each frame. We have a total of 9 different filter pipelines.

Quality Metric. We use PSNR (Eq. 1) as the quality metric for the videos produced by the approximate pipelines. We present the results for two acceptable PSNR thresholds. The threshold of 30 dB is considered a typical lower bound for lossy image and video compres-

Table 1: Summary of the analyzed pipelines. We denote the approximation applied to each filter: Loop Perforation (LP) or Memoization (M)

Name	Description, labeled with Approx. type	Approximation Type	Approximation Levels
DEB	Deflate(LP)-Emboss(LP)-Boxblur(M)	Loop perforation(LP) & Memoization(M)	1-6, 1-6, 1-6
DVE	Deflate(LP)-Vignette(LP)-Emboss(LP)	Loop perforation	1-6, 1-6, 1-6
BVI	Boxblur(M)-Vignette(LP)-Inflate(LP)	Loop perforation & Memoization	1-6, 1-6, 1-6
UIV	Unsharp(LP)-Inflate(LP)-Vignette(LP)	Loop perforation	1-6, 1-6, 1-6
DUE	Dilation(LP)-Unsharp(LP)-Emboss(LP)	Loop perforation	1-6, 1-6, 1-6
BVD	Boxblur(M)-Vignette(LP)-Dilation(LP)	Loop perforation & Memoization	1-6, 1-6, 1-6
UEE	Unsharp(LP)-Erosion(LP)-Emboss(LP)	Loop perforation	1-6, 1-6, 1-6
EUB	Erosion(LP)-Unsharp(LP)-Boxblur(M)	Loop perforation & Memoization	1-6, 1-6, 1-6
BUC	Boxblur(M)-Unsharp(LP)-Colorbalance(LP)	Loop perforation & Memoization	1-6, 1-6, 1-6

sion [48, 16]. The threshold of 20 dB is considered the lower bound for lossy wireless transmission [44].

Evaluation Metrics. We define improvement as decrease in execution time, expressed as a percentage of the competitive protocol. We define the speedup of our approach as $Speedup = \frac{\textit{Speed of our protocol}}{\textit{Speed of compared protocol}} - 1$

Setup. We split the input videos into three groups: training, validation and test, with a share of 50%, 25%, and 25% of the videoset. The experiments are done on an x86 server with a six-core Intel(R) Xeon CPU, 16 GB RAM, and Ubuntu Linux kernel 4.4. We used FFmpeg library version 3.0 (compiled with gcc 5.4.0).

Canary Input Selection. We fixed the canary size to be $1/64$ of the original size because our preliminary experiments showed that it is a good parameter to guarantee a dissimilarity metric value of 10% or less. Thus, the overhead of appropriate canary selection is not included in the results.

5.1 Performance and Quality Comparison for End-to-End Workflow

Figure 3 presents the results of the end-to-end workflow for the nine different video processing pipelines over all videos from the test set. Each plot presents the speedup relative to the exact pipeline for the following configurations (from left to right):

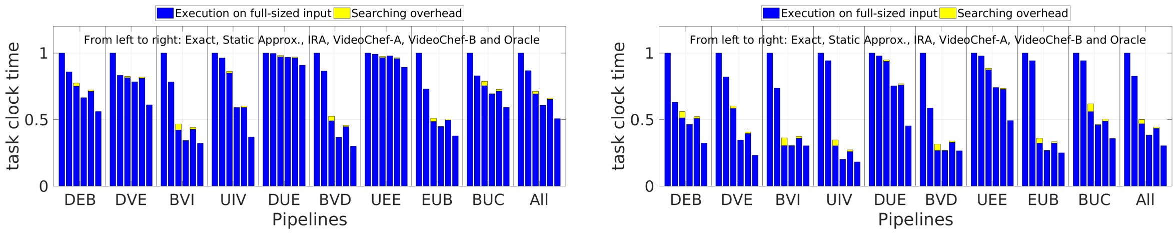
- Exact computation, with default parameters.
- Best static approximation, created by setting the AL that is just over the error threshold for *all* the frames in training videos.
- IRA extended with a simple searching policy that has a fixed interval of 10 frames. This number is chosen according to SAGE [37], which gives an analytic bound for a video processing setting.
- VIDEOCHEF version A – with I-frames detection.
- VIDEOCHEF version B – with scene change detection.
- Oracle version uses exhaustive search but does not incur search overhead. This sets the upper bound of the performance.

For both VIDEOCHEF versions, we used the CAD error model with 3dB margin, as the result of the analysis in Section 5.3.

Performance for 30db Threshold. Figure 3(a) shows that VIDEOCHEF version A reduces the execution time by 39.1% over exact computation and is within 20% of the Oracle. It outperforms both static approximation and IRA, by respectively 29.9% and 14.6% in the aggregate. The advantage exists for all the video filter pipelines with the greatest savings relative to IRA being in Unsharp-Inflate-Vignette (UIV) pipeline. We are 39.2%, 36.8% and 29.5% better than exact computation, static approximation, and IRA, respectively. The search overhead for VIDEOCHEF (both versions A and B) is small – the yellow portions of the bars are almost not visible – and yet it finds more aggressive approximations than the competitive approaches (static or IRA) (the blue portions of the bars are shorter). The IRA approach, due to its assumption that the error in the canary output is identical to the error in the full output, cannot use aggressive ALs and thus cannot achieve the full speedup available through approximation. Within the two variants of VIDEOCHEF, scene change detector (version B) is slower than an I-frame lookup (version A).

Performance for 20db Threshold. We also evaluate on VIDEOCHEF on a different quality thresholds 20dB. Given a larger error budget, Figure 3 shows that VIDEOCHEF is able to achieve more performance gain over exact computation (1.6x speedup). We also outperform static approximation and IRA by 53.4% and 23.1% and within 26.6% from the Oracle results. Notice that the pipelines where we achieve the maximum performance gain over IRA changes from UIV to DVE.

Quality for 30db Threshold. Figure 4(a) shows that IRA and static approximation both achieve much higher quality than what the user specified (30 dB), an undesirable outcome here since this comes at the expense of higher execution time. VIDEOCHEF on the other hand tracks the Oracle quality quite closely, which in turn meets the user requirement. It does however, drop below the threshold on some inputs, albeit by small amounts. This indicates that a future design feature should compensate for the tendency of VIDEOCHEF to sometime drop below the target video quality, say by adding a penalty function when the AL brings it close to the boundary. Further, a carefully designed margin in the searching algorithm can reduce the violation in quality



(a) Quality threshold = 30dB

(b) Quality threshold = 20dB

Figure 3: Mean execution times over all frames of all videos. Geometric means of the speedups are on the right.

(b) Quality threshold = 20dB

Figure 4: Quality of each frame across different video filter pipelines.

requirement but still achieve speedup. The careful reader would have noticed that for some pipelines, some protocol results are missing here. This happens because no approximation is possible for some pipelines and there is no error introduced and hence, PSNR is not defined.

We also use the percentage of frames that violate the quality threshold to characterize the robustness of each protocol. The violation rate of static approximation, IRA, VIDEOCHEF version A and B are 3.27%, 0.64%, 6.6% and 4.79%. Although the two versions of VIDEOCHEF have higher violation rates, they are still within a typical user acceptable threshold (5%). We consider the violation may due to two factors – (1) Inaccurate error prediction in the key frame. (2) The quality of non-key frames degrade and drop below the threshold before a fresh key frame is identified and a search triggered. According to our modeling in Sec 5.3, the violation due to the first factor is limited to at most 5%, while the second error may be inevitable as long as we do not search for every frame. Considering the tradeoff between searching overhead and better error control, VIDEOCHEF is able to largely reduce the searching overhead and still maintain good quality.

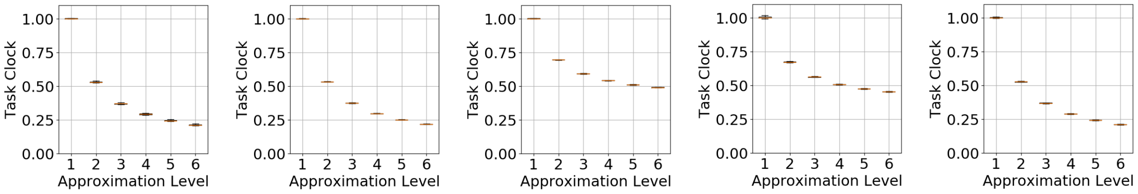
Quality for 20db Threshold. Figure 4(b) shows the quality measurement of different protocols across all the pipelines. The mean violation rate averaged across all pipelines of static approximation, IRA, VIDEOCHEF version A and B are 0%, 0.23%, 7.18% and 3.93%. In the two quality threshold case, we see the advantage of scene change detection as an add-on in VIDEOCHEF version B to decrease the violation rate because it can accurately detect the frame which differs largely from the previous and trigger a required search for optimal approximation levels.

5.2 Speedup and Video Quality versus Approximation Levels

This experiment studies (1) how the execution time of each filter varies with the AL setting for that filter and (2) how the video quality varies with the AL setting. This result is dependent on the approximation technique but is independent of the VIDEOCHEF configuration used to decide on the AL. We show the results with all the videos in our dataset and 5 out of 10 representative filters in Figure 5 (number of executed instructions) and Figure 6 (video quality). When showing the result for a specific filter, we only execute on this filter and not the 3-stage pipeline. Here the results have higher variability due to the content-dependent effect. For the execution time, we normalize by the measure for exact computation.

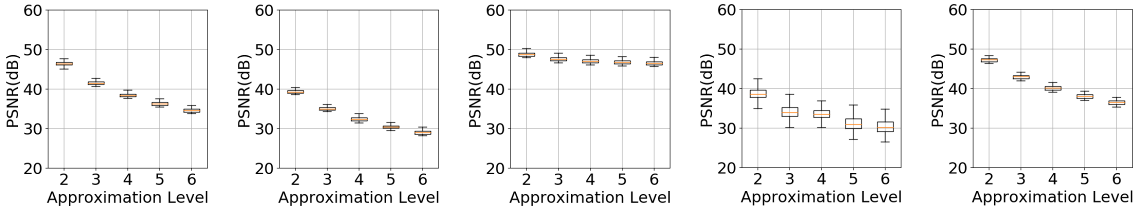
Execution Time. Figure 5 shows that as the AL becomes higher, *i.e.*, the approximation becomes more aggressive, the execution time decreases. But the rate of decrease slows down as the AL becomes higher and the behaviors among the different filters in our evaluation are comparable. Note that this is a box plot, but there is little variation across the different videos and hence each AL gives very tight result. This is expected because the amount of processing done in the filter, whether with exact or approximate computation, is *not* content dependent, but the effect of the approximation *is* content dependent.

Quality. Figure 6 shows the effect of AL on the video quality when the full frame is used. The quality degrades as the approximation gets more aggressive, but the nature of the decrease is not uniform across all the filters. Even within each filter, the effect on quality depends on the ex-



(a) Deflate filter (b) Emboss filter (c) Boxblur filter (d) Histeq filter (e) Vignette filter

Figure 5: The normalized execution time for each filter as the Approximation Level (AL) is varied, across all 106 videos in our dataset. The number of CPU cycles is normalized by the measure for exact computation. As the AL increases, the execution time decreases and this happens consistently across all videos and filters.



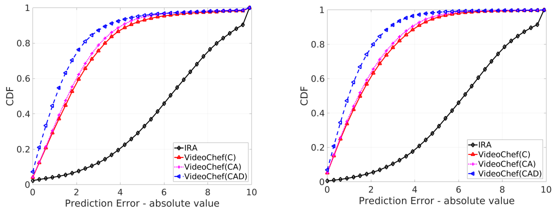
(a) Deflate filter (b) Emboss filter (c) Boxblur filter (d) Histeq filter (e) Vignette filter

Figure 6: The video quality for each filter as the Approximation Level (AL) is varied, across all 106 videos in our dataset. The effect depends on the video content and the filter being used.

act video frame, as implied by the vertical data spread for any given AL. We identify two forms of unpredictability of how AL correlates with video quality: with the content (which video frame is being approximated) and with the filter. Due to these two factors, we do not try to come up with a closed form curve for doing the prediction, rather, we do the actual computation with the canary input for a given AL setting, compute the PSNR, and then map it to the PSNR with the full input (Section 3.5). Contrast this to the execution time where we create a lookup table through training, which is content independent, and just look it up during the online search (Section 3.4.1). The variability due to video content in the PSNR plot validates our rationale for doing the approximation in a content-dependent manner. The rationale is shared with [25], but it sets our work apart from the approximation techniques that select the approximation configuration in a content-independent manner.

5.3 Evaluation of Error Mapping Models

In this experiment, we evaluate the quality of the various error mapping models in VIDEOCHEF. We trained the model on the training video set. Table 2 and Figure 3 present the performance of our model on the validation videos. Figure 7 shows that even a simple model C can greatly reduce the prediction error relative to IRA. Also, as we increase the level of knowledge, the model achieves higher prediction accuracy and model-CAD performs the best due to its good use of the feature extraction from the frames. We can see that with our CAD model, we can successfully control the error within 2dB in 80% of the cases and within 3dB in 90% of the cases. Given these results, we set up a 3dB margin when mapping from the canary error to the full error.



(a) Validation set (b) Test set

Figure 7: Results of the error modeling in VIDEOCHEF mapping error in canary output to error in full output. The CAD model with characteristics of the frame performs best, though it is only slightly better than the CA models.

Table 2: F-1 measure of different error mapping models averaged over all pipelines. We regard IRA as a pass through error mapping.

Models	IRA	C	CA	CAD
30dB threshold	0.8650	0.9576	0.9594	0.9686
20dB threshold	0.8007	0.9679	0.9660	0.9759

The results on the test videos (Section 5.1) show that the cases when we violate the quality requirement are within 10%.

5.4 User Perception Study

To evaluate if the protocols cause any perceptual difference, we conduct a small user study with 16 participants. Users were recruited by emailing students of certain ECE classes. We picked 16 videos, 2 from each YouTube content category, randomly picked from our dataset. We processed each video (a snippet of 20 seconds from each, as in the rest of the evaluation) using the Oracle approach and using VIDEOCHEF for pipeline DBE.

Table 3: Results of the user studies with 16 videos processed using Oracle and VIDEOCHEF

Degree of difference	Percentage
No difference	58.59%
Little difference	34.77%
Large difference	6.64%
Total difference	0

This pipeline was chosen because its result in the rest of the evaluation is representative and it produces videos which are still visually pleasing. In the experiment, we showed the two versions of each of the 16 videos concurrently, processed using the Oracle and VIDEOCHEF tools, without letting the participant know which window corresponded to which tool. All participants watched the videos independently. The participants were asked to rate the videos in four categories: Same, Little difference, Large difference, and Total difference. We gave guidance to the participants for the four categories as difference ∈ [0%,5%),[5%,20%),[20%,50%), and ≥ 50%.

We show the results in Table 3. The percentage figure is the percentage of the total number of videos shown, which is 16 × 16 (number of videos × number of users). We conclude that 58.59% of the videos got no difference rating between the Oracle and the VIDEOCHEF processed videos, while 34.77% got a little difference rating. Although 6.64% of videos got large difference rating, none of the videos got total difference rating. This validates that qualitatively human perception is not seeing significant difference in video quality due to approximate processing using VIDEOCHEF.

6 Related Work

Approximate Tradeoffs in Computations and Data. Researchers presented various techniques for changing computations at the system level to trade accuracy for performance, *e.g.*, in hardware [32, 47, 12, 11, 8], runtime systems [3, 18], and compilers [30, 42, 2, 39, 6]. A key challenge of approximate computing is finding good tradeoffs between accuracy and performance. For this, researchers have looked at both off-line autotuning [30, 42, 29, 38] and on-line dynamic adaptation [3, 18, 37, 22, 17]. In image processing, various techniques exist for synthesizing approximate filter versions, e.g., using genetic programming [45, 41, 13]. Recently, Lou et al. [26] present "image perforation", an adaptive version of loop perforation tailored for individual image filters. Researchers also proposed storing multimedia data in approximate memories, including standard [39, 34], solid-state [40], and multi-level cell memories specialized for video encodings [19]. We consider such storage approaches complementary to our computation-based technique for video encoding.

Input-Aware Approximation. Several techniques provide input-aware approximations to monitor output quality and control the aggressiveness of the approximation during execution. Green [3] was an early approach that applied dynamic quality monitoring to adjust the level of approximation, based on a user-defined quality function. More recently, input-aware approximation identifies classes of similar inputs and applies different approximations for each input class [9, 43]. Opprox [31] learns the control-flow of the input-optimized program and then selects in which phase to approximate as well as how much to approximate. In contrast to our work, all these approaches use off-line models for prediction of input quality and do not craft the smaller inputs at runtime. Ringenburg *et. al.* [35] proposed online monitoring mechanisms, where a random subset of approximate outputs is compared with a precise output on a sampling basis, or the output of the current execution is predicted from past executions with similar inputs. Raha *et al.* [33] present a precise analysis of accuracy for a commonly used reduce-and-rank computational pattern. Rumba [22] and Topaz [1] detect outliers in intermediate computation results. In contrast to IRA [25] and our VIDEOCHEF, these approaches do not use canary inputs to guide the optimization and monitoring and therefore grapple with the overhead issue.

7 Conclusion

Fast and resource efficient processing of videos is required in many scenarios. We built a resource efficient and input-aware approximate video processing pipeline called VIDEOCHEF. VIDEOCHEF controls the approximation in each frame (using the properties of the frame) to meet the user's accuracy requirement. In particular, VIDEOCHEF uses a canary-input based approach for fast searching, as proposed in prior work, but overcomes some fundamental challenges by innovating a machine-learning based accurate error estimation technique and an input-aware search technique that finds best approximation settings. We show that VIDEOCHEF can provide significant speedup in 9 different video processing pipelines while satisfying user's quality requirements.

Abstract

Serverless computing promises to provide applications with cost savings and extreme elasticity. Unfortunately, slow application and container initialization can hurt common-case latency on serverless platforms. In this work, we analyze Linux container primitives, identifying scalability bottlenecks related to storage and network isolation. We also analyze Python applications from GitHub and show that importing many popular libraries adds about 100 ms to startup. Based on these findings, we implement SOCK, a container system optimized for serverless workloads. Careful avoidance of kernel scalability bottlenecks gives SOCK an 18× speedup over Docker. A generalized-Zygote provisioning strategy yields an additional 3× speedup. A more sophisticated three-tier caching strategy based on Zygotes provides a 45× speedup over SOCK without Zygotes. Relative to AWS Lambda and OpenWhisk, OpenLambda with SOCK reduces platform overheads by 2.8× and 5.3× respectively in an image processing case study.

1. Introduction

The effort to maximize developer velocity has driven many changes in the way programmers write and run their code [43]. Programmers are writing code at a higher level of abstraction: JavaScript, Python, Java, Ruby, and PHP are now the most popular languages on GitHub (in that order), surpassing lower-level languages such as C and C++ [51]. Developers also increasingly focus on application-specific logic, reusing existing libraries for general functionality when possible [19, 23, 40].

New programming paradigms are also liberating developers from the distraction of managing servers [18, 52, 54]. In particular, a proliferation of new serverless platforms [5, 6, 14, 17, 20, 39, 45] allow developers to construct applications as a set of handlers, called *lambdas*, commonly written in Python (or some other high-level language), that execute in response to events, such as web requests or data generation. Serverless providers automatically scale the number of handlers up and down to accommodate load so that developers need not worry about the number or configuration of machines serving their workload. Using serverless platforms is often very economical: billing granularity is in fractions of a second, and there is generally no tenant charge for idle time.

These three strategies (*i.e.*, programming at higher abstraction levels, reusing libraries, and decomposing applications into auto-scaling serverless lambdas) improve developer velocity, but they also create new infrastructure problems. Specifically, these techniques make process cold-start more expensive and frequent. Languages such as Python and JavaScript require heavy runtimes, making startup over 10× slower than launching an equivalent C program [1]. Reusing code introduces further startup latency from library loading and initialization [4, 8, 26, 27]. Serverless computing amplifies these costs: if a monolithic application is decomposed to N serverless lambdas, startup frequency is similarly amplified. Lambdas are typically isolated from each other via containers, which entail further sandboxing overheads [31].

Fast cold start is important for both tenants and providers. A graceful reaction to flash crowds [15, 22] requires concurrent low-latency deployment to many workers. From a provider perspective, avoiding cold starts can be quite costly. Most serverless platforms currently wait minutes or hours to recycle idle, unbilled lambda instances [50]. If cold start is made faster, providers will be able to reclaim idle resources and rebalance load across machines more aggressively.

In order to better understand the sandboxing and application characteristics that interfere with efficient cold start, we perform two detailed studies. First, we analyze the performance and scalability of various Linux isolation primitives. Among other findings, we uncover scalability bottlenecks in the network and mount namespaces and identify lighter-weight alternatives. Second, we study 876K Python projects from GitHub and analyzing 101K unique packages from the PyPI repository. We find that many popular packages take 100 ms to import, and installing them can take seconds. Although the entire 1.5 TB package set is too large to keep in memory, we find that 36% of imports are to just 0.02% of packages.

Based on these findings, we implement SOCK (roughly for serverless-optimized containers), a special-purpose container system with two goals: (1) *low-latency invocation* for Python handlers that import libraries and (2) *efficient sandbox initialization* so that individual workers can achieve high steady-state throughput. We integrate SOCK with the OpenLambda [20] serverless platform, replacing Docker as the primary sandboxing mechanism.

SOCK is based on three novel techniques. First, SOCK uses lightweight isolation primitives, avoiding the performance bottlenecks identified in our Linux primitive study, to achieve an 18× speedup over Docker. Second, SOCK provisions Python handlers using a generalized Zygote-provisioning strategy to avoid the Python initialization costs identified in our package study. In the simplest scenarios, this technique provides an additional 3× speedup by avoiding repeated initialization of the Python runtime. Third, we leverage our generalized Zygote mechanism to build a three-tiered package-aware caching system, achieving 45× speedups relative to SOCK containers without Zygote initialization. In an image-resizing case study, SOCK reduces cold-start platform overheads by 2.8× and 5.3× relative to AWS Lambda and OpenWhisk, respectively.

The rest of this paper is structured as follows. We study the costs of Linux provisioning primitives (§2) and application initialization (§3), and use these findings to guide the design and implementation of SOCK (§4). We then evaluate the performance of SOCK (§5), discuss related work (§6), and conclude (§7).

2. Deconstructing Container Performance

Serverless platforms often isolate lambdas with containers [14, 20, 39, 45]. Thus, optimizing container initialization is a key part of the lambda cold-start problem. In Linux, containerization is not a single-cohesive abstraction. Rather, general-purpose tools such as Docker [36] are commonly used to construct containers using a variety of Linux mechanisms to allocate storage, isolate resources logically, and isolate performance. The flexibility Linux provides also creates an opportunity to design a variety of special-purpose container systems. In this section, we hope to inform the design of SOCK and other special-purpose container systems by analyzing the performance characteristics of the relevant Linux abstractions. In particular, we ask *how can one maximize density of container file systems per machine? What is the cost of isolating each major resource with namespaces, and which resources must be isolated in a serverless environment?* And *how can the cost of repeatedly initializing cgroups to isolate performance be avoided?* We perform our analysis on an 8-core m510 machine [11] with the 4.13.0-37 Linux kernel.

2.1 Container Storage

Containers typically execute using a root file system other than the host's file system. This protects the host's data and provides a place for the container's unique dependencies to be installed. Provisioning a file system for a container is a two step procedure: (1) populate a subdirectory of the host's file system with data and code needed by the container, and (2) make the subdirectory the root of the new container, such that code in the container can no longer access other host data. We explore alternative mechanisms for these population and access-dropping steps.

Populating a directory by physical copying is prohibitively slow, so all practical techniques rely on logical copying. Docker typically uses union file systems (*e.g.*, AUFS) for this purpose; this provides a flexible layered-composition mechanism and gives running containers copy-on-write access over underlying data. A simpler alternative is bind mounting. Bind mounting makes the same directory visible at multiple locations; there is no copy-on-write capability, so data that must be protected should only be bind-mounted as read-only in a container. To compare binds to layered file systems, we repeatedly mount and unmount from many tasks in parallel. Figure 1 shows the result: at scale, bind mounting is about twice as fast as AUFS.

Once a subdirectory on the host file system has been populated for use as a container root, the setup process must switch roots and drop access to other host file data. Linux provides two primitives for modifying the file-system visible to a container. The older `chroot` operation simply turns a subdirectory of the original root file system into the new root file system. A newer mount-namespace abstraction enables more interesting transformations: an `unshare` call (with certain arguments) gives a container a new set of mount points, originally identical to the host's set. The container's mount points can then be modified with mount, unmount, and other calls. It is even possible to reorganize the mount namespace of a container such that the container may see file system Y mounted on file system X (the container's root) while the host may see X mounted on Y (the host's root). There are cases where this powerful abstraction can be quite helpful, but overusing mount namespace flexibility "may quickly lead to insanity," as the Linux manpages warn [32].

We measure the scalability of mount namespaces, with results shown in Figure 2. We have a variable number of long-lived mount namespaces persisting throughout the experiment (x-axis). We churn namespaces, concurrently creating and deleting them (concurrency is shown by different lines). We observe that churn performance scales poorly with the number of prior existing namespaces: as the number of host mounts grows large, the rate at which namespaces can be cloned approaches zero. We also evaluate `chroot` (not shown), and find that using it entails negligible overhead (`chroot` latency is $< 1\mu$s).

2.2 Logical Isolation: Namespace Primitives

We have already described how mount namespaces can be used to virtualize storage: multiple containers can have

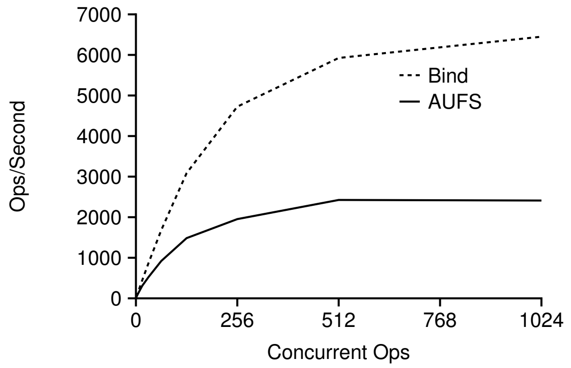

Figure 1. Storage Primitives. *The performance of mounting and unmounting AUFS file systems is compared to the performance of doing the same with bind mounts.*

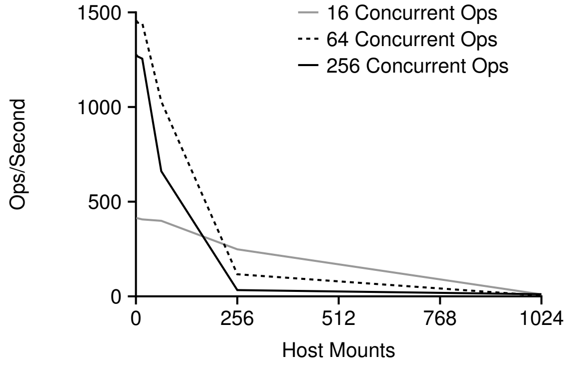

Figure 2. Mount Scalability. *This shows the rate at which processes can be unshared into new mount namespaces (y-axis) as the number of existing mounts varies (x-axis).*

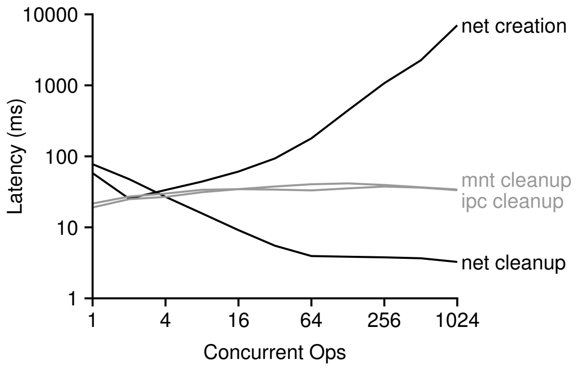

Figure 3. Namespace Primitives. *Lines show the latencies for copy_net_ns, put_mnt_ns and put_ipc_ns, and the average time spent by the network cleanup task per namespace.*

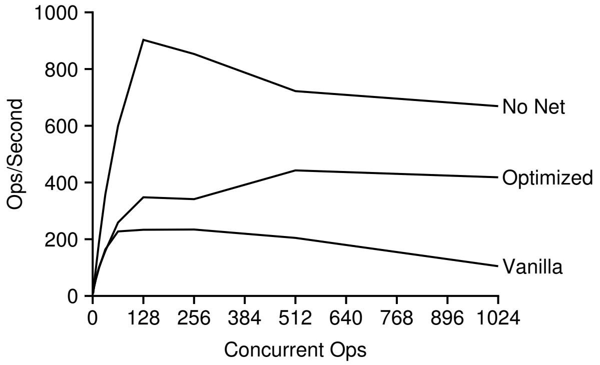

Figure 4. Network Namespace Performance. *A given number of containers (x-axis) are created and deleted in parallel with multiple network namespace configurations.*

access to their own virtual roots, backed by different physical directories in the host. Linux's network namespaces similarly allow different containers to use the same virtual port number (*e.g.*, 80), backed by different physical ports on the host (*e.g.*, 8080 and 8081). In this section, we study the collective use of mount and network namespaces, along with UTS, IPC, and PID namespaces [37] (user and cgroup namespaces are not evaluated here). The `unshare` call allows a process to create and switch to a new set of namespaces. Arguments to `unshare` allow careful selection of which resources need new namespaces. Namespaces are automatically reaped when the last process using them exits.

We exercise namespace creation and cleanup performance by concurrently invoking `unshare` and exiting from a variable number of tasks. We instrument the kernel with `ftrace` to track where time is going. Figure 3 shows the latency of the four most expensive namespace operations (other latencies not shown were relatively insignificant). We observe that mount and IPC namespace cleanup entails latencies in the tens of milliseconds. Upon inspection of the kernel code, we found that both operations are waiting for an RCU grace period [35]. During this time, no global locks are held and no compute is consumed, so these latencies are relatively harmless to overall throughput; as observed earlier (§2.1), it is possible to create ∼1500 mount namespaces per second, as long as churn keeps the number of namespaces small over time.

Network namespaces are more problematic for both creation and cleanup due to a single global lock that is shared across network namespaces [13]. During creation, Linux iterates over all existing namespaces while holding the lock, searching for namespaces that should be notified of the configuration change; thus, costs increase proportionally as more namespaces are created. As with mount and IPC namespaces, network-namespace cleanup requires waiting for an RCU grace period. However, for network namespaces, a global lock is held during that period, creating a bottleneck. Fortunately, network namespaces are cleaned in batches, so the per-namespace cost becomes small at scale (as indicated by the downward-sloping "net cleanup" line).

Figure 4 shows the impact of network namespaces on overall creation/deletion throughput (*i.e.*, with all

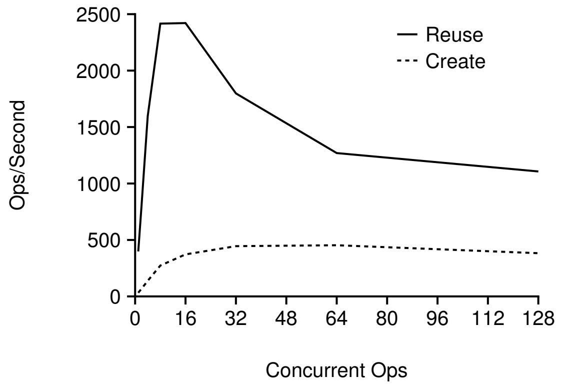

Figure 5. Cgroup Primitives. *Cgroup performance is shown for reuse and fresh-creation patterns.*

five namespaces). With unmodified network namespaces, throughput peaks at about 200 c/s (containers/second). With minor optimizations (disabling IPv6 and eliminating the costly broadcast code), it is possible to churn over 400 c/s. However, eliminating network namespaces entirely provides throughput of 900 c/s.

2.3 Performance Isolation: Cgroup Primitives

Linux provides performance isolation via the cgroup interface [9]. Processes may be assigned to cgroups, which are configured with limits on memory, CPU, file I/O, and other resources. Linux cgroups are easier to configure dynamically than namespaces. The API makes it simple to adjust the resource limits or reassign processes to different cgroups. In contrast, a mechanism for reassigning a process to a new PID namespace would need to overcome obstacles such as potential PID collisions.

The flexibility of cgroups makes two usage patterns viable. The first involves (1) creating a cgroup, (2) adding a process, (3) exiting the process, and (4) removing the cgroup; the second involves only Steps 2 and 3 (*i.e.*, the same cgroup is reused for different processes at different times). Figure 5 compares the cost of these two approaches while varying the numbers of tasks concurrently manipulating cgroups. Reusing is at least twice as fast as creating new cgroups each time. The best reuse performance is achieved with 16 threads (the number of CPU hyperthreads), suggesting cgroups do not suffer from the scaling issues we encountered with namespaces.

2.4 Serverless Implications

Our results have several implications for the design of serverless containers. First, in a serverless environment, all handlers run on one of a few base images, so the flexible stacking of union file systems may not be worth the the performance cost relative to bind mounts. Once a root location is created, file-system tree transformations that rely upon copying the mount namespace are costly at scale. When flexible file-system tree construction is not necessary, the cheaper `chroot` call may be used to drop access. Second, network namespaces are a major scalability bottleneck; while static port assignment may be useful in a server-based environment, serverless platforms such as AWS Lambda execute handlers behind a Network Address Translator [16], making network namespacing of little value. Third, reusing cgroups is twice as fast as creating new cgroups, suggesting that maintaining a pool of initialized cgroups may reduce startup latency and improve overall throughput.

3. Python Initialization Study

Even if lambdas are executed in lightweight sandboxes, language runtimes and package dependencies can make cold start slow [4, 8, 26, 27]. Many modern applications are accustomed to low-latency requests. For example, most Gmail remote-procedure calls are short, completing in under 100 ms (including Internet round trip) [20]. Of the short requests, the average latency is 27 ms, about the time it takes to start a Python interpreter and print a "hello world" message. Unless serverless platforms provide language- and library-specific cold-start optimizations, it will not be practical to decompose such applications into independently scaling lambdas. In this section, we analyze the performance cost of using popular Python libraries and evaluate the feasibility of optimizing initialization with caching. We ask: *what types of packages are most popular in Python applications? What are the initialization costs associated with using these packages?* And *how feasible is it to cache a large portion of mainstream package repositories on local lambda workers?*

3.1 Python Applications

We now consider the types of packages that future lambda applications might be likely to use, assuming efficient platform support. We scrape 876K Python projects from GitHub and extract likely dependencies on packages in the popular Python Package Index (PyPI) repository, resolving naming ambiguity in favor of more popular packages. We expect that few of these applications currently run as lambdas; however, our goal is to identify potential obstacles that may prevent them from being ported to lambdas in the future.

Figure 6 shows the popularity of 20 packages that are most common as GitHub project dependencies. Skew is high: 36% of imports are to just 20 packages (0.02% of the packages in PyPI). The 20 packages roughly fall into five categories: web frameworks, analysis, communication, storage, and development. Many of these use cases are likely applicable to future serverless applications. Current web frameworks will likely need to be replaced by serverless-oriented frameworks, but compute-intense analysis is ideal for lambdas [21]. Many lambdas will need libraries for communicating with other services and for storing data externally [16]. Development

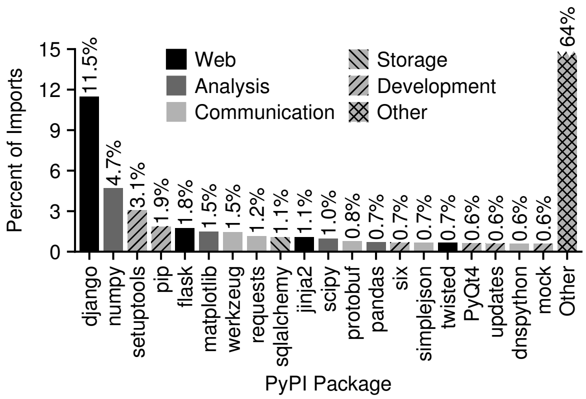

Figure 6. Package Popularity. *The twenty most used PyPI packages are shown. The bar labels represent the percentage of all GitHub-to-PyPI dependencies.*

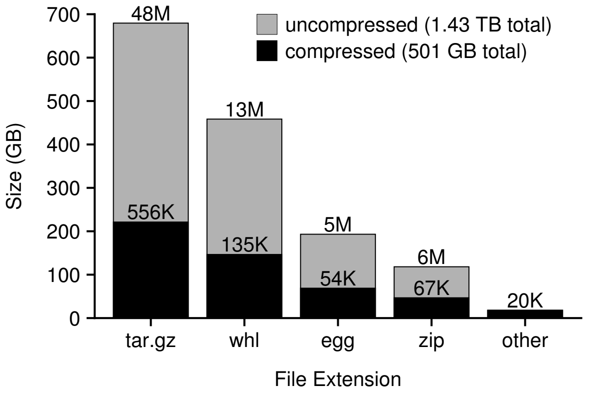

Figure 8. PyPI Package Data. *The size of the PyPI repository is shown, compressed and uncompressed, by file type (as of Mar 31, 2017). Bar labels show file counts.*

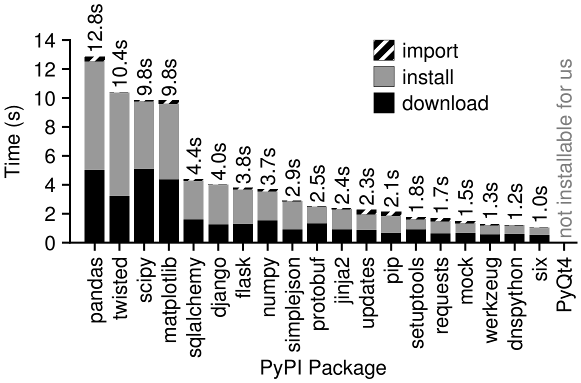

Figure 7. Startup Costs. *The download, install, and import times are shown for 20 popular Python packages, ordered by total initialization time.*

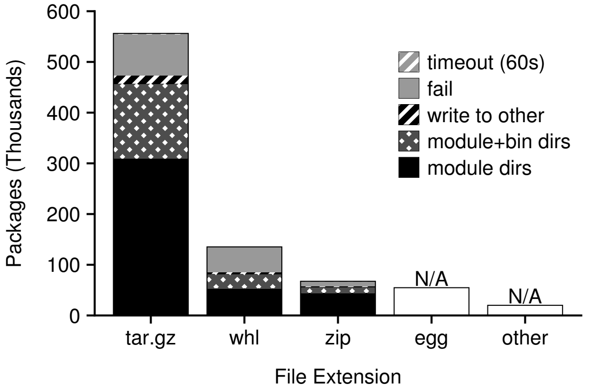

Figure 9. File-System Modifications. *The bars breakdown installations by the types of writes to the file system. The egg and other files can be used without extraction.*

libraries may be somewhat less relevant, but lambda-based parallel unit testing is an interesting use case.

If a package is being used for the first time, it will be necessary to *download* the package over the network (possibly from a nearby mirror), *install* it to local storage, and *import* the library to Python bytecode. Some of these steps may be skipped upon subsequent execution, depending on the platform. Figure 7 shows these costs for each of the popular packages. Fully initializing a package takes 1 to 13 seconds. Every part of the initialization is expensive on average: downloading takes 1.6 seconds, installing takes 2.3 seconds, and importing takes 107 ms.

3.2 PyPI Repository

We now explore the feasibility of supporting full language repositories locally on serverless worker machines. We mirror and analyze the entire PyPI repository, which contains 101K unique packages. Figure 8 shows the footprint of the entire repository, including every version of every package, but excluding indexing files. The packages are about 1.5 TB total, or ~0.5 TB compressed. Most packages are compressed as *.tar.gz* files or a zip-based format (*.whl*, *.egg*, or *.zip*). Across all format types, the average package contains about 100 files (*e.g.*, 135K *.whl* packages hold 13M compressed files).

We wish to understand how many of the PyPI packages could coexist when installed together. PyPI packages that unpack to a single directory can easily coexist with other installed packages, whereas packages that modify shared files may break other packages. We attempt to install every version of every PyPI package in its own Docker Ubuntu container (using a 1-minute timeout) and identify file creations and modifications. We ignore changes to temporary locations. Figure 9 shows the results for *.tar.gz*, *.whl*, and *.zip* distributions (*.egg* libraries are used directly without a prior installation, so we skip those). While fewer than 1% timed out, 18% simply failed to install in our container. 66% of succeeding installs only populate the local Python module directory (the *module dirs* category). Another 31% of succeeding installs modified just the module directories and the local bin directory (Python modules are sometimes bundled with various utilities). We conclude it is possible for 97% of installable packages to coexist in a single local install.

3.3 Serverless Implications

Downloading and installing a package and its dependencies from a local mirror takes seconds; furthermore, import of installed packages takes over 100 ms. Fortunately, our analysis indicates that storing large package repositories locally on disk is feasible. Strong popularity skew further creates opportunities to pre-import a subset of packages into interpreter memory [8].

4. SOCK with OpenLambda

In this section, we describe the design and implementation of SOCK, a container system optimized for use in serverless platforms. We integrate SOCK with the OpenLambda serverless platform, replacing Docker containers as the primary sandboxing mechanism for OpenLambda workers and using additional SOCK containers to implement Python package caching. We design SOCK to handle high-churn workloads at the worker level. The local churn may arise due to global workload changes, rebalancing, or aggressive reclamation of idle resources.

SOCK is based on two primary design goals. First, we want *low-latency invocation* for Python handlers that import libraries. Second, we want *efficient sandbox initialization* so that individual workers can achieve high steady-state throughput. A system that hides latency by maintaining pools of pre-initialized containers (*e.g.*, the LightVM approach [31]) would satisfy the first goal, but not the second. A system that could create many containers in parallel as part of a large batch might satisfy the second goal, but not the first. Satisfying both goals will make a serverless platform suitable for many applications and profitable for providers.

Our solution, SOCK, takes a three-pronged approach to satisfying these goals, based on our analysis of Linux containerization primitives (§2) and Python workloads (§3). First, we build a lean container system for sandboxing lambdas (§4.1). Second, we generalize Zygote provisioning to scale to large sets of untrusted packages (§4.2). Third, we design a three-layer caching system for reducing package install and import costs (§4.3).

4.1 Lean Containers

SOCK creates lean containers for lambdas by avoiding the expensive operations that are only necessary for general-purpose containers. Creating a container involves constructing a root file system, creating communication channels, and imposing isolation boundaries. Figure 10 illustrates SOCK's approach to these three tasks.

Storage: Provisioning container storage involves first populating a directory on the host to use as a container root. Bind mounting is faster using union file systems (§2.1), so SOCK uses bind mounts to stitch together a root from four host directories, indicated by the "F" label in Figure 10. Every container has the same Ubuntu base for its root file system ("base"); we can afford to back this by a RAM disk as every handler is required to use the same base. A packages directory used for package caching ("packages") is mounted over the base, as described later (§4.3). The same base and packages are read-only shared in every container. SOCK also binds handler code ("λ code") as read-only and a writable scratch directory ("scratch") in every container.

Once a directory has been populated as described, it should become the root directory. Tools such as Docker accomplish this by creating a new mount namespace, then restructuring it. We use the faster and simpler `chroot` operation (§2.1) since it is not necessary to selectively expose other host mounts within the container for serverless applications. SOCK containers always start with two processes ("init" and "helper" in Figure 10); both of these use `chroot` during container initialization, and any children launched from these processes inherit the same root.

Communication: The scratch-space mount of every SOCK container contains a Unix domain socket (the black pentagon in Figure 10) that is used for communication between the OpenLambda manager and processes inside the container. Event and request payloads received by OpenLambda are forwarded over this channel.

The channel is also used for a variety of control operations (§4.2). Some of these operations require privileged access to resources not normally accessible inside a container. Fortunately, the relevant resources (*i.e.*, namespaces and container roots) may be represented as file descriptors, which may be passed over Unix domain sockets. The manager can thus pass specific capabilities over the channel as necessary.

Isolation: Linux processes may be isolated with a combination of cgroup (for performance isolation) and namespace primitives (for logical isolation). It is relatively expensive to create cgroups; thus, OpenLambda creates a pool of cgroups (shown in Figure 10) that can be used upon SOCK container creation; cgroups are returned to the pool after container termination.

The "init" process is the first to run in a SOCK container; init creates a set of new namespaces with a call to `unshare`. The arguments to the call indicate that mount and network namespaces should not be used, because these were the two namespaces that scale poorly (§2.1 and §2.2). Mount namespaces are unnecessary because SOCK uses `chroot`. Network namespaces are unnecessary because requests arrive over Unix domain socket, not over a socket attached to a fixed port number, so port virtualization is not required.

4.2 Generalized Zygotes

Zygote provisioning is a technique where new processes are started as forks of an initial process, the Zygote,

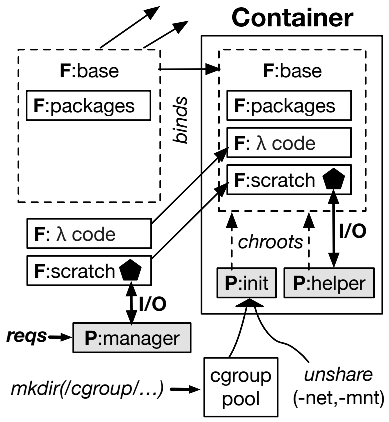

Figure 10. Lean Containers

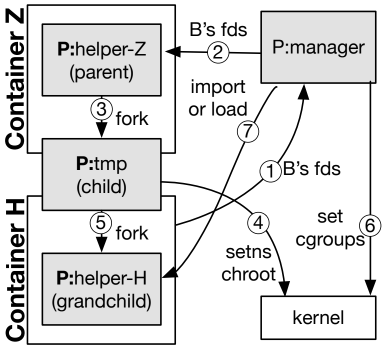

Figure 11. Generalized Zygotes

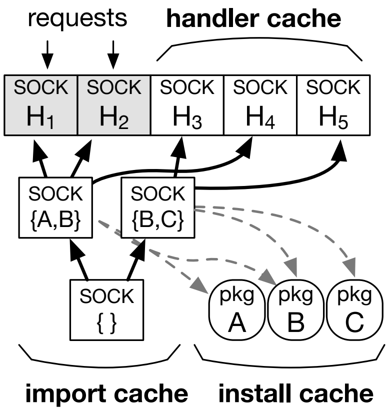

Figure 12. Serverless Caching

that has already pre-imported various libraries likely to be needed by applications, thereby saving child processes from repeatedly doing the same initialization work and consuming excess memory with multiple identical copies. Zygotes were first introduced on Android systems for Java applications [8]. We implement a more general Zygote-provisioning strategy for SOCK. Specifically, SOCK Zygotes differ as follows: (1) the set of pre-imported packages is determined at runtime based on usage, (2) SOCK scales to very large package sets by maintaining multiple Zygotes with different pre-imported packages, (3) provisioning is fully integrated with containers, and (4) processes are not vulnerable to malicious packages they did not import.

As already described, SOCK containers start with two processes, an init process (responsible for setting up namespaces) and a helper process. The helper process is a Python program that listens on the SOCK communication channel; it is capable of (a) pre-importing modules and (b) loading lambda handlers to receive subsequent forwarded events. These two capabilities are the basis for a simple Zygote mechanism. A *Zygote helper* first pre-imports a set of modules. Then, when a lambda is invoked requiring those modules, the Zygote helper is forked to quickly create a new *handler helper*, which then loads the lambda code to handle a forwarded request.

We assume packages that may be pre-imported may be malicious [48], and handlers certainly may be malicious, so both Zygote helpers and handler helpers must run in containers. The key challenge is using Linux APIs such that the forked process lands in a new container, distinct from the container housing the Zygote helper.

Figure 11 illustrates how the SOCK protocol provisions a helper handler ("helper-H" in "Container H") from a helper Zygote ("helper-Z" in "Container Z"). **(1)** The manager obtains references, represented as file descriptors (fds), to the namespaces and the root file system of the new container. **(2)** The fds are passed to helper-Z, which **(3)** forks a child process, "tmp". **(4)** The child then changes roots to the new container with a combination of `fchdir(fd)` and `chroot(".")` calls. The child also calls `setns` (set namespace) for each namespace to relocate to the new container. **(5)** One peculiarity of `setns` is that after the call, the relocation has only partially been applied to all namespaces for the caller. Thus, the child calls fork again, creating a grandchild helper ("helper-H" in the figure) that executes fully in the new container with respect to namespaces. **(6)** The manager then moves the grandchild to the new cgroup. **(7)** Finally, the helper listens on the channel for the next commands; the manager will direct the helper to load the lambda code, and will then forward a request to the lambda.

The above protocol describes how SOCK provisions a handler container from a Zygote container. When OpenLambda starts, a single Zygote that imports no modules is always provisioned. In order to benefit from preimporting modules, SOCK can create additional Zygotes that import various module subsets. Except for the first Zygote, new Zygotes are provisioned from existing Zygotes. The protocol for provisioning a new Zygote container is identical to the protocol for provisioning a new handler container, except for the final step 7. Instead of loading handler code and processing requests, a new Zygote pre-imports a specified list of modules, then waits to be used for the provisioning of other containers.

Provisioning handlers from Zygotes and creating new Zygotes from other Zygotes means that all the interpreters form a tree, with copy-on-write memory unbroken by any call to `exec`. This sharing of physical pages between processes reduces memory consumption [2]. Initialization of the Python runtime and packages will only be done once, and subsequent initialization will be faster.

If a module loaded by a Zygote is malicious, it may interfere with the provisioning protocol (*e.g.*, by modifying the helper protocol so that calls to `setns` are skipped). Fortunately, the Zygote is sandboxed in a container, and

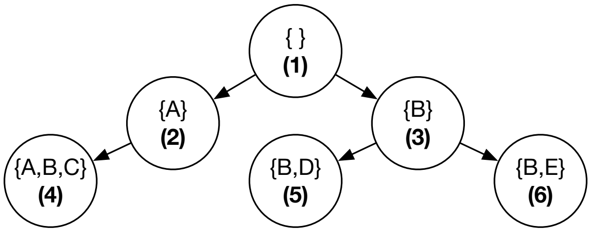

Figure 13. Tree Cache. *Numbered circles represent Zygotes in the cache, and sets of letters indicate the packages imported by a process. Arrows represent the parent-child relationships between interpreter processes.*

will never be passed descriptors referring to unrelated containers, so a malicious process cannot escape into arbitrary containers or the host. SOCK protects innocent lambdas by never initializing them from a Zygote that has pre-imported modules not required by the lambda.

4.3 Serverless Caching

We use SOCK to build a three-tier caching system, shown in Figure 12. First, a *handler cache* maintains idle handler containers in a paused state; the same approach is taken by AWS Lambda [49]. Paused containers cannot consume CPU, and unpausing is faster than creating a new container; however, paused containers consume memory, so SOCK limits total consumption by evicting paused containers from the handler cache on an LRU basis.

Second, an *install cache* contains a large, static set of pre-installed packages on disk. Our measurements show that 97% of installable PyPI packages could coexist in such a installation. This installation is mapped read-only into every container for safety. Some of the packages may be malicious, but they do no harm unless a handler chooses to import them.

Third, an *import cache* is used to manage Zygotes. We have already described a general mechanism for creating many Zygote containers, with varying sets of packages pre-imported (§4.2). However, Zygotes consume memory, and package popularity may shift over time, so SOCK decides the set of Zygotes available based on the import-cache policy. Import caching entails new decisions for handling hits. In traditional caches, lookup results in a simple hit or miss; in contrast, SOCK always hits at least one cache entry and often must decide between alternative Zygotes. Eviction is also complicated by copy-on-write sharing of memory pages between Zygotes, which obfuscates the consumption of individuals. We now describe SOCK's selection and eviction policies.

Import-Cache Selection: Suppose (in the context of Figure 13) that a handler is invoked that requires packages A and B. Entry 4 is a tempting choice to use as the template for our new interpreter; it would provide the best performance because all requisite packages are already imported. However, if package C is malicious, we expose the handler to code that it did not voluntarily import. We could potentially vet a subset of packages to be deemed safe, but we should generally not use cache entries that pre-import packages not requested by a handler. This leaves cache Entries 2 and 3 as reasonable candidates. The import cache decides between such alternatives by choosing the entry with the most matching packages, breaking ties randomly. When SOCK must use an entry X that is not an exact match, it first replicates X to a new entry Y, imports the remaining packages in Y, and finally replicates from Y to provision for the handler.

Import-Cache Eviction: The import cache measures the cumulative memory utilization of all entries; when utilization surpasses a limit, a background process begins evicting entries. Deciding which interpreters to evict is challenging because the shared memory between interpreters makes it difficult to account for the memory used by a particular entry. The import cache relies on a simple runtime model to estimate potential memory reclamation; the model identifies the packages included by an interpreter that are not included by the parent entry. The model uses the on-disk size of the packages as a heuristic for estimating memory cost. The import cache treats the sum of these sizes as the *benefit* of eviction and the number of uses over a recent time interval as the *cost* of eviction, evicting the entry with highest benefit-to-cost ratio.

5. Evaluation

We now evaluate the performance of SOCK relative to Docker-based OpenLambda and other platforms. We run experiments on two m510 machines [11] with the 4.13.0-37 Linux kernel: a package mirror and an OpenLambda worker. The machines have 8-core 2.0 GHz Xeon D-1548 processors, 64 GB of RAM, and a 256 GB NVMe SSD. We allocate 5 GB of memory for the handler cache and 25 GB for the import cache. We consider the following questions: *What speedups do SOCK containers provide OpenLambda* (§5.1)? *Does built-in package support reduce cold-start latency for applications with dependencies* (§5.2)? *How does SOCK scale with the number of lambdas and packages* (§5.3)? And *how does SOCK compare to other platforms for a real workload* (§5.4)?

5.1 Container Optimizations

SOCK avoids many of the expensive operations necessary to construct a general-purpose container (*e.g.*, network namespaces, layered file systems, and fresh cgroups). In order to evaluate the benefit of lean containerization, we concurrently invoke no-op lambdas on OpenLambda, using either Docker or SOCK as the container engine. We disable all SOCK caches and Zygote preinitialization. Figure 14 shows the request throughput and average latency as we vary the number of concurrent outstanding requests. SOCK is strictly faster on both metrics, regardless of concurrency. For 10 concurrent re-

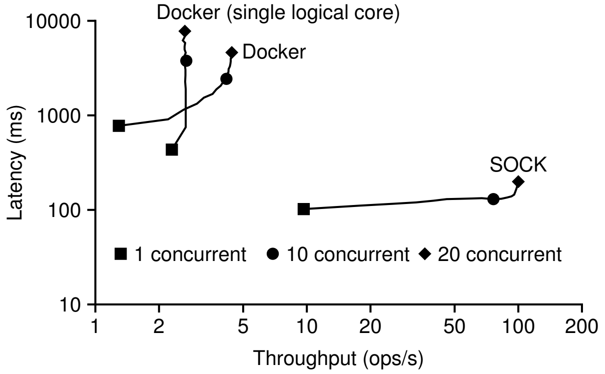

Figure 14. Docker vs. SOCK. *Request throughput (x-axis) and latency (y-axis) are shown for SOCK (without Zygotes) and Docker for varying concurrency.*

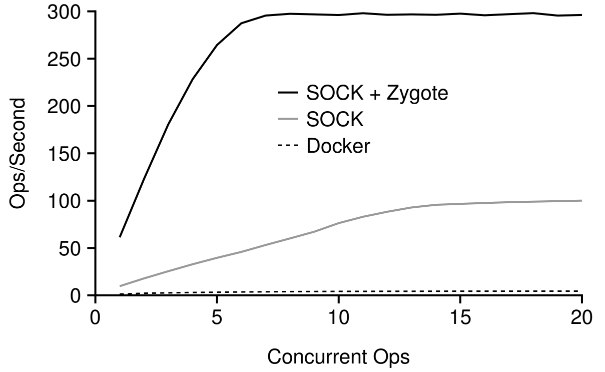

Figure 15. Interpreter Preinitialization. *HTTP Request Throughput is shown relative to number of concurrent requests.*

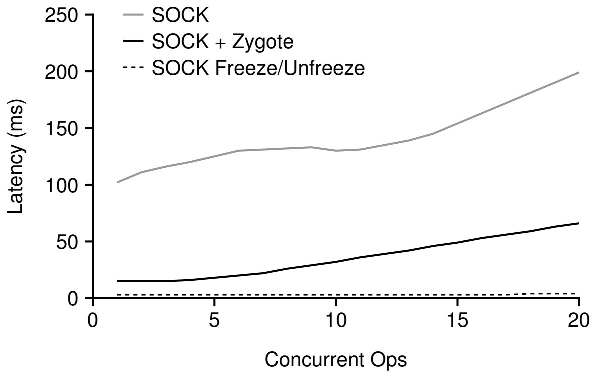

Figure 16. Container Reuse vs. Fast Creation. *SOCK container creation is compared to the freeze/unfreeze operation that occurs when there are repeated calls to the same lambda.*

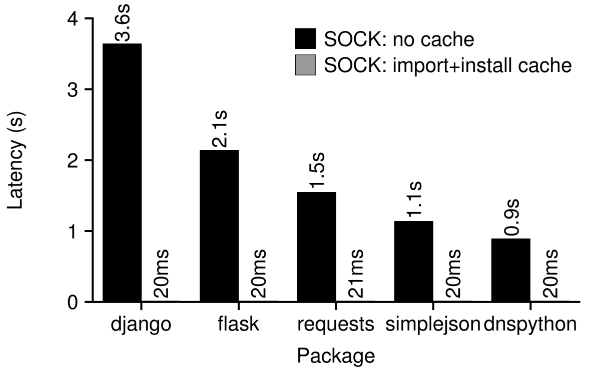

Figure 17. Pre-Imported Packages. *SOCK latency with and without package caches are shown.*

quests, SOCK has a throughput of 76 requests/second (18× faster than Docker) with an average latency of 130 milliseconds (19× faster). Some of the namespaces used by Docker rely heavily on RCUs (§2.2), which scale poorly with the number of cores [34]. Figure 14 also shows Docker performance with only one logical core enabled: relative to using all cores, this reduces latency by 44% for $concurrency = 1$, but throughput no longer scales with concurrency.

SOCK also improves performance by using Zygote-style preinitialization. Even if a lambda uses no libraries, provisioning a runtime by forking an existing Python interpreter is faster than starting from scratch. Figure 15 compares SOCK throughput with and without Zygote preinitialization. Using Zygotes provides SOCK with an additional 3× throughput improvement at scale.

OpenLambda, like AWS Lambda [49], keeps recently used handlers that are idle in a paused state in order to avoid cold start should another request arrive. We now compare the latency of SOCK cold start to the latency of unpause, as shown in Figure 16. Although Zygotes have reduced no-op cold-start latency to 32 ms ($concurrency = 10$), unpausing takes only 3 ms. Although SOCK cold-start optimizations enable more aggressive resource reclamation, it is still beneficial to pause idle handlers before immediately evicting them.

5.2 Package Optimizations

SOCK provides two package-oriented optimizations. First, SOCK generalizes the Zygote approach so that new containers can be allocated by one of many different Zygote containers, each with different packages pre-imported, based on the current workload (import caching). Second, a large subset of packages are pre-installed to a partition that is bind-mounted read-only in every container (install caching).

We first evaluate these optimizations together with a simple workload, where a single task sequentially invokes different lambdas that use the same single library, but perform no work. Figure 17 shows the result. Without optimizations, downloading, installing, and importing usually takes at least a second. The optimizations reduce latency to 20 ms, at least a 45× improvement.

To better understand the contributions of the three caching layers (*i.e.*, the new import and install caches and the old handler cache), we repeat the experiment in Figure 17 for django, evaluating all caches, no caches, and

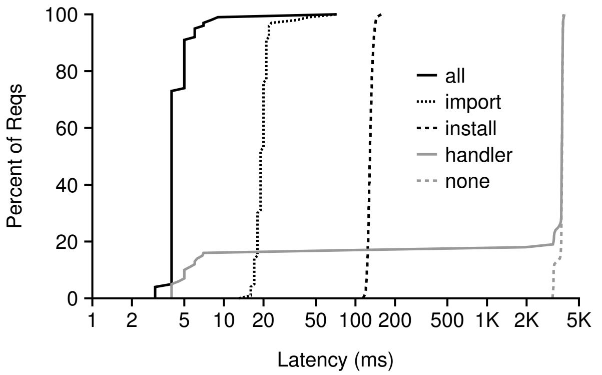

Figure 18. Individual Caches. *Each line shows a latency CDF for a different configuration for the django experiment.*

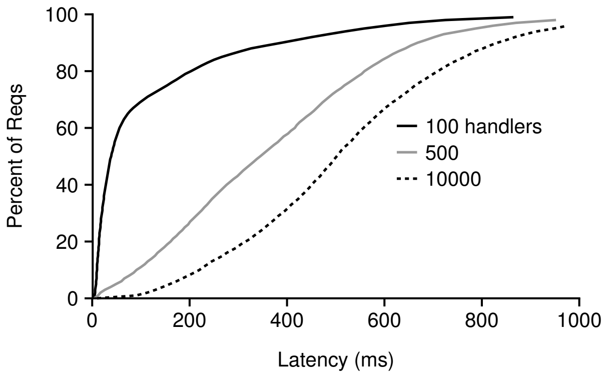

Figure 20. Scalability: Synthetic Packages. *Each line represents a CDF of latencies for a different working-set size.*

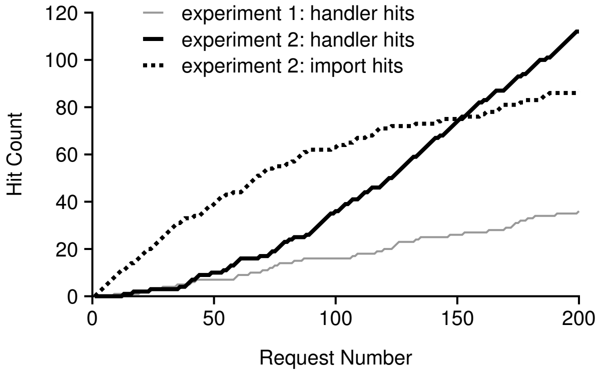

Figure 19. Handler/Import Cache Interactions. *Hit counts are shown during cache warmup (the first 200 requests) for two cache configurations.*

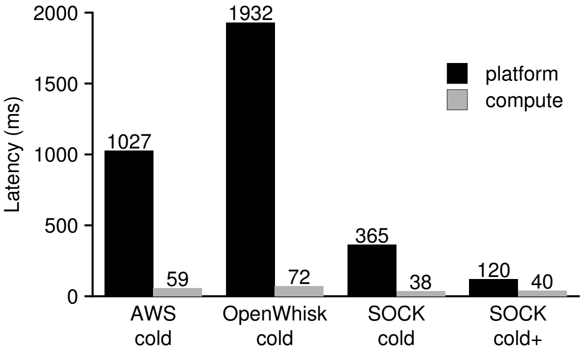

Figure 21. AWS Lambda and OpenWhisk. *Platform and compute costs are shown for cold requests to an image-resizing lambda. S3 latencies are excluded to minimize noise.*

each cache in isolation. For each experiment, 100 different lambdas import django, and a single task sequentially invokes randomly-chosen lambdas. Figure 18 shows the results. The handler cache has bimodal latency: it usually misses, but is fastest upon a hit. The working set fits in the import cache, which provides consistent latencies around 20 ms; the install cache is also consistent, but slower. Using all caches together provides better performance than any one individually.

When import caching is enabled, processes in the handler cache and processes in the import cache are part of the same process tree. This structure leads to deduplication: multiple processes in the handler cache can share the same memory page on a copy-on-write basis with a parent process in the import cache. This allows the handler cache to maintain more cache entries. Figure 19 illustrates this helpful interaction. We issue 200 requests to many different lambdas, all of which import django, without an import cache (experiment 1) and with an import cache (experiment 2). In the first experiment, the handler cache has 18% hits. In the second, deduplication allows the handler cache to maintain more entries, achieving 56% hits.

5.3 Scalability

We stress test SOCK with a large set of artificial packages (100K). The packages generate CPU load and memory load, similar to measured overheads of 20 popular packages (§3.1). We create dependencies between packages similar to the PyPI dependency structure. Each handler imports 1-3 packages directly. The packages used are decided randomly based on package popularity; popularity is randomly assigned with a Zipfian distribution, $s = 2.5$. All packages are pre-installed to the install cache.

We also vary the number of handlers (100 to 10K). A small working set exercises the handler cache, and a large working set exercises the install cache. The import cache should service mid-sized working sets. Handlers are executed uniformly at random as fast as possible by 10 concurrent tasks. Figure 20 shows a latency CDF for each working set size. With 100 handlers, SOCK achieves low latency (39 ms median). For 10K handlers, 88% percent of requests must be serviced from the install cache, so the median latency is 502 ms. For 500 handlers, the import cache absorbs 46% of the load, and the handler cache absorbs 6.4%, resulting in 345 ms latencies.

5.4 Case Study: Image Resizing

In order to evaluate a real serverless application, we implement on-demand image resizing [28]. A lambda reads an image from AWS S3, uses the Pillow package to resize it [10], and writes the output back to AWS S3. For this experiment, we compare SOCK to AWS Lambda and OpenWhisk, using 1 GB lambdas (for AWS Lambda) and a pair of m4.xlarge AWS EC2 instances (for SOCK and OpenWhisk); one instance services requests and the other hosts handler code. We use AWS's US East region for EC2, Lambda, and S3.

For SOCK, we preinstall Pillow and the AWS SDK [44] (for S3 access) to the install cache and specify these as handler dependencies. For AWS Lambda and OpenWhisk, we bundle these dependencies with the handler itself, inflating the handler size from 4 KB to 8.3 MB. For each platform, we exercise cold-start performance by measuring request latency after re-uploading our code as a new handler. We instrument handler code to separate compute and S3 latencies from platform latency.

The first three bars of Figure 21 show compute and platform results for each platform (average of 50 runs). "SOCK cold" has a platform latency of 365 ms, 2.8× faster than AWS Lambda and 5.3× faster than OpenWhisk. "SOCK cold" compute time is also shorter than the other compute times because all package initialization happens after the handler starts running for the other platforms, but SOCK performs package initialization work as part of the platform. The "SOCK cold+" represents a scenario similar to "SOCK cold" where the handler is being run for the first time, but a different handler that also uses the Pillow package has recently run. This scenario further reduces SOCK platform latency by 3× to 120 ms.

6. Related Work

Since the introduction of AWS Lambda in 2014 [5], many new serverless platforms have become available [6, 14, 17, 39, 45]. We build SOCK over OpenLambda [20]. SOCK implements and extends our earlier Pipsqueak proposal for efficient package initialization [38].

In this work, we benchmark various task-provisioning primitives and measure package initialization costs. Prior studies have ported various applications to the lambda model in order to evaluate platform performance [21, 33]. Spillner *et al.* [46] ported Java applications to AWS Lambda to compare performance against other platforms, and Fouladi *et al.* [16] built a video encoding platform over lambdas. Wang *et al.* [50] reverse engineer many design decisions made by major serverless platforms.

There has been a recent revival of interest in sandboxing technologies. Linux containers, made popular through Docker [36], represent the most mainstream technology; as we show herein, the state of the art is not yet tuned to support lambda workloads. OpenWhisk, which uses Docker containers, hides latency by maintaining pools of ready containers [47]. Recent alternatives to traditional containerization are based on library operating systems, enclaves, and unikernels [7, 24, 29, 31, 41, 42].

The SOCK import cache is a generalization of the Zygote approach first used by Android [8] for Java processes. Akkus *et al.* [1] also leverage this technique to efficiently launch multiple lambdas in the same container when the lambdas belong to the same application. Zygotes have also been used for browser processes (sometimes in conjunction with namespaces [12]). We believe SOCK's generalized Zygote strategy should be generally applicable to other language runtimes that dynamically load libraries or have other initialization costs such as JIT-compilation (*e.g.*, the v8 engine for Node.js [25] or the CLR runtime for C# [3, 30]); however, it is not obvious how SOCK techniques could be applied to statically-linked applications (*e.g.*, most Go programs [53]).

Process caching often has security implications. For example, HotTub [27] reuses Java interpreters, but not between different Linux users. Although the Zygote approach allows cache sharing between users, Lee *et al.* [26] observed that forking many child processes from the same parent without calling `exec` undermines address-space randomization; their solution was Morula, a system that runs `exec` every time, but maintains a pool of preinitialized interpreters; this approach trades overall system throughput for randomization.

7. Conclusion

Serverless platforms promise cost savings and extreme elasticity to developers. Unfortunately, these platforms also make initialization slower and more frequent, so many applications and microservices may experience slowdowns if ported to the lambda model. In this work, we identify container initialization and package dependencies as common causes of slow lambda startup. Based on our analysis, we build SOCK, a streamlined container system optimized for serverless workloads that avoids major kernel bottlenecks. We further generalize Zygote provisioning and build a package-aware caching system. Our hope is that this work, alongside other efforts to minimize startup costs, will make serverless deployment viable for an ever-growing class of applications.

DynaMix: Dynamic Mobile Device Integration for Efficient Cross-device Resource Sharing

Dongju Chae[¶] Joonsung Kim[†] Gwangmu Lee[†]

Abstract

In the era of the Internet of Things, users desire more valuable services by simultaneously utilizing various resources available in remote devices. As a result, cross-device resource sharing, a capability to utilize the resources of a remote device, becomes a desirable feature to enable interesting multi-device services. However, the existing resource sharing mechanisms either have limited resource coverage, involve complex programming efforts for utilizing multiple devices, or more importantly, incur huge inter-device network traffic.

We propose DynaMix, a novel framework that realizes efficient cross-device resource sharing. First, DynaMix maximizes resource coverage by dynamically integrating computation and I/O resources of remote devices with distributed shared memory and I/O request forwarding. Second, DynaMix obviates the need for multi-device programming by providing the resource sharing capability at the low level. Third, DynaMix minimizes inter-device network traffic by adaptively redistributing tasks between devices based on their dynamic resource usage. By doing so, DynaMix achieves efficient resource sharing along with dynamic plug-and-play and reconfigurability. Our example implementation on top of Android and Tizen devices shows that DynaMix enables efficient cross-device resource sharing in multi-device services.

1 Introduction

In the era of the Internet of Things, a user can access an increasing number of heterogeneous devices (e.g., smartphones, wearable devices, smart TVs) equipped with diverse, and possibly different, hardware resources (e.g., CPU, memory, camera, screen). As a result, such an environment poses the need for multi-device services which simultaneously utilize the diverse resources of the heterogeneous devices. For instance, when watching movies or viewing PDF files, a user can use a large TV screen rather than a smaller smartphone screen. Also, a user can take pictures from various angles by using multiple remote cameras. In a similar sense, a number of recent studies [33,37,38] develop and demonstrate multi-device services utilizing resources of multiple devices.

However, the existing cross-device resource sharing schemes suffer from several challenges. First, using network libraries explicitly imposes significant programming burden on developers [2, 3, 6] as they should follow a server-client model that involves careful task distribution between server and client processes. Distributed programming platform [54] may reduce the programming burden; however, they still impose the burden of efficiently partitioning an application. Second, code offloading [19, 21, 28] and remote I/O [11] can enable cross-device resource sharing without the programming burden. Unfortunately, neither of them supports all computation (e.g., CPU, memory) and I/O sharing at the same time, which limits their applicability. More importantly, the existing schemes do not optimize the placement of tasks and hence suffer when running on slow wireless networks.

Motivated by the limitations of the existing mechanisms, we need a new cross-device resource sharing mechanism achieving all of the following design goals. First, it should fully integrate the diverse resources of different devices including CPU, memory, and I/O resources. Second, it should achieve good programmability by not exposing any cross-device resource sharing details to the application layer. Third, it should dynamically redistribute tasks between devices to minimize the negative performance impacts of slow wireless networks.

In this paper, we propose **DynaMix**, a novel framework to enable **Dyna**mic **M**obile device **i**ntegration for efficient **cross**-device resource sharing. First, DynaMix fully integrates diverse resources using Distributed Shared Memory (DSM) and I/O request forwarding; DSM integrates CPU and memory, and I/O request forwarding integrates I/O resources. Second, as DSM and I/O request forwarding enable low-level resource sharing below the application level, DynaMix does not demand applications to be aware of multiple devices, achieving good programmability. Third, DynaMix dynamically redistributes tasks between devices in a way that minimizes inter-device communication by monitoring per-device resource usage and inter-device network usage. In addition, DynaMix supports seamless plug-and-play of remote devices by monitoring their connectivity and by taking checkpoints of an application's states.

For evaluation, we implement DynaMix on various Android and Tizen devices (e.g., Google Nexus, Samsung Smart TV). We also introduce three multi-device services to demonstrate the effectiveness of DynaMix: home theater, smart surveillance, and photo classification. The experimental results clearly show that DynaMix enables efficient cross-device resource sharing by fully integrating diverse resources and by dynamically redistributing tasks between devices. For instance, DynaMix achieves the target performance goal of home theater (i.e., 24 FPS when playing HD movies), whereas the existing mechanisms suffer from severe performance degradation (e.g., only 8.2 FPS with request forwarding).

In summary, our contributions are as follows:

- **Novel Platform.** We propose DynaMix, a novel framework to fully integrate remote resources for efficient cross-device resource sharing.
- **High Applicability.** DynaMix can easily be deployed to existing devices, and its low-level resource sharing enables easy programmability.
- **High Performance.** DynaMix minimizes the inter-device communication overheads by dynamically redistributing tasks between devices.
- **High Reliability.** DynaMix supports seamless plug-and-play of remote devices, improving the reliability of multi-device services.

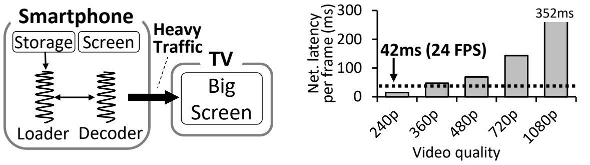
2 Background and Motivation

In the IoT environment, cross-device resource sharing is a promising solution to satisfy various service demands of users who can access an increasing number of heterogenous devices. The users can select favorable resources in different devices, so that they enjoy the same application in different ways depending on their resource configurations.

2.1 Limitations of Existing Schemes

To enable multi-device services, researchers have proposed various resource sharing schemes. We group them into three categories and compare their tradeoffs.

I/O Request Forwarding. The I/O request forwarding is a method to utilize remote I/O resources (e.g., camera, screen, audio, sensor) by forwarding I/O requests to the target device, which then accesses the requested resources on behalf of the requesting device. The request forwarding schemes can forward the I/O requests in different layers (e.g., kernel, platform, user). For example, Rio [11] forwards I/O requests at the kernel level to a remote device which then performs the delivered I/O requests. M+ [43] provides cross-device functionality sharing at the platform level by forwarding IPC messages. Both schemes enable the transparent access to remote I/O resources. On the other hand, user-level [2,3,6] request forwarding schemes make programmers explicitly handle the remote I/O requests.



(a) An example setup

(b) Network latency

Figure 1: An example setup to play a video on a remote screen and network latency to send a single frame

However, the applicability of the existing request forwarding schemes is limited as follows. First, they support only I/O resources for resource sharing[1]. Next, they require carefully-designed abstraction layers to support single-device applications. Furthermore, they can suffer from severe network overheads unless they access resources in an optimized task distribution. Figure 1a shows an example kernel-level request forwarding setup configured to use a remote screen to play a video. Since the local device forwards the decoded frame to the remote screen, it can suffer from the severe communication overhead as the video quality increases. Figure 1b shows that only the lowest resolution quality can barely meet the 24 frames per second (FPS) performance goal. Actually, moving `Decoder` task from the smartphone to the TV would greatly reduce the network overheads as only the small traffic between `Loader` and `Decoder` is exposed. From this example, we can see why the resource-aware task redistribution is important.

Code Offloading and Distributed Computation. The code offloading [19, 21] and distributed computation [28] schemes utilize remote computation resources (e.g., CPU, memory) by offloading performance-critical code regions to more powerful devices. They can not only improve the performance but also save the power consumption of the requesting device by using a faster CPU or exploiting the increased parallelism with more cores. In addition, COMET [28] implements a software-based distributed shared-memory (DSM) framework to support efficient thread offloading among devices.

However, the applicability of the existing code of-

[1] Note that M+ [43] restrictively uses CPU and memory resources for specific platform services.

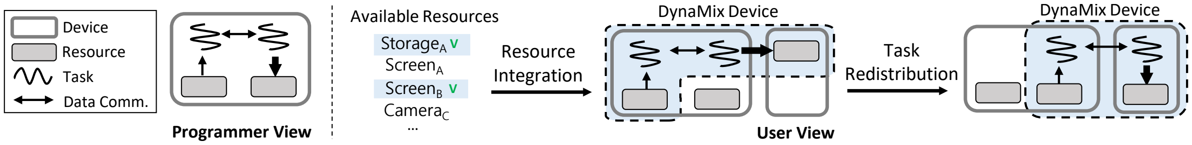


Figure 2: An example workflow of the DynaMix framework. Though programmers develop single-device applications, users can configure their services (i.e., DynaMix devices) by selecting desired resources to access remote resources.

floading schemes is limited as follows. First, they support only computation resources for cross-device sharing, which leaves I/O resources to be wasted. Next, their migration points of non-DSM schemes are restricted to specific function entries, similar to Remote Procedure Calls (RPC). Also, the migrated tasks should eventually go back to the requesting device which restricts the scope of performance-critical task redistributions.

Distributed Programming Platform. A distributed programming platform such as Sapphire [54] is similar to the distributed computation scheme but provides an interface to enable more flexible task migrations. Once the tasks are deployed by the platform-defined unit objects, the platform supports a limited form of task redistributions to reduce the performance overhead.

However, such distributed programming platform suffers from the following limitations. First of all, the resource coverage is still limited to computation resources for cross-device sharing. Next, the scheme leaves the burden of difficult multi-device programming (e.g., device-aware task partitioning, dynamic exception handling) to application developers.

2.2 Design Goals

Motivated by the limitations, we claim that an ideal resource sharing framework must satisfy the following.

High Resource Coverage. The framework should cover both I/O and computation resources for cross-device sharing. Various types of I/O resources enable the framework to provide interesting multi-device services which are infeasible in a single device alone due to its limited capabilities (e.g., device's unsupported resource types and physical location). In addition, sharing computation resources allows an application to run in a more efficient way by distributing its tasks across other devices.

Single-device Application Support. The framework should transparently support single-device applications for multi-device services. Developing multi-device applications [2, 3, 6] using a server-client model often imposes an excessive burden on developers (e.g., statically separated multiple programs). Also, this approach is practically limited toward satisfying users' various demands and developers have to manually handle dynamic behaviors. On the other hand, if the framework transparently supports a single-device application to access remote resources, developers no longer consider how remote resources are accessed. Users create their own service by selecting favorable resources and the framework provides seamless mechanisms to access them, significantly reducing the programming burden.

Resource-aware Task Redistribution. The framework should minimize the inter-device communication overhead with dynamic inter-device task redistributions. The communication overhead incurred by the remote access highly depends on dynamic factors, such as the reconfiguration of the resource sharing, the available network bandwidth, and runtime behaviors of tasks in an application. Therefore, it is important to adaptively redistribute tasks to the optimal devices to minimize the overhead.

3 DynaMix Framework

3.1 Overview

Figure 2 shows an example workflow of DynaMix framework. First, programmers develop DynaMix applications. To reduce the burden of the programmers, DynaMix requires neither any special programming concepts nor special APIs except the underlying memory consistency model described in §4.1. Therefore, programmers can write ordinary multi-threaded programs on a single device with multi-thread libraries without concerns about remote resources. This single-device programming model of DynaMix makes developing new applications and porting existing applications easy. Second, users can select desired resources (e.g., Storage_A and Screen_B in Figure 2) to execute DynaMix applications at runtime. DynaMix framework dynamically integrates the selected resources and constructs a single virtual device called a *DynaMix device*. Third, DynaMix detects the network traffic and automatically redistributes tasks across the devices to minimize the network overhead. Within the DynaMix device, tasks (i.e., threads) of the DynaMix applications can freely access remote resources or be migrated for the optimal task redistribution.

3.2 DynaMix Operations

DynaMix framework has two basic operation models: *remote resource integration* and *resource-aware task redistribution*. To support the operations, users should first make their devices DynaMix-enabled by installing two software components on each device: *resource integrator* and *thread migrator*. The resource integrator integrates both computation and I/O resources (or constructs a DynaMix device) by applying a distributed shared

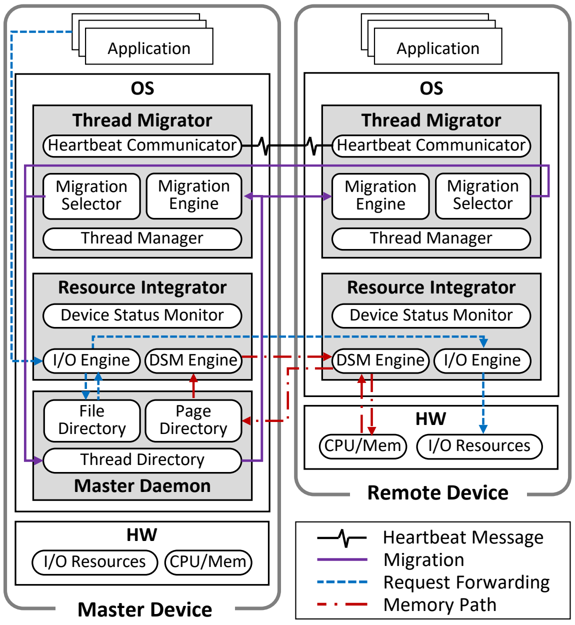

Figure 3: DynaMix architectural overview

memory (DSM) model and I/O request forwarding together (§3.2.1). The thread migrator monitors both inter-thread communication and device connectivity, and dynamically redistributes threads to their optimal locations to minimize the communication overhead (§3.2.2).

3.2.1 Remote Resource Integration

The resource integrators installed on each device collaboratively apply a DSM model and a kernel-level I/O request forwarding to integrate both computation (e.g., CPU, memory) and I/O (e.g., display, storage) resources. This mechanism enables DynaMix to satisfy two design goals of ideal resource sharing: **single-device programming model** and **high resource coverage**.

The resource integrator performs the integration in three steps. First, the resource integrator collects the information of remote resources (e.g., CPU frequency, memory size, I/O type), broadcasted by remote resource integrators, and makes the resources available for user applications. Second, if an application tries to use a remote resource, the resource integrator forwards the request to the target resource integrator. Third, the target resource integrator delivers the outcome to the application through the shared memory for computation results or through forwarding for I/O results.

3.2.2 Resource-aware Task Redistribution

With only the I/O request forwarding, DynaMix can incur severe inter-device communications. Therefore, DynaMix applies a resource-aware task redistribution mechanism by adaptively migrating threads to the optimal devices in a way to minimize the overall inter-device traffic. This mechanism satisfies the design goal of **resource-aware task redistributions**.

The resource integrator and the thread migrator work together to enable task redistributions as follows. First, the resource integrator monitors per-thread resource usage (e.g., CPU, network) to detect possible resource contentions. Second, on detecting a contention, the thread migrator compares tradeoffs of various thread allocation scenarios, and finds the best one. Third, the thread migrator migrates threads based on the scenario by delivering their execution contexts to the target devices.

4 Implementation

This section describes how we implement the aforementioned core components (*resource integrator* and *thread migrator*) and a newly introduced *master demon* component to correctly orchestrate operations. The master daemon runs on a failure-free master device on which a user launches applications. Note that we regard failures in the master device as user-intended ones such as device shutdown. Figure 3 illustrates the overall architecture.

4.1 Resource Integrator

The resource integrator consists of three components: a DSM engine, an I/O engine, and a device status monitor. The DSM and I/O engines integrate computation and I/O resources, respectively, and the device status monitor detects intra-device resource contentions.

4.1.1 DSM Engine

The DSM engine integrates the memory regions of multiple devices into a single memory space in a DSM manner. On receiving a memory access request, the DSM engine either delivers its local memory data or forwards a request to the destination DSM engine owning the data. It also works with the master daemon to orchestrate these communications for globally consistent memory management (§4.3.2). The DSM engine applies three performance optimizations as follows. First, it adopts a lazy release consistency (LRC) model [32] to safely delay memory synchronization within acquire-release block, similar to previous work [27,28]. Second, it actively performs memory prefetches on detecting sequential memory access patterns. Third, it uses a page-level coherence block to reduce the coherence overheads.

To support the page-level DSM, the DSM engine leverages a page fault handler in Linux kernel which manages page permissions. When an application enters a critical section (i.e., lock acquire), the DSM engine disables write permissions of all shareable pages in the target application. In this way, the DSM engine can detect the page modifications during a critical section. On the exit of the critical section (i.e., lock release), it recovers the write permissions. Due to the LRC model, the memory transfer of the modified pages occurs only when another device newly acquires the same lock, which minimizes unnecessary network communications.

To further reduce the network traffic, the DSM engine transfers only the updated contents called *diffs*. On a lock release, the DSM engine generates diffs by comparing the contents of original and modified pages. When another device acquires the same lock, its DSM engine receives the corresponding diffs from the previous lock holder and applies them into the original pages.

4.1.2 I/O Engine

The I/O engine manages the access to local and remote I/O resources through kernel-level request forwarding. For the purpose, the I/O engine provides a *device file* boundary for cross-device I/O sharing similar to previous approaches [10, 11]. Mobile platforms with the Linux kernel base (e.g., Android, Tizen) use device files as their I/O abstraction layer because such files are device-agnostic. In this way, DynaMix can support a wide spectrum of I/O resources. To forward incoming requests from the host to a remote target device, the I/O engine intercepts I/O-related system calls (e.g., *open*, *read*, *write*, *ioctl*) and delivers them to the remote device with their input parameters. The remote device then performs the forwarded requests and returns the results to the host. The I/O engine also cooperates with a platform to allow users to access remote I/O resources transparently.

For example, to access audio peripherals (e.g., speaker, microphone) on a remote device, the I/O engine creates virtual device files corresponding to device files for audio peripherals (e.g., `/dev/snd/pcmCxDxx`, `/dev/snd/control`). The host I/O engine transfers requests coming through a virtual device file to the remote I/O engine which executes the requests with the corresponding original device file. Note that an audio Hardware Abstraction Layer (HAL) library (e.g., tinyalsa) is modified to access virtual device files instead of original device files. In this way, DynaMix applications can transparently access the remote audio peripherals.

Unfortunately, such kernel-level request forwarding does not directly support some I/O resources (e.g., a screen, file system) that require special management. For example, to display frame data from a frame buffer (`/dev/graphics/fb0`) in the host, the remote I/O engine should cooperate with graphics APIs in a platform to follow the existing graphics stack (i.e., SurfaceFlinger). In particular, to access a file on a remote storage, the I/O engine works with the master daemon which keeps a file directory containing the file metadata. Therefore, devices joining the DynaMix device should upload their file metadata information to the shared file directory. On receiving a file access request, the I/O engine first checks the local file directory. If the file does not exist, the I/O engine asks the master daemon to find the location in the shared file directory and forwards the request to the owner device.

4.1.3 Device Status Monitor

The device status monitor periodically collects various system information (e.g., per-thread CPU utilization, network stall time) to detect CPU and network contentions. The device status monitor is implemented as a kernel thread, which enables more accurate resource monitoring. It detects CPU contentions when CPUs are fully utilized but each thread has low CPU utilization without the existence of other bottlenecks (e.g., no I/O wait). On the other hands, it detects network contentions when the stalled time due to remote I/O accesses or memory synchronization exceeds a pre-defined threshold [2] (e.g., 30% in our environment). On detecting such contentions, the device status monitor immediately notifies the master daemon to initiate thread redistributions.

4.2 Thread Migrator

The thread migrator consists of four components: a thread manager, a migration selector, a migration engine, and a heartbeat communicator.

4.2.1 Thread Manager

The thread manager preserves various information of running threads such as execution states, resource usage, and locks. On resource contentions, the thread manager calculates threads' data communications[3] (i.e., thread-to-thread and thread-to-resource) and sends the results to the migration selector which determines the best victim for migration and its destination device. The thread manager also implements kernel-level locks to synchronize threads across different devices. Note that we modify a user-level multi-thread library (e.g., POSIX) to access these locks internally. The thread manager checks with the master daemon before allowing a thread to acquire a lock. The master daemon then forces the prior lock holder to transfer the updated memory within the acquire-release block, following the LRC model.

For reliable execution, the master thread manager keeps execution contexts of the migrated threads as a *checkpoint*, so it can consistently recover missing threads for an unintended device disconnection. After the checkpoint is created, non-migrated threads in the same application update memory pages in a copy-on-write manner to maintain original contents of shared pages. The checkpoint is updated only when the size of copied data exceeds a threshold (e.g., 20% of total memory size). As

[2] This conservative detection using the static threshold works well in DynaMix because the migration selector (§4.2.2) considers the trade-offs of all candidates and eventually decides the best migration target.

[3] DSM and I/O engine provide the information of data communications. The profiling overhead of each engine is typically insignificant because DSM engine measures the communication only in critical sections and I/O engine merely records the size of transferred data.

Algorithm 1: Migration Selector

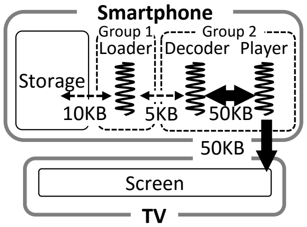
```
input    : the analyzed data communication result, $C$.
input    : a set of local threads, $threads_{local}$.
input    : a set of remote devices, $devices$.
output   : a tuple of a migration victim thread group to recommend,
           its destination device, and the network gain.
/* Construct thread groups                                  */
$tgroups = [[T]$ for $thread\ T$ in $threads_{local}]$
do
    /* Compare the amount of inter-thread comm.             */
    foreach $(tg1, tg2)$ where $tg1, tg2 \in tgroups$ do
        if $communication(tg1, tg2, C) > D_{thre}$ then
            $merge\_groups(tg1, tg2, tgroups)$
        end
    end
while $tgroups\ changed$;
/* Find a victim thread group and a destination device
   that yields the largest network gain                     */
$(victim\_tg, dest\_dev, max\_gain) = (null, null, 0)$
foreach $tg \in tgroups$ do
    /* Consider devices with enough idle CPU BW             */
    foreach $dev \in possible\_devices(tg, devices)$ do
        $net\_gain = estimate\_net\_gain(tg, dev, C)$
        if $net\_gain > max\_gain$ then
            $(victim\_tg, dest\_dev, max\_gain) = (tg, dev, net\_gain)$
        end
    end
end
return $(victim\_tg, dest\_dev, max\_gain)$
```

the threshold can affect memory pressure on a device, it is experimentally decided by considering an available memory size not to hurt other applications' performance.

4.2.2 Migration Selector

With the information delivered by a thread manager, the migration selector determines the best victim thread for migration and its destination device. The estimation relies on recent access patterns of an application with the assumption that similar behaviors appear in the near future. This assumption is reasonable in DynaMix's target applications which mainly access remote resources (e.g., repeatedly accessing a remote screen or camera) unless a user changes the resource configuration. The migration selector determines the best victim thread for migration and its destination device, and notifies the information to the master daemon as *migration recommendation*. Algorithm 1 describes how the migration selector finds the migration recommendation.

The migration selector first groups tightly coupled threads as a *thread group* which is a minimal migration unit. Such grouping simplifies the selection process and prevents unnecessary migration initiations. The algorithm sets threads as a thread group if their inter-thread communication amount is larger than a predefined threshold (D_{thre}). Next, it finds the best victim group and its destination device in a way to maximize the network overhead reduction, *network gain*. Note that the selected victim group is temporarily excluded in the next target selection during a specific time period to avoid frequent migration invocations on the same group. The time period is extended using exponential backoff.



(a) Thread grouping

Status	Value
$CPU_{\mathtt{thread}}$	30%
$idle_{tv}$	70%
$Perf_{tv,phone}$	0.9
$NAcq_{\mathtt{load,dec}}$	10
$lat_{tv,phone}$	0.01s
$BW_{tv,phone}$	100KB/s

(b) Device status

Thread Placement	T_{ct}	T_{dt}	T_{gain}
Group 1 on TV	-0.1 s	-0.15 s	-0.25 s
Group 2 on TV	-0.1 s	0.45 s	0.35 s

(c) Network gain estimation

Figure 4: Migration victim and destination selection

The destination device should have idle CPU bandwidth enough to accommodate the migrated threads. To consider the different CPU performance of devices, the algorithm uses a scaling factor, $Perf_{dest,source}$. For example, if $Perf_{dest,source}$ is 0.9, the destination device's CPU is slower than the source's CPU by 10%.

Calculating the network gain. The network gain T_{gain} quantifies how much the thread migration will improve the network performance in terms of the latency to transfer control messages (T_{ct}) and data (T_{dt}): $T_{gain} = T_{ct} + T_{dt}$.

A lock-acquire operation is the most critical source of the control messages, and each one incurs a three-hop latency (§4.2.1). The latency between thread i and j is the number of acquire operations ($NAcq_{i,j}$) times the three-hop latency between them ($lat_{D(i),D(j)}$), where $D(i)$ and $D(j)$ indicate the devices running thread i and j. Therefore, the total transfer latency is $\Sigma_{i \in tg} \Sigma_{j \in tcom} NAcq_{i,j} \times lat_{D(i),D(j)}$, where tg is the thread group and $tcom$ is a set of communicating threads. Then, the network gain of control message transfer, T_{ct}, is the latency difference due to the migration to the destination, dst:

$$T_{ct} = \sum_{i \in tg} \sum_{j \in tcom} NAcq_{i,j} \times (lat_{D(i),D(j)} - lat_{dst,D(j)})$$

The data transfer latency gain can also be calculated in a similar manner. If $D_{i,j}$ is the size of transferred data between thread i and j, and $BW_{Di,Dj}$ is the network bandwidth between them, the data transfer latency is $D_{i,j}/BW_{Di,Dj}$. Then, the network latency gain of data transfer, T_{dt}, is the latency difference due to the migration to the destination, dst:

$$T_{dt} = \sum_{i \in tg} \sum_{j \in tcom} (D_{i,j}/BW_{D(i),D(j)} - D_{i,j}/BW_{dst,D(j)})$$

Example Victim/Destination Selection Scenario. We illustrate example operations of the migration selector. Figure 4a shows the data communication status collected by the thread manager, and Figure 4b shows the status of devices collected by the device status monitor and the heartbeat communicator. Figure 4a also shows two thread groups, where the `Loader` and the `Decoder` thread are allocated in the same group because they heavily communicate each other. As the TV has enough idle CPU bandwidth ($70\% \times 0.9 = 63\%$) to accommodate either thread group (30% for Group 1, $30\% \times 2 = 60\%$ for Group 2), both groups can be migrated to the TV. Next, the migration selector compares the network gains of migrating either thread group (Figure 4c), and reports the best group and destination (i.e., Group 2 and TV) to the master daemon.

4.2.3 Migration Engine

After the migration selector decides the victim threads (i.e., thread group) and its destination device, the migration engine eventually performs a thread migration. DynaMix supports a low-overhead migration by adopting thread cloning and live migration. It minimizes the downtime, a suspended time period during migration, by transferring essential pages in a short time.

First, the source device sends only the memory layout (e.g., heap, stack) of the victim threads to the destination device which then creates their clone threads suspended during the migration. Next, for a short period (e.g., 2 secs), the migration engine transfers the most recently accessed pages (e.g., using the LRU-based page cache in Linux kernel) to the destination device, while the victim threads run on the original device. Using write permission faults (similar to §4.1.1), the migration engine detects and records the updated pages during the memory transfer. After finishing (i.e., timeout) the memory transfer, it sends the victim thread's execution context (e.g., process control blocks) with the updated pages in the meanwhile. This transparent live migration (similar to [20]) effectively hides the migration latency and minimizes the service downtime. Finally, the clone threads continue their execution on the destination device after the victim threads are suspended on the original device.

4.2.4 Heartbeat Communicator

For dynamic resource integration, DynaMix supports seamless operations whiles devices are plugged in and out. The heartbeat communicators periodically exchange heartbeat messages to check the device connectivity and share their resource status (e.g., CPU idleness, network latency, bandwidth). The resource status information is then delivered to the migration selector. Note that the inter-device network latency can be estimated from the round-trip latency of heartbeat messages.

The heartbeat communicator can detect which remote device joins or leaves a DynaMix device. For a newly joined device, its heartbeat communicator broadcasts heartbeat messages. On receiving the message, the master daemon enlists the new device in the DynaMix device. The heartbeat communicator also detects unstable devices by monitoring the connectivity (e.g., the number of packet drops). If a device becomes unstable, the heartbeat communicator notifies the master daemon to initiate migrating the threads in the device to more stable devices to avoid thread recovery that may cause the loss of the overall progress. For an unexpected disconnection. the master heartbeat communicator notifies the thread manager to recover from the latest checkpoint (§4.2.1).

4.3 Master Daemon

A DynaMix device has a single master daemon[4] that manages various system states (e.g., threads, locks, memory pages, files) to orchestrate DynaMix operations and components. The master daemon runs on the failure-free master device, and consists of three components: a thread directory, a page directory, and a file directory.

4.3.1 Thread Directory

The thread directory manages the global states of threads such as thread locations, and arbitrates the thread migration process. It collects resource contention signals from the device status monitors, and migration recommendations from the migration selectors. On receiving recommendations, the thread directory selects the best migration victim and its destination to achieve the highest network gain, and then manages the migration engines to perform the designed migrations.

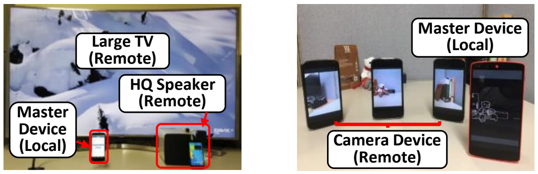
The thread directory also keeps the lock information (e.g., current owner, status). To acquire a lock, each device should consult the master device's thread directory. To reduce the lock acquisition overhead, the thread directory can speculatively grant the lock to frequent lock holding devices. When another device attempts to acquire the lock, the thread directory reclaims the speculatively given lock. Note that when a device is disconnected, the thread directory immediately reclaims all locks held by the device to avoid a deadlock.

4.3.2 Page Directory

The page directory manages the sharing state of memory pages to orchestrate memory synchronization operations. When a device sends a remote read request due to a page fault, the page directory consults a sharer table which keeps the sharer device lists of each page. It then relays the request to one of the sharer devices which will deliver the page to the requesting device.

On a lock release, the lock owner device reports the address list of updated pages to the page directory. In this way, the page directory identifies which pages should be sent to the next owner. When another device acquires the lock, the page directory manages its prior owner to forward the updated pages or their diffs if the new owner has old copies. Note that the transfers of shared pages

[4] Such a centralized approach enables easy management but might limit scalability. We believe that composing multiple DynaMix devices rather than a single large one is much preferable in our scenarios.



(a) Home Theater (b) Smart Surveillance

Figure 5: Two example DynaMix applications

mostly occur when a device newly acquires a lock due to LRC memory model.

4.3.3 File Directory

The file directory manages the file metadata and the physical locations of shared files for the globally consistent file view. Whenever a new device joins the DynaMix device or a device updates the metadata, the master daemon updates its file directory and then notifies the updated information to other devices. Note that except the device which owns a file, each device holds the file's read-only copy in memory.

5 Evaluation

5.1 Experimental Setup

We implemented our example DynaMix prototype which can be easily installed on top of existing Android and Tizen devices. For our evaluation, we installed DynaMix on Google Nexus smartphones (i.e., Nexus 4 and 5) and an in-house Samsung Smart TV. The smartphones run Android 5.1.1 (CyanogenMod 12.1) with Linux kernel version 3.4 patch, and the Samsung Smart TV runs Tizen 2.3 with Linux kernel version 3.0 patch. All devices are connected to the same Wi-Fi network (IEEE 802.11ac) with the maximum bandwidth of 100Mbps.

To evaluate the DynaMix prototype, we introduce three example multi-device use cases (i.e., home theater, smart surveillance, and photo classification) designed to utilize both computation and I/O resources simultaneously. We believe users can easily make other interesting services using our framework.

Home Theater. The home theater is a typical multi-threaded movie player application which loads and decodes a movie file from a storage, shows the video on a screen, and plays the audio through a speaker. DynaMix allows users to configure resources (e.g., a large TV, an HQ speaker) used to run the home theater. Figure 5a shows the example home theater setup with three devices. We used FFmpeg [4] to decode video and audio frames. Here, the home theater plays a movie with both video and audio frames synchronized.

Smart Surveillance. The smart surveillance is another possible service that performs image processing (e.g., edge detection) with preview images from a remote camera. Figure 5b shows the example smart surveillance setup using four devices. A processing thread performs edge detection on preview images from a selected camera device, and a UI thread displays the processed image on the screen. We used the Canny edge detection algorithm [16] to detect moving objects in the service.

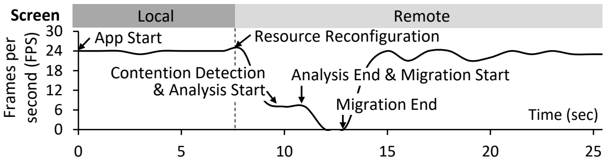


Figure 6: Perf. timeline of the home theater application

Photo Classification. Lastly, integrating storage resources enables a shared storage system across devices where users can observe scattered remote files (e.g., photos, videos) in the same hierarchy and easily access them at any device. To evaluate the storage system, we perform object classifications for photos scattered in the connected devices. For the purpose, we used an object classifier with the pre-trained CNN model (SSD_MobileNet [31]) using a TensorFlow [9] library. Each thread classifies its assigned photos with the classifier and reports the results to the collector thread.

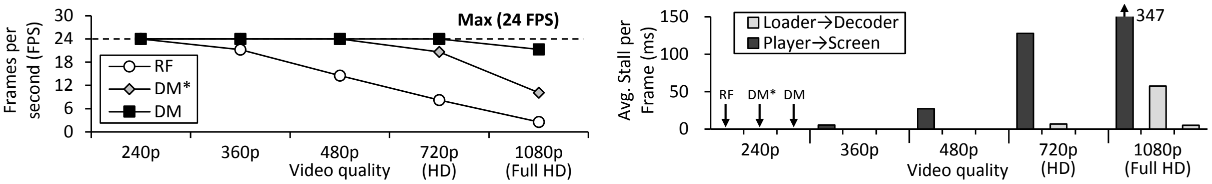
5.2 Operation Models

This evaluation revisits the basic operation models of DynaMix in §3.2. We use the multi-threaded home theater with loader, decoder, and player threads. It runs on the DynaMix device (Figure 5a) configured with a Samsung Smart TV as the remote screen, an HQ speaker attached to Nexus 4 as the remote audio, and a Nexus 5 smartphone as the master device. We play an HD (720p) movie and measure its frames per second (FPS).

Figure 6 shows its performance timeline. When the user initially plays a movie on the master device, the home theater displays video frames on the local smartphone screen with the target performance of 24 FPS. However, after the user suddenly switches the screen device to the remote TV (8 sec), it suffers from significant FPS drops due to the huge network traffic caused by forwarding HD video frames to the TV. Therefore, DynaMix immediately detects a network contention (10 sec), decides the best task redistribution plan (11 sec), and migrates the video decoder and player threads to the TV (13 sec). Although the performance temporarily degrades due to the increased network consumption caused by the migration, DynaMix quickly restores the target performance (14 sec) with a negligible service downtime. This experiment verifies that DynaMix enhances the service quality with resource-aware task redistribution even in the sudden resource reconfiguration.

5.3 Service Quality

We now evaluate three use cases (i.e., home theater, smart surveillance, and photo classification) to verify that



(a) Throughput (FPS)

(b) Frame-average network stall time

Figure 8: The smart surveillance performance for Request Forwarding (RF) and DynaMix (DM)

DynaMix significantly enhances the service quality. To show the benefit of resource-aware task redistribution, we compare DynaMix with Request Forwarding (RF) as a representative baseline because its resource sharing mechanism conceptually includes the state-of-the-art work (e.g., Rio [11]), which accesses a remote resource and receives the result via a wireless network. We also evaluate DynaMix without memory prefetching.

Home Theater. We configure a DynaMix device as explained in §5.2, and measure the throughput (i.e., frames per second) of the home theater on the DynaMix device. RF forwards decoded frames to the remote device because all threads run on the master device.

Figure 7a compares the throughput (FPS) of the home theater for RF and DynaMix. While RF suffers from increasing throughput degradations with the target video quality improved, DynaMix successfully achieves the target throughput up to the decent quality (480p) even without memory prefetching. Enabling the prefetching further enhances the throughput, which makes DynaMix achieve the throughput close to the maximum for the full HD quality (1080p). DynaMix achieves 8.3x higher throughput than RF, while paying only 11% performance drop from the maximum throughput for 1080p.

Figure 7b compares the network stall time of three design points to process a video frame for the various video qualities. The network stall time means how much network traffic affects the per-frame latency, and helps to clearly investigate why RF suffers from the low throughput. First, RF incurs severe network traffic to transfer a decoded frame between the player thread and the remote TV screen even for a relatively inferior quality (360p). Moreover, RF suffers from a huge amount of network stall as the video quality increases. On the other hand, as DynaMix can migrate the video decoder and player threads to the TV, the loader thread on the master device can timely transfer small-sized encoded frames to the decoder threads on the TV. As a result, DynaMix effectively hides the network stall up to 480p, and applying the memory prefetching further amortizes the network overheads (i.e., near-zero network stall for 1080p).

Smart Surveillance. We configure a DynaMix device to use a Nexus 5 device as a master device with a screen, and three Nexus 4 devices as remote cameras, as shown in Figure 5b. As this application allows a user to select a target remote camera, we randomly choose one camera as the current input feeder. RF receives preview images from the remote camera because a processing thread runs on the master device. We now assume that DynaMix is equipped with memory prefetching by default.

Figure 8a compares the throughput (FPS) of the smart surveillance for RF and DynaMix. While RF suffers from significant throughput degradation with the preview resolution increased, DynaMix retains moderate performance drop as only 24.7% compared with the target throughput for the highest preview resolution (720x480). Figure 8b shows the breakdown of the average latency in detecting edges of a preview image. After analyzing the tradeoff, DynaMix migrates the edge-detector threads to the camera devices to avoid the network contention. As a result, it achieves far less network latency than forwarding raw preview images from the camera to the master device. Note that the computation still occupies a significant portion of the total latency due to the lack of sufficient computation resources. This result suggests deploying faster CPUs on remote cameras so that DynaMix can completely remove the computation overhead.

Photo Classification. We configure a DynaMix device to use up to four Nexus 5 smartphones to construct the shared storage system. Each device has 100MB of photos with different sizes ranging from 4KB to 10MB. A user can choose the number of classifier threads and

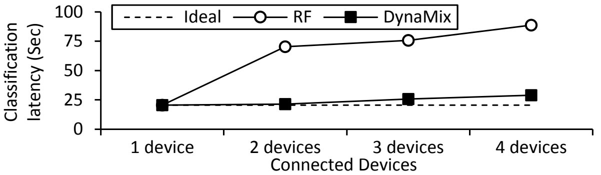

Figure 9: The total latency of the photo classification for all photo files on the shared storage system

	Remote File Size (B)				
	<10K	<100K	<1M	<5M	≤10M
RF (%)	87.8	64.4	33.3	13.9	0
Mig. (%)	12.2	35.6	66.7	86.1	100

Table 1: DynaMix's request forwarding (RF) vs. migration (Mig.) ratio on the photo classification

would launch threads in proportion to the total size of photos. In our four-device configuration, we assume that four threads classify total 400MB of photos.

We then measure the latency to perform the classification for all photos, and compare the performance of RF and DynaMix. We also mark the ideal performance to identify the bottleneck. We assume that the ideal one classifies all files on the remote devices without any network overheads. Note that RF forwards remote files to the threads running on the master device.

Figure 9 compares the performance of the total classification latency. As the number of connected devices increases, RF suffers from high latency due to the increasing network overheads incurred by forwarding remote files to the classifiers. On the other hand, DynaMix is barely affected by the network overheads and thus achieves the latency close to the ideal one, even for the four-device configuration. It is because DynaMix dynamically redistributes the threads across devices to minimizes the network overheads.

Furthermore, DynaMix can dynamically use either of request forwarding and the adaptive task migration, based on their tradeoffs. Note that the migrated threads should use request forwarding during a certain time period to prevent frequent migrations (§4.2.2). To emphasize the point, Table 1 shows the percentage of the two cases in the four-device configuration. DynaMix is likely to use the request forwarding more for small files (i.e., <100KB) to avoid the migration overhead, whereas it is likely to migrate threads for large-sized files (i.e., >1MB) to avoid the transfer overhead.

5.4 Network Sensitivity

To identify the performance impact for a given network bandwidth, we measure the performance of the home theater by playing an HD movie on RF and DynaMix. For this experiment, we vary the available bandwidth with Linux `tc` utility, and measure the average FPS as the performance metric.

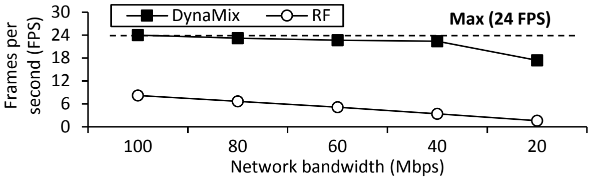

Figure 10: The home theater performance on various network bandwidth to play an HD video

	Average Power (mW)		
	Master Device	Screen Device	Total
RF	4985.90	5151.37	10137.27
DynaMix	2956.55	6480.51	9427.06

Table 2: The power consumption of the home theater for Request Forwarding (RF) and DynaMix

Figure 10 shows that RF severely suffers from its performance drops even with the maximum network bandwidth available (100Mbps) and further as the network bandwidth decreases. On the other hand, DynaMix maintains the target 24 FPS with only 40Mbps of bandwidth available. This result indicates that DynaMix effectively minimizes the network overhead by adaptively redistributing tasks among devices.

5.5 Power Consumption

In this experiment, we measure the power consumption of DynaMix while playing an HD movie clip, and compare it against RF. To measure the impact of inter-device traffic reduction, we use two Nexus 5 smartphones as a master device and a screen device. We use Monsoon power monitor [5] to measure the power consumption.

Table 2 measures the power consumption of the devices. First, the master device consumes much less power with DynaMix than RF by migrating a rendering task to the remote device and thus reducing the network traffic. On the other hand, the screen device consumes little more power with DynaMix than RF by running a relocated rendering task. As a result, DynaMix reduces the total power by 7% mainly due to the reduced network overhead. More importantly, as DynaMix's service quality (or performance) is 3-4 times higher than RF (Figure 10) and their power consumptions are similar (Table 2), DynaMix's overall energy efficiency can be considered 3-4 times higher for the target service quality. For further energy reduction, DynaMix may redistribute tasks in a way to maximize the energy efficiency.

6 Discussion

Heterogeneous ISA/OS. One interesting issue related to our work is to extend the coverage of architecture and operating system used by DynaMix devices. However, it is a well-known challenge to seamlessly share resources in heterogeneous devices using different ISAs and OSes. Therefore, existing work often assume either homogeneous ISA/OS [11,43] or expensive VM supports to emulate the homogeneous platform [19,21,28].

In this work, DynaMix also assumes homogeneous ISA/OS environments for the most popular mobile platform (i.e., Andriod/ARM). However, we showed that its OS coverage can be easily extended to Tizen which shares the Linux kernel base. To improve the platform coverage further, we believe that the following directions seem to be promising. For non-Linux based OSes (e.g., iOS), DynaMix may implement a compatibility layer between kernel and application by taking approaches similar to existing OS-compatibility schemes [8,12]. To support cross-ISA (e.g., ARM to x86) migrations, DynaMix may implement a native offloading using the compiler-assisted method [39] or dynamic binary translation [51].

Developing DynaMix Applications. To fully utilize DynaMix's resource-aware task redistribution, programmers are recommended to compose applications with multiple threads, specialized in certain computing jobs or I/O resource accesses. We believe this guideline is not burdensome to programmers, as many recent programming conventions also recommend similar guidelines for optimal performance [1, 7]. To further accommodate easy application development, DynaMix may adopt existing automatic code parallelization techniques [34, 40, 49] to maximize the effectiveness of resource-aware task redistribution without additional programming effort.

Security Concerns. Another assumption of this work is that a user shares resources in only user-owned trusted devices, as existing schemes such as task offloading [19, 21, 28] and remote IO forwarding [11]. In fact, resource sharing with untrusted devices is not common scenarios that DynaMix considers. Therefore, the security issues related to untrusted devices are beyond the scope of our work. However, we believe that DynaMix can resolve such security issues by adopting existing secure task-offloading schemes [26,42,45,47], without a noticeable increase in complexity.

7 Related Work

Cross-device Resource Sharing. Single system image (SSI) [17, 18, 25] is traditional work to integrate resources by creating one single system with a cluster of machines connected to a fast and stable wired network. However, its complex operations and huge synchronization overheads are not suitable to the mobile environment with limited communication capabilities. Thus, similar studies in mobile computing have focused on how to selectively integrate remote resources. For example, offloading schemes [19,21,28] offload compute-intensive tasks to powerful servers, even for heterogeneous ISAs [39, 51]. Solutions to utilize other resources such as GPU [22], screen [14], storage [23, 44, 46], generic I/O resources [11] and platform-level services [43] have also been proposed. While they only support specific types of resources, DynaMix integrates a wide spectrum of computation and I/O resources. On the other hand, some studies [50, 53] have optimized spectrum utilization sharing in cellular networks. Such techniques are orthogonal to our work but we can adopt them to more efficiently communicate between devices.

Multi-device Programming Platform. To facilitate easy application development in the multi-device environment, [54] allows programmers to develop unit objects and automatically deploys them across devices. [27] also provides a DSM platform and APIs for multi-device applications. Such platforms, however, still force programmers to explicitly partition applications with special APIs. [24] provides a control interface to access various home appliances with unified APIs, but it does not distribute tasks for efficient resource utilization. DynaMix, on the other hand, enables task redistributions of single-device applications for multi-device services, without explicit application partitioning.

Thread Migration. The thread migration is a widely supported feature in distributed computing platforms [13,41,52,55]. Especially, to reduce a service downtime during migration, various VM platforms [15,29,36] have implemented the pre-copy [20] or the post-copy [30,35] live migrations, depending on the timing to send execution contexts. DynaMix also applies such live migration schemes to our environment. Researchers have proposed an online thread distribution algorithm [48] to minimize inter-thread network overheads. However, DynaMix resolves CPU contention as well as network contention, optimized to the mobile environment.

8 Conclusion

In the era of the Internet of Things, a user can access an increasing number of heterogeneous devices. We proposed DynaMix, a novel framework to enable efficient cross-device resource sharing by integrating diverse resources and dynamically redistribute tasks. Our example implementation on the top of Android and Tizen devices showed that DynaMix can efficiently support multi-device services using single-device applications.

The Battle of the Schedulers: FreeBSD ULE vs. Linux CFS

Abstract

This paper analyzes the impact on application performance of the design and implementation choices made in two widely used open-source schedulers: ULE, the default FreeBSD scheduler, and CFS, the default Linux scheduler. We compare ULE and CFS in otherwise identical circumstances. We have ported ULE to Linux, and use it to schedule all threads that are normally scheduled by CFS. We compare the performance of a large suite of applications on the modified kernel running ULE and on the standard Linux kernel running CFS. The observed performance differences are solely the result of scheduling decisions, and do not reflect differences in other subsystems between FreeBSD and Linux.

There is no overall winner. On many workloads the two schedulers perform similarly, but for some workloads there are significant and even surprising differences. ULE may cause starvation, even when executing a single application with identical threads, but this starvation may actually lead to better application performance for some workloads. The more complex load balancing mechanism of CFS reacts more quickly to workload changes, but ULE achieves better load balance in the long run.

1 Introduction

Operating system kernel schedulers are responsible for maintaining high utilization of hardware resources (CPU cores, memory, I/O devices) while providing fast response time to latency-sensitive applications. They have to react to workload changes, and handle large numbers of cores and threads with minimal overhead [12]. This paper provides a comparison between the default schedulers of two of the most widely deployed open-source operating systems: the Completely Fair Scheduler (CFS) used in Linux, and the ULE scheduler used in FreeBSD. Our goal is *not* to declare an overall winner. In fact, we find that for some workloads ULE is better and for others CFS is better. Instead, our goal is to illustrate how differences in the design and the implementation of the two schedulers are reflected in application performance under different workloads.

ULE and CFS are both designed to schedule large numbers of threads on large multicore machines. Scalability considerations have led both schedulers to adopt per-core runqueues. On a context switch, a core accesses only its local runqueue to find the next thread to run. Periodically and at select times, e.g., when a thread wakes up, both ULE and CFS perform load balancing, i.e., they try to balance the amount of work waiting in the runqueues of different cores.

ULE and CFS, however, differ greatly in their design and implementation choices. FreeBSD ULE is a simple scheduler (2,950 lines of code in FreeBSD 11.1), while Linux CFS is much more complex (17,900 lines of code in the latest LTS Linux kernel, Linux 4.9). FreeBSD runqueues are FIFO. For load balancing, FreeBSD strives to even out the number of threads per core. In Linux, a core decides which thread to run next based on prior execution time, priority, and perceived cache behavior of the threads in its runqueue. Instead of evening out the number of threads between cores, Linux strives to even out the average amount of pending work.

The major challenge in comparing ULE and CFS is that application performance depends not only on the scheduler, but also on other OS subsystems, such as networking, file systems and memory management, which also differ between FreeBSD and Linux. To isolate the effect of differences between CFS and ULE, we have ported ULE to Linux, and we use it as the default scheduler to run all threads on the machine (including kernel threads that are normally scheduled by CFS). Then, we compare application performance between this modified Linux with ULE and the default Linux kernel with CFS.

We first examine the impact of the per-core scheduling decisions made by ULE and CFS, by running applications and combinations of applications on a single core, We then run the applications on all cores of the machine, and study the impact of the load balancer. We use 37 applications ranging from scientific HPC applications to databases. While offering similar performance in many circumstances, CFS and ULE occasionally behave very differently, even on simple workloads consisting of one application running one thread per core.

This paper makes the following contributions:

- We provide a complete port of FreeBSD's ULE scheduler in Linux and release it as open source [21]. Our implementation contains all the features and heuristics used in the FreeBSD 11.1 version.
- We compare the application performance under the ULE and CFS schedulers in an otherwise identical environment.
- Unlike CFS, ULE may starve threads that it deems non-interactive for an unbounded amount of time. Surprisingly, starvation may also occur when the system executes only a single application consisting of identical threads. Even more surprising, this behavior actually proves beneficial for some workloads (e.g., a database workload).
- CFS converges faster towards a balanced load, but ULE achieves a better load balance in the long run.
- The heuristics used by CFS to avoid migrating threads can hurt performance in HPC workloads that only use one thread per core, because CFS sometimes places two threads on the same core, while ULE always places one thread on each core.

The outline of the rest of this paper is as follows. Section 2 presents the CFS and ULE schedulers. Section 3 describes our port of ULE to Linux and the main differences between the native ULE implementation and our port. Sections 4 presents the machines and the workloads used in our experiments. Section 5 analyzes the impact of per-core scheduling in CFS and ULE. Section 6 analyzes the load balancer of CFS and ULE. Section 7 presents related work and Section 8 concludes.

2 Overview of CFS and ULE

2.1 Linux CFS

Per-core scheduling: Linux's CFS implements a weighted fair queueing algorithm: it evenly divides CPU cycles between threads weighted by their priority (represented by their niceness, high niceness meaning low priority and vice versa) [18]. To that end, CFS orders threads by a multi-factor value called *vruntime*, representing the amount of CPU time a thread has already used divided by the thread's priority. Threads with the same priority and same vruntime have executed the same amount of time, meaning that core resources have been shared fairly between them. To ensure that the vruntime of all threads progresses fairly, when the current running thread is preempted, CFS schedules the thread with the lowest vruntime to run next.

Since Linux 2.6.38 the notion of fairness in CFS has evolved from fairness between threads to fairness between applications. Before Linux 2.6.38 every thread was considered as an independent entity and got the same share of resources as other threads in the system. This meant that an application that used many threads got a larger share of resources than single-threaded applications. In more recent kernel versions, threads of the same application are grouped into a structure called a *cgroup*. A cgroup has a vruntime that corresponds to the sum of the vruntimes of all of its threads. CFS then applies its algorithm on cgroups, ensuring fairness between groups of threads. When a cgroup is chosen to be scheduled, its thread with the lowest vruntime is executed, ensuring fairness within a cgroup. Cgroups can also be nested. For instance, systemd automatically configures cgroups to ensure fairness between different users, and then fairness between the applications of a given user.

CFS avoids thread starvation by scheduling all threads within a given time period. For a core executing fewer than 8 threads the default time period is 48ms. When a core executes more than 8 threads, the time period grows with the number of threads and is equal to $6 * number\ of\ threads$ ms; the 6ms value was chosen to avoid preempting threads too frequently. Threads with a higher priority get a higher share of the time period. Since CFS schedules the thread with the lowest vruntime, CFS needs to prevent a thread from having a vruntime much lower than the vruntimes of the other threads waiting to be scheduled. If that were to happen, the thread with the low vruntime could run for a long time, starving the other threads. In practice, CFS ensures that the vruntime difference between any two threads is less than the preemption period (6ms). It does so at two key points: (i) when a thread is created, the thread starts with a vruntime equal to the maximum vruntime of the threads waiting in the runqueue, and (ii) when a thread wakes up after sleeping, its vruntime is updated to be at least equal to the minimum vruntime of the threads waiting to be scheduled. Using the minimum vruntime also ensures that threads that sleep a lot are scheduled first, a desirable strategy on desktop systems, because it minimizes the latency of interactive applications. Most interactive applications sleep most of the time, waiting for user input, and are immediately scheduled as soon as the user interacts with them.

CFS also uses heuristics to improve cache usage. For instance, when a thread wakes up, it checks the difference between its vruntime and the vruntime of the currently running thread. If the difference is not significant (less than 1ms), the current running thread is not preempted – CFS sacrifices latency to avoid frequent thread preemption, which may negatively impact caches.

Load balancing: In a multicore setting, Linux's CFS evens out the amount of *work* on all cores of the machine. This is different from evening out the number of threads. For instance, if a user runs 1 CPU-intensive thread and 10 threads that mostly sleep, CFS might schedule the 10 mostly sleeping threads on a single core.

To balance the amount of work, CFS uses a *load* metric for threads and cores. The load of a thread corresponds to the average CPU utilization of a thread: a thread that never sleeps has a higher load than one that sleeps a lot. Like the vruntime, the load of a thread is weighted by the thread's priority. The load of a core is the sum of the loads of the threads that are runnable on that core. CFS tries to even out the load of cores.

CFS takes into account the loads of cores when creating or waking up threads. The scheduler first decides which cores are suitable to host the thread. This decision involves many heuristics, such as the frequency at which the thread that initiated the wakeup wakes up threads. For instance, if CFS detects a 1-to-many producer-consumer pattern, then it spreads out the consumer threads as much as possible on the machine, and most cores of the machine are considered suitable to host woken up threads. In a 1-to-1 communication pattern, CFS restricts the list of suitable cores to cores sharing a cache with the thread that initiated the wakeup. Then, among all suitable cores, CFS chooses the core with the lowest load on which to wake up or create the thread.

Load balancing also happens periodically. Every 4ms every core tries to steal work from other cores. This load balancing takes into account the topology of the machine: cores try to steal work more frequently from cores that are "close" to them (e.g., sharing a cache) than from cores that are "remote" (e.g., on a remote NUMA node). When a core decides to steal work from another core, it tries to even out the load between the two cores by stealing as many as 32 threads from the other core. Cores also immediately call the periodic load balancer when they become idle.

On large NUMA machines, CFS does not compare the load of all cores against each other, but instead balances the load in a hierarchical way. For instance, on a machine with 2 NUMA nodes, CFS balances the load of cores inside the NUMA nodes, and then compares the load of the NUMA nodes (defined as the average load of their cores) to decide whether or not to balance the load between nodes. If the load difference between the nodes is small (less than 25% in practice), then no load balancing is performed. The greater the distance between two cores (or groups of cores), the higher the imbalance has to be for CFS to balance the load.

2.2 FreeBSD ULE

Per-core scheduling: ULE uses two runqueues to schedule threads: one runqueue contains *interactive* threads, and the other contains *batch* threads. A third runqueue called *idle* is used when a core is idle. This runqueue only contains the idle task.

The goal of having two runqueues is to give priority to interactive threads. Batch processes usually execute without user interaction, and thus scheduling latency is less important. ULE keeps track of the *interactivity* of a thread using an *interactivity penalty* metric between 0 and 100. This metric is defined as a function of the time r a thread has spent running and the time s a thread has spent voluntarily sleeping (not including the time spent waiting for the CPU), and is computed as follows:

$$scaling\,factor = m = 50$$

$$penalty(r,s) = \begin{cases} \frac{m}{\frac{s}{r}} & s > r \\ \frac{m}{\frac{r}{s}} + m & otherwise \end{cases}$$

A penalty in the lower half of the range (≤ 50) means that a thread has spent more time voluntarily sleeping than running, while a penalty above means the opposite.

The amount of history kept for the sleep and running times is (by default) limited to the last 5 seconds of the thread's lifetime. On the one hand, having a large amount of history would lengthen the time required to detect batch threads. On the other hand, too little history would induce noise in the classification [15].

To classify threads, ULE first computes a *score* defined as *interactivity penalty* + *niceness*. A thread is considered interactive if its score is under a certain threshold, 30 by default as in FreeBSD11.1. With a niceness value of 0, this corresponds roughly to spending more than 60% of the time sleeping. Otherwise, it is classified as batch. A negative *nice* value (high priority) makes it easier for a thread to be considered interactive.

When a thread is created, it inherits the runtime and sleeptime (and thus the interactivity) of its parent. When a thread dies, its runtime in the last 5 seconds is returned to its parent. This penalizes parents that spawn batch children when being interactive.

Inside the interactive and batch runqueues, threads are further sorted by *priority*. The priority of interactive threads is a linear interpolation of their *score* (i.e., a thread with a penalty of 0 has the highest interactive priority, while a thread with a penalty of 30 has the lowest interactive priority). Inside the interactive runqueue, there is one FIFO per priority. To add a thread to a runqueue, the scheduler inserts the thread at the end of the FIFO indexed by the thread's priority. Picking a thread to run from this runqueue is simply done by taking the first thread in the highest-priority non-empty FIFO.

The priority of batch threads depends on their runtime: the more a thread runs, the lower its priority. The niceness of the thread is added to get a linear effect on the priority. Inside the batch runqueue, there is also one FIFO per priority. Insertion and removal work as in the interactive case, with a slight difference. To avoid starvation between batch threads, ULE tries to be fair among batch threads by minimizing the difference of runtime between threads, similarly to what CFS does with the vruntime.

When picking the next thread to run, ULE first searches in the interactive runqueue. If an interactive thread is ready to be scheduled, it returns that thread. If the interactive runqueue is empty, ULE searches in the batch runqueue instead. If both runqueues are empty, that means that the core is idle, and no thread is scheduled.

The order in which ULE searches the runqeues effectively gives interactive threads absolute priority over batch threads. Batch threads may potentially starve if the machine executes too many interactive threads. However, it is thought that, as interactive threads by definition sleep more than they execute, starvation does not occur.

A thread runs for a limited period of time defined as a *timeslice*. Contrary to CFS, the rate at which a thread's timeslice expires is the same regardless of its priority. However, the value of a timeslice changes with the number of threads currently running on the core. When a core executes 1 thread, the timeslice is 10 ticks (78ms). When multiple threads are running, this value is divided by the number of threads while being constrained to a lower bound of 1 tick (1/127th of a second). In ULE, full preemption is disabled, meaning that only kernel threads can preempt others.

Load balancing: ULE only aims to even out the number of threads per core. In ULE, the load of a core is simply defined as the number of threads currently runnable on this core. Unlike CFS, ULE does not group threads into cgroups, but rather considers each thread as an independent entity.

When choosing a core for a newly created or awoken thread, ULE uses an affinity heuristic. If the thread is considered cache affine on the last core it ran on, then it is placed on this core. Otherwise, ULE finds the highest level in the topology that is considered affine, or the entire machine if none is available. From there, ULE first tries to find a core on which the minimum priority is higher than that of this thread. If that fails, ULE tries again, but now on all cores of the machine. If this also fails, ULE simply picks the core with the lowest number of running threads on the machine.

ULE also balances threads periodically, every 500-1500ms (the duration of the period is chosen randomly). Unlike CFS, the periodic load balancing is performed only by core 0. Core 0 simply tries to even out the number of threads amongst the cores as follows: a thread from the most loaded core, the (*donor*), is migrated to the less loaded core, the (*receiver*). A core can only be a donor or a receiver once, and the load balancer iterates until no donor or receiver is found, meaning that a core may give away or receive at most one thread per load balancer invocation.

ULE also balances threads when the interactive and batch runqueues of a core are empty. ULE tries to steal from the most loaded core with which the idle core shares a cache. If ULE fails to steal a thread, it tries at a higher level of the topology and so on, until it finally manages to steal a thread. As with the periodic load balancer, the idle stealing mechanism steals at most one thread.

Periodic load balancing in ULE happens less often than in CFS, but more computation is involved in selecting a core during thread placement in ULE. The rationale is that having a better initial thread placement avoids the need for frequently running a global load balancer.[1]

3 Porting ULE to the Linux kernel

In this section we describe the problems encountered when porting ULE to Linux, and the main differences between our port and the original FreeBSD code.

The Linux kernel offers an API to add new schedulers to the kernel. Schedulers must implement the set of functions presented in Table 1. These functions are responsible for adding and removing threads in runqueues, picking threads to be scheduled, and placing threads on cores.

FreeBSD does not offer such an API to schedulers. Instead, it declares prototypes of the functions that must be defined, meaning that only one scheduler can be used at a time, as opposed to Linux, in which multiple scheduling classes can co-exist. Fortunately, functions inside the ULE scheduler can easily be mapped to their counterparts in Linux (see Table 1). In the few cases where the interfaces do not match, it was possible to find a workaround. For instance, Linux uses a single function to enqueue newly created threads and threads that have been woken up, while FreeBSD uses two functions. Linux uses a flag parameter in its function to distinguish between the two cases. It then suffices to use this flag to choose the corresponding FreeBSD function.

[1] In recent versions of FreeBSD, due to a bug, the periodic load balancer never executes [1]. In our ULE code we fixed the bug, and the load balancer is executed periodically.

Linux	FreeBSD equivalent	Usage
`enqueue_task`	`sched_add` for new threads `sched_wakeup` for woken up threads	Enqueue a thread in a runqueue
`dequeue_task`	sched_rem	Remove a thread from a runqueue
`yield_task`	sched_relinquish	Yield the CPU back to the scheduler
`pick_next_task`	sched_choose	Select the next task to be scheduled
`put_prev_task`	sched_switch	Update statistics about the task that just ran
`select_task_rq`	sched_pickcpu	Choose the CPU on which a new (or waking up) thread should be placed

Table 1: Linux scheduler API and equivalent functions in FreeBSD.

Other than interfaces, CFS and ULE also differ in some low-level assumptions. The most notable difference is related to the presence or absence of the current thread in the runqueue data structures. The Linux scheduling class mechanism relies on the assumption that the current thread stays in the runqueue data structure while it runs on a core. In ULE, a thread that runs on a core is removed from the runqueue data structure, and added back when its timeslice is depleted, so that the FIFO property holds. When trying to implement this behavior in Linux, we encountered several showstopper issues, such as kernel crashes for threads that tried to change their scheduling class. We decided instead to adhere to the Linux way of doing things, and leave the currently running thread in the runqueue. Because of that, we had to slightly change the ULE load balancing to avoid migrating a currently running thread.

Furthermore, in ULE, when migrating a thread from one CPU to another, the scheduler acquires the lock on both runqueues. In Linux, this locking mechanism lead to deadlocks. Therefore, we modified the ULE load balancing code to use the same mechanism as that of CFS.

Finally, in FreeBSD, ULE is responsible for scheduling all threads, whereas Linux uses different scheduling policies for different priority ranges (e.g., a realtime scheduler for high priority threads). In this work, we are mainly interested in comparing workloads with priorities falling in the CFS range (100-139). Hence, we scaled down the ULE penalty scores to fit within the CFS range.

4 Experimental environment

4.1 Machines

We evaluate ULE on a 32-core machine (AMD Opteron 6172) with 32GB of RAM. All experiments were performed on the latest LTS Linux kernel (4.9). We also ran experiments on a smaller desktop machine (8-core Intel i7-3770), reaching similar conclusions. Due to space limitations, we omit these results from the paper.

4.2 Workloads

To assess the performance of CFS and ULE, we used both synthetic benchmarks and realistic applications. Fibo is a synthetic application computing Fibonacci numbers. Hackbench [10] is a benchmark designed by the Linux community to stress the scheduler. It creates a large number of threads that run for a short amount of time and exchange data using pipes. We also selected 16 applications from the Phoronix test suite [2] based on their completion time. We excluded Phoronix applications that take more than 10 minutes to complete on a single core, or that were too short to allow reliable time measurements. The 16 Phoronix applications are: compilation benchmarks (build-apache, build-php), compression (7zip, gzip), image processing (c-ray, dcraw), scientific (himeno, hmmer, scimark), cryptography (john-the-ripper) and web (apache). We use the NAS benchmark suite [6] to benchmark HPC applications, the Parsec benchmark suite [7] to benchmark parallel applications, and Sysbench [3] with MySQL and RocksDB [16] as database benchmarks. We use a read-write workload for sysbench and RocksDB to schedule threads with different behaviors.

5 Evaluation of per-core scheduling

In this section, we run applications on a single core to avoid possible side effects introduced by the load balancer. The main difference between CFS and ULE in per-core scheduling is in the handling of batch threads: CFS tries to be fair to all threads, while ULE gives priority to interactive threads. We first analyze the impact of this design decision by co-scheduling a batch and an interactive application on the same core, and we show that under ULE batch applications can starve for an unbounded amount of time. We then show that starvation under ULE can occur even when the system is only running a single application. We conclude this section by comparing the performance of 37 applications, and show how different choices regarding the preemption of threads impact performance.

5.1 Fairness and starvation when co-scheduling applications

In this section, we analyse the behavior of CFS and ULE running a multi-application workload consisting of a compute-intensive thread that never sleeps (fibo, computing numbers), and an application whose threads mostly sleep (sysbench, a database, using 80 threads). Having more than 80 threads per core is not uncommon in datacenters [12]. These threads are never all active at the same time; they mostly wait for incoming requests, or for data stored on disk.

Fibo runs alone for 7 seconds, and then sysbench is launched. Both applications then run to completion. Figure 1(a) presents the runtime accumulated by fibo and sysbench on CFS, and Figure 1(b) presents the same quantities on ULE.

On CFS, sysbench completes in 235s, and then fibo runs alone. Both fibo and sysbench threads share the machine. When sysbench executes, the cumulative runtime of fibo progresses roughly half as fast as when it runs alone, meaning that fibo gets 50% of the core. This is expected: CFS tries to share the core fairly between the two applications. In practice, fibo gets a bit less than half of the CPU due to rounding errors.

On ULE, sysbench is able to complete the same workload in 143s, and then fibo runs by itself. fibo starves while sysbench is running. sysbench threads mainly sleep, so they are classified as interactive and get absolute priority over fibo. Since sysbench uses 80 threads, these threads are able to saturate a core, and prevent fibo from running. Figure 2 presents the evolution of the interactivity penalty of fibo and sysbench over time. Both applications start out as interactive (penalty of 0). The penalty of fibo quickly rises to the maximum value, and then fibo is no longer considered interactive. Sysbench threads, in contrast, remain interactive during their entire execution (penalty below the 30 limit). Thus, sysbench threads get absolute priority over the fibo thread. This situation persists as long as sysbench is running (i.e., the starvation time is not bounded by ULE).

Table 2 presents the total execution time of fibo and sysbench on CFS and ULE, and the latency of requests for sysbench. Sysbench runs 50% slower on CFS, because it shares the CPU with fibo, instead of running in isolation, as it does with ULE (290 transactions/s with CFS vs. 532 with ULE). Fibo is “stopped” during the execution of sysbench on ULE, but then gets to execute by itself, and thus can use the cache more efficiently than when running simultaneously with sysbench on CFS. Thus, fibo runs slightly faster on ULE than on CFS.

We found the strategy used by the ULE scheduler to work well with latency-sensitive applications. These applications are usually correctly classified as interactive and get priority over background threads. To achieve the same result in Linux, the latency-sensitive application would have to be executed by the realtime scheduler, which gets absolute priority over CFS.

	CFS	ULE
Fibo - Runtime	160s	158s
Sysbench - Transactions/s	290	532
Sysbench - Avg. latency	441ms	125ms

Table 2: Execution time of fibo and sysbench using CFS and ULE, average latency of requests in sysbench using CFS and ULE.

5.2 Fairness and starvation within a single application

The starvation exhibited by ULE in the multi-application scenario above also occurs in single-application workloads. We now exemplify this behavior using sysbench.

In ULE, newly created threads inherit the interactivity penalty of their parent at the time of the fork. In sysbench, the master thread is created with the interactivity penalty of the bash process from which it was forked. Since bash mostly sleeps, sysbench is created as an interactive process. The sysbench master thread initializes data and creates threads. While doing so, it never sleeps, and its interactivity penalty increases. The first threads are created with an interactivity penalty below the interactive threshold, while the remaining threads are created with an interactivity penalty above it. As a consequence, the first threads get absolute priority over the remaining ones. Since these threads spend most of their time waiting for new requests, their interactivity penalty stays low (it decreases to 0), and their priority remains higher than that of threads that were forked late in the initialization process. The latter threads sysbench may starve forever, if the interactive threads keep the CPU busy at all times.

Figure 3 presents the cumulative runtime of sysbench threads, and Figure 4 presents their interactivity penalty. Sysbench is configured to use 128 threads. The threads created early execute, and their interactivity penalty drops to 0. The threads created later never execute.

Counterintuitively, in this benchmark ULE actually performs better than CFS, because it avoids oversubscription: the machine runs as many threads as it can. As a consequence, ULE has a lower average latency than CFS. In general, we found that this starvation mechanism, seemingly problematic on paper, performs very well in applications where all threads compete to perform the same job.

In contrast to sysbench, the scientific applications we tested are not impacted by starvation, because their threads never sleep. After a short initialization period

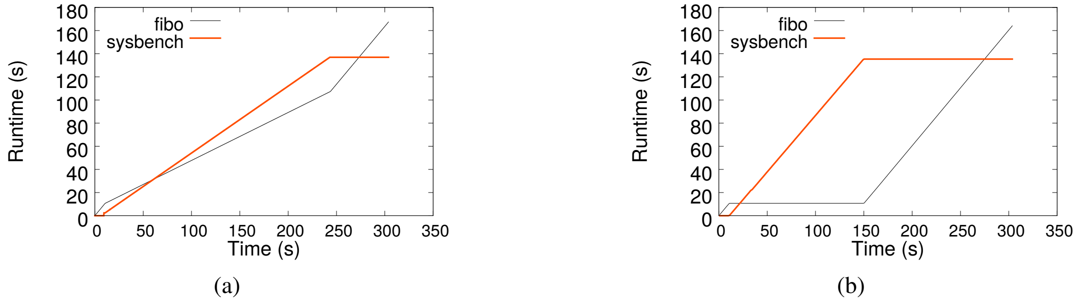

Figure 1: Cumulative runtime of fibo, and sysbench on (a) CFS, and (b) ULE. (a) On CFS, fibo continues to accumulate runtime, albeit more slowly, when sysbench executes, meaning that fibo is not starved. (b) On ULE, when sysbench executes, fibo stops accumulating runtime, meaning that it is starved.

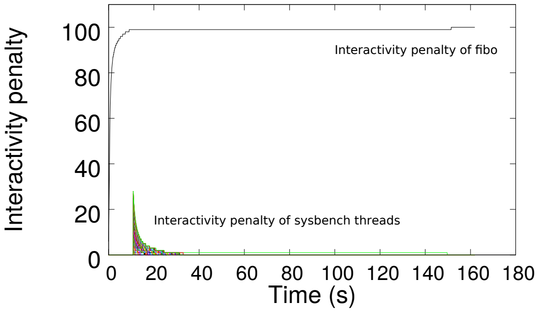

Figure 2: Interactivity penalty of threads over time. Fibo's penalty quickly rises to the maximum value, while the penalty of sysbench threads drops to 0.

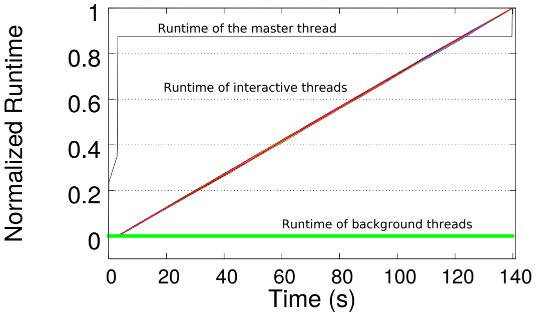

Figure 3: Cumulative runtime of threads of sysbench on ULE. The master thread first spawns 128 threads. 80 threads are classified as interactive and are executed, and 48 threads are classified as background and starve.

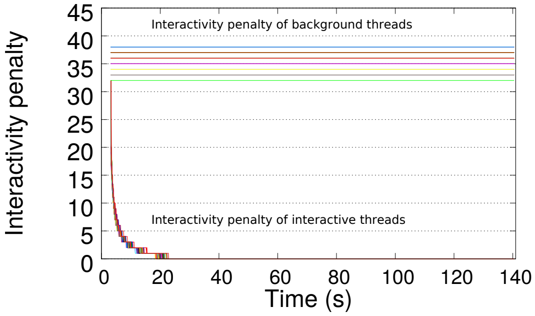

Figure 4: Interactivity penalty of the threads presented in Figure 3. Threads inherit the interactivity penalty of their parent when created. Some are created with a low penalty, and their penalty decreases as they execute (bottom of the graph), while other threads are created with a high penalty and never execute (top of the graph).

all threads are considered as background threads and are scheduled in a fair manner.

5.3 Performance analysis

We now analyze the impact of the per-core scheduling on the performance of 37 applications. We define "performance" as follows: for database workloads and NAS applications, we compare the number of operations per second, and for the other applications we compare "1/execution time". The higher the "performance", the better a scheduler performs. Figure 5 presents the performance difference between CFS and ULE on a single core, with percentages above 0 meaning that the application executes faster with ULE than CFS.

Overall, the scheduler has little influence on most workloads. Indeed, most applications use threads that all perform the same work, thus both CFS and ULE end up scheduling all of the threads in a round-robin fashion. The average performance difference is 1.5%, in favor of

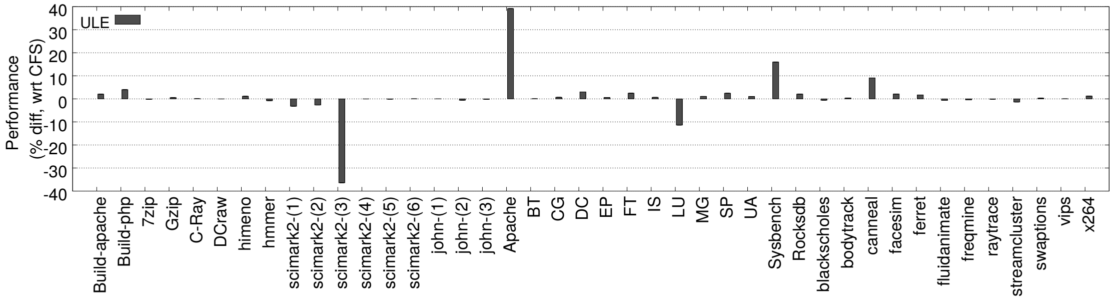

Figure 5: Performance of ULE with respect to CFS on a single core. A number higher than 0 means that the application runs faster on ULE than on CFS.

ULE. Still, scimark is 36% slower on ULE than CFS, and apache is 40% faster on ULE than CFS.

Scimark is a single-threaded Java application. It launches one compute thread, and the Java runtime executes other Java system threads in the background (for the garbage collector, I/O, etc.). When the application is executed with ULE, the compute thread can be delayed, because Java system threads are considered interactive and get priority over the computation thread.

The apache workload consists of two applications: the main server (*httpd*) running 100 threads, and *ab*, a single-threaded load injector. The performance difference between ULE and CFS is explained by different choices regarding thread preemption.

In ULE, full preemption is disabled, while CFS preempts the running thread when the thread that has just been woken up has a vruntime that is much smaller than the vruntime of the currently executing thread (1ms difference in practice). In CFS, *ab* is preempted 2 million times during the benchmark, while it never preempted with ULE. This behavior is explained as follows: *ab* starts by sending 100 requests to the httpd server, and then waits for the server to answer. When *ab* is woken up, it checks which requests have been processed and sends new requests to the server. Since *ab* is single-threaded, all requests sent to the server are sent sequentially. In ULE, *ab* is able to send as many new requests as it has received responses. In CFS, every request sent by *ab* wakes up a *httpd* thread, which preempts *ab*.

6 Evaluation of the load balancer

In this section, we analyze the impact of the load balancing and thread placement strategies on performance. In CFS and ULE, load balancing happens periodically, and thread placement occurs when threads are created or woken up. We first analyze the time it takes for the periodic load balancer to balance a static workload on all cores of the machine. We then analyze design choices made by CFS and ULE when placing threads. Next, we compare the performance of 37 applications running on CFS vs. ULE. Finally, we analyze the performance of multi-application workloads.

6.1 Periodic load balancing

CFS relies on a rather complex load metric. It uses a hierarchical load balancing strategy that runs every 4ms. ULE only tries to even out the number of threads on the cores. Load balancing happens less often (the period varies between 0.5s and 1.5s) and ignores the hardware topology. We now evaluate how these strategies impact the time needed to balance the load on the machine.

To that end, we pin 512 spinning threads on core 0, we launch a taskset command to unpin the threads, and we let the load balancer balance the load between cores. All threads perform the same work (an infinite empty loop), so we expect the load balancer to place 16 threads on each of the 32 cores. Figure 6 presents the evolution over time of the number of threads per core. In the figure, each of the 32 lines represents the number of threads on a given core. The taskset command that unpins threads is launched at 14.5s.

On ULE, as soon as the threads are unpinned, idle cores steal threads (at most one per core) from core 0, thus right after the unpinning, core 0 has $512-31=481$ threads while every other core has 1 thread. Over time, the periodic load balancer is triggered and tries to balance the thread count. However, as the load balancer only migrates one thread at a time from core 0, it takes more that 450 load balancer invocations or about 240 seconds to reach a balanced state.

CFS balances the load much faster. 0.2 seconds after the unpinning, CFS has migrated more that 380 threads from core 0. Surprisingly, CFS never achieves perfect load balance. CFS only balances the load between NUMA nodes when the imbalance between the two nodes is “big enough” (25% load difference in practice). So cores in one node can have 18 threads while cores in another only have 15.

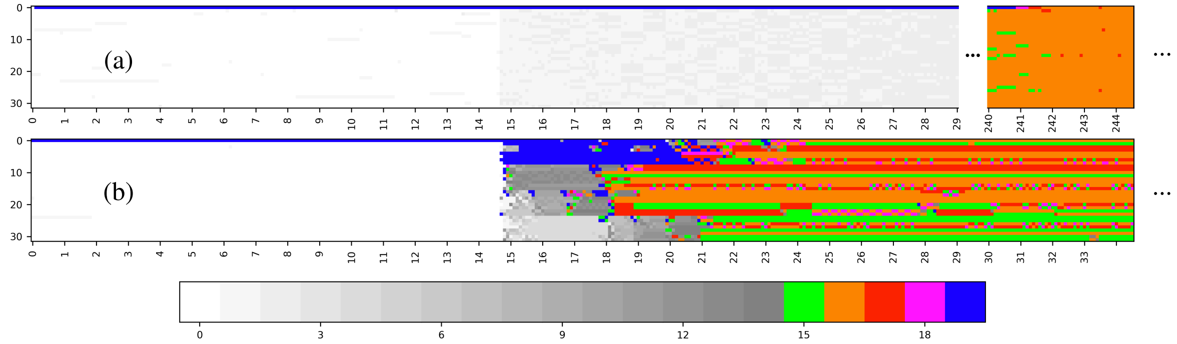

Figure 6: Number of threads per core over time on (a) ULE and (b) CFS. Each line represents a core (32 in total), time passes on the x-axis (in seconds), and colors represent the numbers of threads on the core. Thread counts below 15 are represented in shades of grey. Threads are pinned on core 0 for the first 14.5 seconds of the execution.

While the load balancing strategy used by CFS is well suited for solving a large imbalance loads in the system, it is less suited when a perfect load balance is important for performance.

6.2 Thread placement

We study placement of threads using c-ray, an image processing application from the phoronix benchmark suite. C-ray starts by creating 512 threads. Threads are not pinned at creation time, so the scheduler chooses a core for each thread. Then all threads wait on a barrier before performing the computation. Since all threads behave in the same way, we would expect ULE to perform better than CFS in that configuration: ULE always forks threads on the core with the lowest number of threads, so the load should be perfectly balanced from the start.

Figure 7 presents the evolution in the number of runnable threads per core over time. Load is always balanced in ULE, but surprisingly it takes more than 11 seconds for ULE to have all threads runnable, while it only takes 2 seconds for CFS. This delay is explained by starvation. C-ray uses a cascading barrier in which thread 0 wakes up thread 1, thread 1 wakes up thread 2, etc. Threads are originally created with different interactivity penalties, and some threads are initially interactive, while others are initially batch (same reason as in sysbench, see Section 5.2). When a batch thread is woken up, it might starve until all interactive threads are done, or until their penalty has increased enough for them to be downgraded to the batch runqueue. In practice, in c-ray, threads never sleep after the barrier, so eventually all threads become batch, but, before they do, threads that were initially categorized as batch cannot wake up other threads. Thus, it takes 11 seconds for all threads to be woken up after the barrier.

CFS on the contrary is fair, and all threads are quickly woken up. Then, CFS runs into the imperfect load balancing issue that we explained in Section 6.1.

Despite these load balancing differences, c-ray completes in the same time on CFS and ULE, because c-ray creates more threads than cores, and because both schedulers always keep all cores busy. Preemptions do occur more often with CFS, but do not affect the performance.

6.3 Performance analysis

Figure 8 presents the performance difference between CFS and ULE in a multicore context. The average performance difference between CFS and ULE is small: 2.75% in favor of ULE.

MG, from the NAS benchmark suite, benefits the most from ULE's load balancing strategy: it is 73% faster on ULE than on CFS. MG spawns as many threads as there are cores in the machine, and all threads perform the same computations. When a thread has finished its computation, it waits on a spin-barrier for 100ms and then sleeps if some threads are still computing. ULE correctly places one thread per core, and then never migrates them again. Threads spend very little time waiting for each other in the barriers, and never sleep. In contrast, CFS reacts to micro changes in the load of cores (e.g., due to a kernel thread waking up), and sometimes wrongly places two MG threads on the same core. Since MG uses barriers, the two threads scheduled on the same core end up delaying the whole application. The delay is more than 50% because threads scheduled alone on their cores go to sleep, and then have to be woken up, thus adding latency to the barriers. This suboptimal thread placement also explains the performance difference between CFS and ULE on FT and UA. The simple approach of balancing the number of threads used by ULE works better on HPC-like applications because it ends up placing one thread per core and then never migrates them again.

Sysbench, is slower on ULE due to the overhead of the ULE load balancer. When a thread wakes up, ULE scans

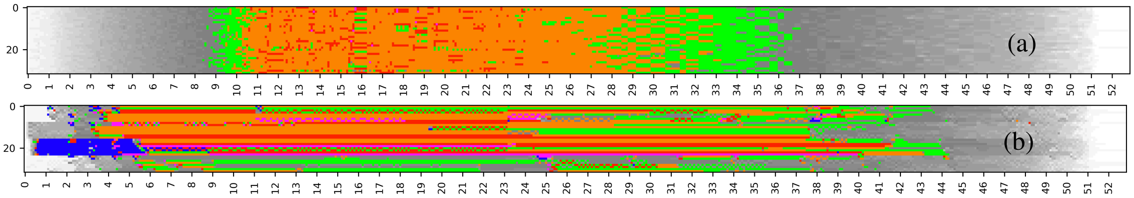

Figure 7: Number of threads per core over time on c-ray on (a) ULE and (b) CFS. Contrary to Figure 6, threads do not start pinned on core 0.

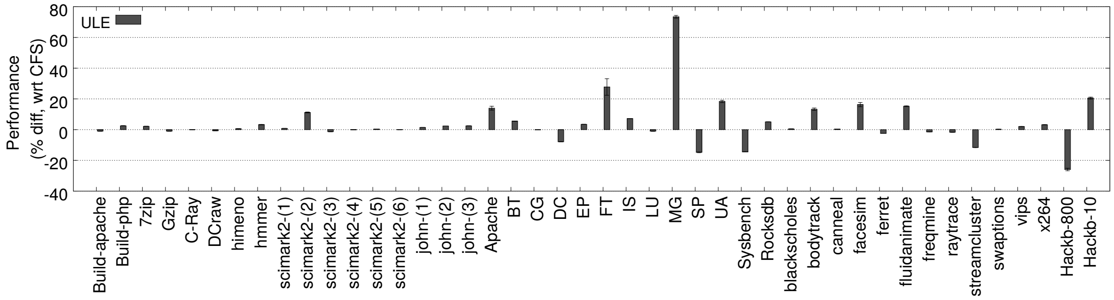

Figure 8: Performance of ULE with respect to CFS on a multicore.

the cores of the machine to find an appropriate core for the thread, and, at worst, may scan all cores three times. This worst case scenario happens on most wakeups in sysbench, resulting in 13% of all CPU cycles being spent on scanning cores. To validate this assumption, we replaced the ULE wakeup function by a simple one that returns the CPU on which the thread was previously running, and then observed no difference between ULE and CFS.

In all the benchmarks we tested, 13% is the highest time spent in the scheduler we observed in ULE, and 2.6% is the highest time spent in the scheduler we observed in CFS. Note that ULE runs into a corner case situation with sysbench, but has a low overhead on other benchmarks, even when they spawn a large number of threads: for instance in hackbench (32 000 threads), the overhead of ULE is 1% (compared to 0.3% for CFS).

6.4 Multi application workloads

Finally, we evaluate the combination of interactive and background workloads using a set of different applications: c-ray + EP (from NAS) is a workload where both applications are considered background by ULE, fibo + sysbench and blackscholes + ferret are workloads where only one application is interactive, and apache + sysbench is a fully interactive workload. Figure 9 shows the performance of CFS and ULE with respect to the performance of the application running alone on the machine (higher is better). Overall, most applications run slower when they are co-scheduled with another application.

When both applications are non-interactive (c-ray + EP), CFS and ULE perform similarly. This is expected, as they schedule background threads in a similar way. EP runs slightly faster on ULE when executed alone, and this performance difference is still present when it is co-scheduled with c-ray. When both applications are interactive, CFS and ULE also perform similarly.

For blackscholes + ferret, ULE gives priority to the interactive application, and ferret is not impacted by being co-scheduled with blackscholes. Blackscholes however runs more than 80% slower. In that context, blackscholes does not fully starve because ferret does not use 100% of all cores. CFS on the contrary shares the CPU fairly, and both applications suffer equally (the impact of co-scheduling on these applications is less than 50% because neither ferret nor blackscholes scales to 32 cores).

Surprisingly when co-scheduled with fibo, sysbench performs worse on ULE than on CFS even though it is correctly categorized as interactive and gets priority over fibo threads. The lack of preemption in ULE explains the performance difference. MySQL does not achieve perfect scaling and, when executed on 32 cores, lock contention forces the threads to sleep when waiting for the locks to be released. Thus, fibo does not starve. When a MySQL lock is released, ULE does not preempt the currently running thread (usually fibo) to schedule a new MySQL thread to enter the critical section. This adds delays (of up to the length of fibo's timeslice, between 7.8ms and 78ms) to the execution of sysbench.

7 Related work

Previous works have compared the design choices made by FreeBSD and Linux. Abaffy et al. [4, 5] compare the

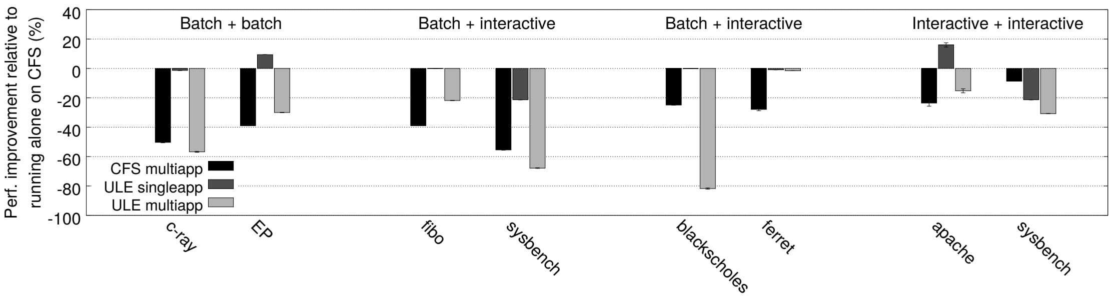

Figure 9: Performance of CFS and ULE on multi application workloads with respect to the performance of the application running alone on CFS.

average waiting time of threads in scheduler runqueues. Schneider et al. [17] compare the networking stack performance of the two operating systems. Design choices made by FreeBSD are also frequently discussed on the Linux kernel mailing list [20]. This study differs in its approach: instead of comparing two complete operating systems, we ported the FreeBSD ULE scheduler to Linux. To the best of our knowledge, this is the first apples-to-apples comparison of the design of ULE and CFS.

The Linux scheduler design has also been discussed in previous works. Torrey et al. [19] compare the latency of the Linux scheduler against a custom implementation of a multilevel feedback queue. Wong et al. compare the fairness of CFS with the O(1) scheduler that was the default Linux scheduler prior to 2.6.23 [23], and with a RSDL scheduler (Rotating Staircase Deadline Scheduler) [22]. Groves et al. [9] compare the overhead of CFS against BFS (Brain Fuck Scheduler), a simplistic scheduler aimed at improving responsiveness on machines with few cores. Other work has studied the overhead of schedulers. Kanev et al. [12] report that the CFS alone accounts for more than 5% of all datacenter cycles.

The performance of operating systems is frequently assessed by measuring the evolution of performance between kernel versions. The Linux Kernel Performance project [8] started in 2005 to measure performance regressions in the Linux Kernel. Mollison et al. [14] propose Litmus tests to find performance regressions in schedulers. Performance issues in operating systems are also frequently reported in the Systems community. Lozi et al. [13] report bugs in the Linux scheduler that could lead to cores being permanently left idle while work was waiting to be scheduled on other cores. Harji et al. [11] report similar performance bugs in earlier kernel versions. During the work on this paper we also reported bugs in the scheduler to the FreeBSD community [1]. In this study we chose to compare "glitch free" versions of ULE and CFS by fixing obvious bugs that were not intended as features of the schedulers.

8 Conclusion

Scheduling threads on a multicore machine is hard. In this paper, we perform a fair comparison of the design choices of two widely used schedulers: the ULE scheduler from FreeBSD and CFS from Linux. We show that they behave differently even on simple workloads, and that no scheduler performs better than the other on all workloads.

The Design and Implementation of Hyperupcalls

Abstract

The virtual machine abstraction provides a wide variety of benefits which have undeniably enabled cloud computing. Virtual machines, however, are a double-edged sword as hypervisors they run on top of must treat them as a black box, limiting the information which the hypervisor and virtual machine may exchange, a problem known as the *semantic gap*. In this paper, we present the design and implementation of a new mechanism, hyperupcalls, which enables a hypervisor to safely execute verified code provided by a guest virtual machine in order to transfer information. Hyperupcalls are written in C and have complete access to guest data structures such as page tables. We provide a complete framework which makes it easy to access familiar kernel functions from within a hyperupcall. Compared to state-of-the-art paravirtualization techniques and virtual machine introspection, Hyperupcalls are much more flexible and less intrusive. We demonstrate that hyperupcalls can not only be used to improve guest performance for certain operations by up to 2× but hyperupcalls can also serve as a powerful debugging and security tool.

1 Introduction

Hardware virtualization introduced the abstraction of a virtual machine (VM), enabling hosts known as *hypervisors* to run multiple operating systems (OSs) known as *guests* simultaneously, each under the illusion that they are running in their own physical machine. This is achieved by exposing a hardware interface which mimics that of true, physical hardware. The introduction of this simple abstraction has led to the rise of the modern data center and the cloud as we know it today. Unfortunately, virtualization is not without drawbacks. Although the goal of virtualization is for VMs and hypervisors to be oblivious from each other, this separation renders both sides unable to understand decisions made on the other side, a problem known as the *semantic gap*.

		Paravirtual, Executed by:		**Uncoordinated**
		Hypervisor	Guest	Introspection
Requestor	Guest	Hypercalls	Pre-Virt [42]	HVI [72]
	HV	**Hyperupcalls**	Upcalls	VMI [25]

Table 1: *Hypervisor-Guest Communication Mechanisms.* Hypervisors (HV) and guests may communicate through a variety of mechanisms, which are characterized by who initiates the communication, who executes and whether the channel for communication is coordinated (paravirtual). Shaded cells represent channels which require context switches.

Addressing the semantic gap is critical for performance. Without information about decisions made in guests, hypervisors may suboptimally allocate resources. For example, the hypervisor cannot know what memory is free in guests without understanding their internal OS state, breaking the VM abstraction. State-of-the-art hypervisors today typically bridge the semantic gap with *paravirtualization* [11, 58], which makes the guest aware of the hypervisor. Paravirtualization alleviates the guest from the limitations of the physical hardware interface and allows direct information exchange with the hypervisor, improving overall performance by enabling the hypervisor to make better resource allocation decisions.

Paravirtualization, however, involves the execution of code both in the context of the hypervisor and the guest. *Hypercalls* require that the guest make a request to be executed in the hypervisor, much like a system call, and *upcalls* require that the hypervisor make a request to be executed in the guest. This design introduces a number of drawbacks. First, paravirtual mechanisms introduce context switches between hypervisors and guests, which may be substantial if frequent interactions between guests and the hypervisor are needed [7]. Second, the requestor of a paravirtual mechanism must wait for it to be serviced in another context which may be busy, or waking the guest if it is idle. Finally, paravirtual mechanisms couple the design of the hypervisor and guest: paravirtual mechanisms need to be implemented for each guest and hypervisor, increasing complexity [46] and hampering maintainability [77]. Adding paravirtual features requires updating both the guest and hypervisor with a new interface [69] and has the potential to introduce bugs and the attack surface [47, 75].

A different class of techniques, VM introspection (VMI) [25] and the reverse, hypervisor introspection (HVI) [72] aim to address some of the shortcomings of paravirtualization by *introspecting* the other context, enabling communication transfer without context switching or prior coordination. These techniques however, are fragile: small changes in data structures, behavior or even security hardening [31] can break introspective mechanisms, or worse, introduce security vulnerabilities. As a result, introspection is usually relegated to the area of intrusion detection systems (IDSs) which detect malware or misbehaving applications.

In this paper, we describe the design and implementation of hyperupcalls [1], a technique which enables a hypervisor to communicate with a guest, like an upcall, but without a context switch, like VMI. This is achieved through the use of verified code, which enables a guest to communicate to the hypervisor in a flexible manner while ensuring that the guest cannot provide misbehaving or malicious code. Once a guest registers a hyperupcall, the hypervisor can execute it to perform actions such as locating free guest pages or running guest interrupt handlers without switching into the guest.

Hyperupcalls are easy to build: they are written in a high level language such as C, and we provide a framework which allows hyperupcalls to share the same codebase and build system as the Linux kernel that may be generalized to other operating systems. When the kernel is compiled, a toolchain translates the hyperupcall into verifiable bytecode. This enables hyperupcalls to be easily maintained. Upon boot, the guest registers the hyperupcalls with the hypervisor, which verifies the bytecode and compiles it back into native code for performance. Once recompiled, the hypervisor may invoke the hyperupcall at any time.

We show that using a hyperupcalls can significantly improve performance by allowing a hypervisor to be proactive about resource allocation, rather than waiting for guests to react through existing mechanisms. We build hyperupcalls for memory reclamation and dealing with interprocessor interrupts (IPIs) and show a performance improvement of up to 2×. In addition to improving performance, hyperupcalls can also enhance both the security and debuggability of systems in virtual environments. We develop a hyperupcall to enables guests to write-protect memory pages without the use of specialized hardware, and another which enables `ftrace` [57] to capture both guest and hypervisor events in a unified trace, allowing us to gain new insights on performance in virtualized environments.

This paper makes the following contributions:

- We build a taxonomy of mechanisms for bridging the semantic gap between hypervisor and guests and place hyperupcalls within that taxonomy (§2).
- We describe and implement hyperupcalls (§3) with:
  - An environment for writing hyperupcalls and a framework for using guest code (§3.1)
  - A compiler (§3.2) and verifier (§3.4) for hyperupcalls which addresses the complexities and limitations of verified code.
  - Registration (§3.3) and execution (§3.5) mechanisms for hyperupcalls.
- We prototype and evaluate hyperupcalls and show that hyperupcalls can improve performance (§4.3, §4.2), security (§4.5) and debuggability (§4.4).

2 Communication Mechanisms

It is now widely accepted that in order to extract the most performance and utility from virtualization, hypervisors and their guests need to be aware of one another. To that end, a number of mechanisms exist to facilitate communication between hypervisors and guests. Table 1 summarizes these mechanisms, which can be broadly characterized by the requestor, the executor, and whether the mechanism requires that the hypervisor and the guest coordinate ahead of time.

In the next section, we discuss these mechanisms and describe how hyperupcalls fulfill a need for a communication mechanism where the hypervisor makes and executes its own requests without context switching. We begin by introducing state-of-the-art paravirtual mechanisms in use today.

2.1 Paravirtualization

Hypercalls and upcalls. Most hypervisors today leverage paravirtualization to communicate across the semantic gap. Two mechanisms in widespread use today are *hypercalls*, which allow guests to invoke services provided by the hypervisor, and *upcalls*, which enable the hypervisor to make requests to guests. Paravirtualization means that the interface for these mechanisms are coordinated ahead of time between hypervisor and guest [11].

One of the main drawbacks of upcalls and hypercalls is that they require a context switch as both mechanisms are executed on the opposite side of the request. As a result, these mechanisms must be invoked with care. Invoking

[1] Hyperupcalls were previously published as “hypercallbacks” [5].

a hypercall or upcall too frequently can result in high latencies and computing resource waste [3].

Another drawback of upcalls in particular that the requests are handled by the guest, which could be busy handling other tasks. If the guest is busy or if a guest is idle, upcalls incur the additional penalty of waiting for the guest to be free or for the guest or woken up. This can take an unbounded amount of time, and hypervisors may have to rely on a penalty system to ensure guests respond in a reasonable amount of time.

Finally, by increasing the coupling between the hypervisor and its guests, paravirtual mechanisms can be difficult to maintain over time. Each hypervisor have their own paravirtual interfaces, and each guest must implement the interface of each hypervisor. The paravirtual interface is not thin: Microsoft's paravirtual interface specification is almost 300 pages long [46]. Linux provides a variety of paravirtual hooks, which hypervisors can use to communicate with the VM [78]. Despite the effort to standardize the paravirtualization interfaces they are incompatible with each other, and evolve over time, adding features or even removing some (e.g., Microsoft hypervisor event tracing). As a result, most hypervisors do not fully support efforts to standardize interfaces and specialized OSs look for alternative solutions [45, 54].

Pre-virtualization. Pre-virtualization [42] is another mechanism in which the guest requests services from the hypervisor, but the requests are served in the context of the guest itself. This is achieved by code injection: the guest leaves stubs, which the hypervisor fills with hypervisor code. Pre-virtualization offers an improvement over hypercalls, as they provide more flexible interface between the guest and the hypervisor. Arguably, pre-virtualization suffers from a fundamental limitation: code that runs in the guest is deprivileged and cannot perform sensitive operations, for example, accessing shared I/O devices. As a result, in pre-virtualization, the hypervisor code that runs in the guest still needs to communicate with the privileged hypervisor code using hypercalls.

2.2 Introspection

Introspection occurs when a hypervisor or guest attempts to infer information from the other context without directly communicating with it. With introspection, no interface or coordination is required. For instance, a hypervisor may attempt to infer the state of completely unknown guests simply by their memory access patterns. Another difference between introspection and paravirtualization is that no context switch occurs: all the code to perform introspection is executed in the requestor.

Virtual machine introspection (VMI). When a hypervisor introspects a guest, it is known as VMI [25]. VMI was first introduced to enhance VM security by providing intrusion detection (IDS) and kernel integrity checks from a privileged host [10, 24, 25]. VMI has also been applied to checkpointing and deduplicating VM state [1], as well as monitoring and enforcing hypervisor policies [55]. These mechanisms range from simply observing a VM's memory and I/O access patterns [36] to accessing VM OS data structures [16], and at the extreme end they may modify VM state and even directly inject processes into it [26, 19]. The primary benefits of VMI are that the hypervisor can directly invoke VMI without a context switch, and the guest does not need to be "aware" that it is inspected for VMI to function. However, VMI is fragile: an innocuous change in the VM OS, such as a hotfix which adds an additional field to a data structure could render VMI non-functional [8]. As a result, VMI tends to be a "best effort" mechanism.

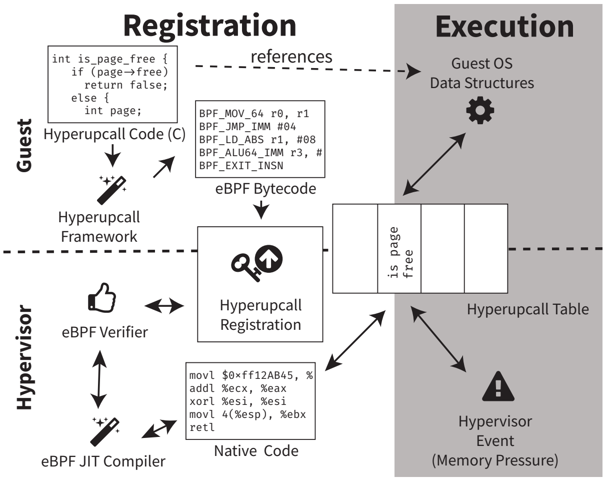
HVI. Used to a lesser extent, a guest may introspect the hypervisor it is running on, known as hypervisor introspection (HVI) [72, 61]. HVI is typically employed either to secure a VM from untrusted hypervisors [62] or by malware to circumvent hypervisor security [59, 48].

2.3 Extensible OSes

While hypervisors provide a fixed interface, OS research suggested along the years that flexible OS interfaces can improve performance without sacrificing security. The Exokernel provided low level primitives, and allowed applications to implement high-level abstractions, for example for memory management [22]. SPIN allowed to extend kernel functionality to provide application-specific services, such as specialized interprocess communication [13]. The key feature that enables these extensions to perform well without compromising security, is the use of a simple byte-code to express application needs, and running this code at the same protection ring as the kernel. Our work is inspired by these studies, and we aim to design a flexible interface between the hypervisor and guests to bridge the semantic gap.

2.4 Hyperupcalls

This paper introduces hyperupcalls, which fulfill a need for a mechanism for the hypervisor to communicate to the guest which is coordinated (unlike VMI), executed by the hypervisor itself (unlike upcalls) and does not require context switches (unlike hypercalls). With hyperupcalls, the VM coordinates with the hypervisor by registering verifiable code. This code is then executed by the hypervisor in response to events (such as memory pressure, or



```
int is_page_free {
   if (page→free)
     return false;
   else {
     int page;
```

```
BPF_MOV_64 r0, r1
BPF_JMP_IMM #04

BPF_ALU64_IMM r3, #
BPF_EXIT_INSN
```

```
movl $0×ff12AB45, %
addl %ecx, %eax
xorl %esi, %esi
movl 4(%esp), %ebx
retl
```

Figure 1: *System Architecture.* Hyperupcall registration (left) consists of compiling C code, which may reference guest data structures, into verifiable bytecode. The guest registers the generated bytecode with the hypervisor, which verifies its safety, compiles it into native code and sets it in the VM hyperupcall table. When the hypervisor encounters an event (right), such as a memory pressure, it executes the respective hyperupcall, which can access and update data structures of the guest.

VM entry/exit). In a way, hyperupcalls can be thought of as upcalls executed by the hypervisor.

In contrast to VMI, the code to access VM state is provided by the guest so the hyperupcalls are fully aware of guest internal data structures— in fact, hyperupcalls are built with the guest OS codebase and share the same code, thereby simplifying maintenance while providing the OS with an expressive mechanism to describe its state to underlying hypervisors.

Compared to upcalls, where the hypervisor makes asynchronous requests to the guest, the hypervisor can execute a hyperupcall at any time, even when the guest is not running. With an upcall, the hypervisor is at the mercy of the guest, which may delay the upcall [6]. Furthermore, because upcalls operate like remote requests, upcalls may be forced to implement OS functionality in a different manner. For example, when flushing remote pages in memory ballooning [71], the canonical technique for identifying free guest memory, the guest increases memory pressure using a dummy process to free pages. With a hyperupcall, the hypervisor can act as if it were a guest kernel thread and scan the guest for free pages directly.

Hyperupcalls resemble pre-virtualization, in that code is transferred across the semantic gap. Transferring code not only allows for more expressive communication, but it also moves the execution of the request to the other side of the gap, enhancing performance and functionality. Unlike pre-virtualization, the hypervisor cannot trust the code being provided by the virtual machine, and the hypervisor must ensure that execution environment for the hyperupcall is consistent across invocations.

	Local Hyperupcalls	**Global Hyperupcalls**
event examples	VM-exit VM-entry interrupt injection page mapping	memory reclaim memory aging VCPU preemption

preemptable	yes	no
memory mappings	host user-space	host kernel-space
memory limit	high	low
memory pinning	no	yes
callback chaining	yes	no
hyperupcall examples	IPI handling security agent tracing	scheduler activation memory discard hints

Table 2: *Hyperupcall event types.* The hypervisor enforces certain limitations on global hyperupcalls, which are used to make policy decisions.

3 Architecture

Hyperupcalls are short verifiable programs provided by guests to the hypervisor to improve performance or provide additional functionality. Guests provide hyperupcalls to the hypervisor through a *registration* process at boot, allowing the hypervisor to access the guest OS state and provide services by *executing* them after verification. The hypervisor runs hyperupcalls in response to events or when it needs to query guest state. The architecture of hyperupcalls and the system we have built for utilizing them is depicted in Figure 1.

We aim to make hyperupcalls as simple as possible to build. To that end, we provide a complete *framework* which allows a programmer to write hyperupcalls using the guest OS codebase. This greatly simplifies the development and maintenance of hyperupcalls. The framework compiles this code into verifiable code which the guest registers with the hypervisor. In the next section, we describe how an OS developer writes a hyperupcall using our framework.

3.1 Building Hyperupcalls

Guest OS developers write hyperupcalls for each hypervisor event they wish to handle. Hypervisors and guests agree on these events, for example VM entry/exit, page mapping or virtual CPU (VCPU) preemption. Each hyperupcall is identified by a predefined identifier, much like the UNIX system call interface [56]. Table 2 gives examples of events a hyperupcall may handle.

3.1.1 Providing Safe Code

One of the key properties of hyperupcalls is that the code must be guaranteed to not compromise the hypervisor. In order for a hyperupcall to be safe, it must only be able to access a restricted memory region dictated by the hypervisor, run for a limited period of time without blocking, sleeping or taking locks, and only use hypervisor services that are explicitly permitted.

Since the guest is untrusted, hypervisors must rely on a security mechanism which guarantees these safety properties. There are many solutions that we could have chosen: software fault isolation (SFI) [70], proof-carrying code [51] or safe languages such as Rust. To implement hyperupcalls, we chose the enhanced Berkeley Packet Filter (eBPF) VM.

We chose eBPF for several reasons. First, eBPF is relatively mature: BPF was introduced over 20 years ago and is used extensively throughout the Linux kernel, originally for packet filtering but extended to support additional use cases such as sandboxing system calls (`seccomp`) and tracing of kernel events [34]. eBPF enjoys wide adoption and is supported by various runtimes [14, 49]. Second, eBPF can be provably verified to have the safety properties we require, and Linux ships with a verifier and JIT which verifies and efficiently executes eBPF code [74]. Finally, eBPF has a LLVM compiler backend, which enables eBPF bytecode to be generated from a high level language using a compiler frontend (Clang). Since OSes are typically written in C, the eBPF LLVM backend provides us with a straightforward mechanism to convert unsafe guest OS source code into verifiably safe eBPF bytecode.

3.1.2 From C to eBPF — the *Framework*

Unfortunately, writing a hyperupcall is not as simple recompiling OS code into eBPF bytecode. However, our framework aims to make the process of writing a hyperupcalls simple and maintainable as possible. The framework provides three key features that simplify the writing of hyperupcalls. First, the framework takes care of dealing with guest address translation issues so guest OS symbols are available to the hyperupcall. Second, the framework addresses limitations of eBPF, which places significant constraints on C code. Finally, the framework defines a simple interface which provides the hyperupcall with data so it can execute efficiently and safely.

Guest OS symbols and memory. Even though hyperupcalls have access to the entire physical memory of the guest, accessing guest OS data structures requires knowing where they reside. OSes commonly use kernel address space layout randomization (KASLR) to randomize the virtual offsets for OS symbols, rendering them unknown during compilation time. Our framework enables OS symbol offsets to be resolved at runtime by associating pointers using address space attributes and injecting code to adjust the pointers. When a hyperupcall is registered, the guest provides the actual symbol offsets enabling a hyperupcall developer to reference OS symbols (variables and data structures) in C code as if they were accessed by a kernel thread.

Global / Local Hyperupcalls. Not all hyperupcalls need to be executed in a timely manner. For example, notifications informing the guest of hypervisor events such as a VM-entry/exit or interrupt injection only affect the guest and not the hypervisor. We refer to hyperupcalls that only affect the guest that registered it as local, and hyperupcalls that affect the hypervisor as a whole as global. If a hyperupcall is registered as local, we relax the timing requirement and allow the hyperupcall to block and sleep. Local hyperupcalls are accounted in the VCPU time of the guest similar to a trap, so a misbehaving hyperupcall penalizes itself.

Global hyperupcalls, however, must complete their execution in a timely manner. We ensure that for the guest OS pages requested by global hyperupcalls are pinned during the hyperupcall, and restrict the memory that can be accessed to 2% (configurable) of the guest's total physical memory. Since local hyperupcalls may block, the memory they use does not need to be pinned, allowing local hyperupcalls to address all of guest memory.

Addressing eBPF limitations. While eBPF is expressive, the safety guarantees of eBPF bytecode mean that it is not Turing-complete and limited, so only a subset of C code can be compiled into eBPF. The major limitations of eBPF are that it does not support loops, the ISA does not contain atomics, cannot use self-modifying code, function pointers, static variables, native assembly code, and cannot be too long and complex to be verified.

One of the consequences of these limitations is that hyperupcall developers must be aware of the code complexity of the hyperupcall, as complex code will fail the verifier. While this may appear to be an unintuitive restriction, other Linux developers using BPF face the same restriction, and we provide a helper functions in our framework to reduce complexity, such as `memset` and `memcpy`, as well as functions that perform native atomic

Helper Name	Function
send_vcpu_ipi	Send an interrupt to VCPU
get_vcpu_register	Read a VCPU register
set_vcpu_register	Read a VCPU register
memcpy	memcpy helper function
memset	memset helper function
cmpxchg	compare-and-swap
flush_tlb_vcpu	Flush VCPU's TLB
get_exit_info	Get info on an VM_EXIT event

Table 3: *Selected hyperupcall helper functions.* The hyperupcall may call these functions implemented in the hypervisor, as they cannot be verified using eBPF.

operations such as cmpxchg. A selection of these helper functions is shown in Table 3. In addition, our framework masks memory accesses (§3.4), which greatly reduces the complexity of verification. In practice, as long as we were careful to unroll loops, we did not encounter verifier issues while developing the use cases in (§4) using a setting of 4096 instructions and a stack depth of 1024.

Hyperupcall interface. When a hypervisor invokes a hyperupcall, it populates a context data structure, shown in Table 4. The hyperupcall receives an event data structure which indicates the reason the callback was called, and a pointer to the guest (in the address space of the hypervisor, which is executing the hyperupcall). When the hyperupcall completes, it may return a value, which can be used by the hypervisor.

Writing the hyperupcall. With our framework, OS developers write C code which can access OS variables and data structures, assisted by the helper functions of the framework. A typical hyperupcall will read the event field, read or update OS data structures and potentially return data to the hypervisor. Since the hyperupcall is part of the OS, the developers can reference the same data structures used by the OS itself—for example, through header files. This greatly increases the maintainability of hyperupcalls, since data layout changes are synchronized between the OS source and the hyperupcall source.

It is important to note that a hyperupcall cannot invoke guest OS functions directly, since that code has not been secured by the framework. However, OS functions can be compiled into hyperupcalls and be integrated in the verified code.

3.2 Compilation

Once the hyperupcall has been written, it needs to be compiled into eBPF bytecode before the guest can register it with the hypervisor. Our framework generates this bytecode as part of the guest OS build process by running the hyperupcall C code through Clang and the eBPF LLVM backend, with some modifications to assist with address translation and verification:

Input field	Function
event	Event specific data including event ID.
hva	Host virtual address (HVA) in which the guest memory is mapped.
guest_mask	Guest address mask to mask bits which are higher than the guest memory address-width. Used for verification (§ 3.4).
vcpus	Pointers to the hypervisor VCPU data structure, if the event is associated with a certain VCPU, or a pointer to the guest OS data structure. Inaccessible to the hyperupcall, but used by helper functions.
vcpu_reg	Frequently accessed VCPU registers: instruction pointer and VCPU ID.
env	Environment variables, provided by the guest during hyperupcallregistration. Used to set address randomization offsets.

Table 4: *Hyperupcall context data.* These fields are populated by the hypervisor when a hyperupcall is called.

Guest memory access. To access guest memory, we use eBPF's direct packet access (DPA) feature, which was designed to allow programs to access network packets safely and efficiently without the use of helper functions. Instead of passing network packets, we utilize this feature by treating the guest as a "packet". Using DPA in this manner required a bug fix [2] to the eBPF LLVM backend, as it was written with the assumption that packet sizes are ≤64KB.

Address translations. Hyperupcalls allow the hypervisor to seamlessly use guest virtual addresses (GVAs), which makes it appear as if the hyperupcall was running in the guest. However, the code is actually executed by the hypervisor, where host virtual address (HVAs) are used, rendering guest pointers invalid. To allow the use of guest pointers transparently in the host context, these pointers therefore need to be translated from GVAs into HVAs. We use the compiler to make these translations.

To make this translation simple, the hypervisor maps the GVA range contiguously in the HVA space, so address translations can easily be done by adjusting the base address. As the guest might need the hyperupcall to access multiple contiguous GVA ranges—for example, one for the guest 1:1 direct mapping and of the OS text section [37]—our framework annotates each pointer with its respective "address space" attribute. We extend the LLVM compiler to use this information to inject eBPF code that converts each of the pointer from GVA to HVA by a simple subtraction operation. It should be noted that the generated code safety is not assumed by the hypervisor and is verified when the hyperupcall is registered.

Bound Checks. The verifier rejects code with direct memory accesses unless it can ensure the memory accesses are within the "packet" (in our case, guest memory) bounds. We cannot expect the hyperupcall programmer to perform the required checks, as the burden of adding them is substantial. We therefore enhance the compiler to automatically add code that performs bound checks prior to each memory access, allowing verification to pass. As we note in Section 3.4, the bounds checking is done using masking and not branches to ease verification.

Context caching. Our compiler extension introduces intrinsics to get a pointer to the context or to read its data. The context is frequently needed along the callback for calling helper functions and for translating GVAs. Delivering the context as a function parameter requires intrusive changes and can prevent sharing code between the guest and its hyperupcall. Instead, we use the compiler to cache the context pointer in one of the registers and retrieve it when needed.

3.3 Registration

After a hyperupcall is compiled into eBPF bytecode, it is ready to be registered. Guests can register hyperupcalls at any time, but most hyperupcalls are registered when the guest boots. The guest provides the hyperupcall event ID, hyperupcall bytecode and the virtual memory the hyperupcall will use. Each parameter is described below:

Hyperupcall event ID. ID of the event to handle.

Memory registration. The guest registers the virtual contiguous memory regions used by the hyperupcall. For global hyperupcalls, this memory is restricted to a maximum of 2% of the guest's total physical memory (configurable and enforced by the hypervisor).

Hyperupcall bytecode. The guest provides a pointer to the hyperupcall bytecode with its size.

3.4 Verification

The hypervisor verifies that each hyperupcall is safe to execute at registration time. Our verifier is based on the Linux eBPF verifier and checks three properties of the hyperupcall: memory accesses, number of runtime instructions, and helper functions used.

Ideally, verification is *sound*, ensuring only safe code passes verification, and *complete*, successfully verifying any safe program. While soundness cannot be compromised as it might jeopardize the system safety, many verification systems, including eBPF, sacrifice completeness to keep the verifier simple. In practice, the verifier requires programs to be written in a certain way to pass verification [66], and even then verification can fail due to path explosion. These limitations are at odds of our goal of making hyperupcalls simple to build.

We discuss the properties our verifier checks below, and how we simplify these checks to make verification as straightforward as possible.

Bounded runtime instructions. For global hyperupcalls, the eBPF verifier ensures that any possible execution of the hyperupcall contains a limited number of instructions, which is set by the hypervisor (defaulted to 4096). This ensures that the hypervisor can execute the hyperupcall in a timely manner, and that there are no infinite loops which can cause the hyperupcall not to exit.

Memory access verification. The verifier ensures that memory accesses only occur in the region bounded by the "packet", which in a hyperupcall is the virtual memory region provided during registration. As noted before, we enhance the compiler to automatically add code that proves to the verifier that each memory access is safe.

However, adding such code naively results in frequent verification failures. The current Linux eBPF verifier is quite limited in its ability to verify the safety of memory accesses, as it requires that they will be preceded by compare and branch instructions to prevent out of bound accesses. The verifier explores the possible execution paths and ensures their safety. Although the verifier employs various optimizations to prune branches and avoid walking every possible branch, verification often exhausts available resources and fails as we and others have experienced [65].

Therefore, instead of using compare and branch to ensure memory access safety, our enhanced compiler adds code that masks memory accesses offset within each range, preventing out-of-bounds memory accesses. We enhance the verifier to recognize this masking as safe. After applying this enhancement, all the programs we wrote passed verification.

Helper function safety. Hyperupcalls may call helper functions to both improve performance and to help limit the number of runtime instructions. Helper functions are a standard eBPF feature and the verifier enforces the helper functions which can be called, which may vary from event to event depending on hypervisor policy. For example, the hypervisor may disallow the use of `flush_tlb_vcpu` during memory reclamation, as it may block the system for an extended amount of time.

The verifier checks to ensure that the inputs to the helper function are safe, ensuring that the helper function only accesses memory which it is permitted to access. While these checks could be done in the helper function, new eBPF extensions allow the verifier to statically verify the helper function inputs. Furthermore, the hypervisor can also set a policy for inputs on a per-event basis (e.g, `memcpy` size for global hyperupcalls).

The number and complexity of helper functions should be limited as well, as they become part of the trusted computing base. We therefore only introduce simple helper functions, which mostly rely on code that the guest can already trigger today directly or indirectly, for example interrupt injection.

eBPF security. Two of the proof-of-concept exploits of the recently discovered “Spectre” hardware vulnerabilities [38, 30] targeted eBPF, which might raise concerns about eBPF and hyperupcall safety. While exploiting these vulnerabilities is simpler if an attacker can run unprivileged code in privileged context, just as hyperupcalls do, discovered attacks can be prevented [63]. In fact, these security vulnerabilities can make hyperupcalls more compelling as their mitigation techniques (e.g, return stack buffer stuffing [33]) induce extra overheads when context switches take place using traditional paravirtual mechanisms such as upcalls and hypercalls.

3.5 Execution

Verified hyperupcalls are installed into a per guest hyperupcall table. Once the hyperupcall has been registered and verified, the hypervisor executes hyperupcalls in response to events.

Hyperupcall patching. To avoid the overhead of testing whether hyperupcall is registered, the hypervisor uses a code patching technique, known in Linux as “static keys” [12]: a no-op instruction is set on each of the hypervisor hyperupcall invocation code only when hyperupcalls are registered.

Accessing remote VCPU state. Some hyperupcalls read or modify the state of remote VCPUs. These VCPUs may not be running or their state may be accessed by a different thread of the hypervisor. Even if the remote VCPU is preempted, the hypervisor may have already read some registers and not expect them to change until the VCPU resumes execution. If the hyperupcall writes to remote VCPU registers, it may break the hypervisor invariants and even introduce security issues.

Furthermore, reading remote VCPU registers can induce high overheads, as part of the VCPU state may be cached in another CPU, and must be written back to memory first if the VCPU state is to be read. More importantly, in Intel CPUs the VCPU state cannot be accessed by common instructions, and the VCPU must be “loaded” first before its state can be accessed by using special instructions (`VMREAD` and `VMWRITE`). Switching the loaded VCPU incurs significant overhead, which roughly 1800 cycles on our system.

For performance, we define synchronization points where the hypervisor is commonly preempted, and accessing the VCPU state is known to be safe. At these points we “decache” VCPU registers from the VMCS and write them to the memory so the hyperupcall can read them. The hyperupcall writes to remote VCPU registers and updates the decached value to flag the hypervisor to reload the register values into the VMCS before resuming that VCPU. Hyperupcalls that access remote VCPUs are executed on a best-effort basis, running only if the VCPU is in a synchronization point. The remote VCPU is prevented from resuming execution while the hyperupcall is running.

Using guest OS locks. Some of the OS data-structures are protected by locks. Hyperupcalls that require consistent guest OS data structure view should abide the synchronization scheme that the guest OS dictates. Hyperupcall, however, can only acquire locks opportunistically, since a VCPU might be preempted while holding a lock. The lock implementation might need to be adapted to support locking by an external entity, different than any VCPU. Releasing a lock can require relatively large code to handle slow-paths, which might prevent the timely verification of the hyperupcall.

While various ad-hoc solutions may be proposed, it seems a complete solution requires the guest OS locks to be hyperupcall-aware. It also necessitates support for calling eBPF function from eBPF code to avoid inflated code size that might cause verification failures. Since this support has been added very recently, our implementation does not include lock support.

4 Use Cases and Evaluation

Our evaluation is guided by the following questions:

- What are the overheads of using verified code (eBPF) versus native code? (§4.1).
- How do hyperupcalls compare to other paravirtual mechanisms (§4.3, 4.2, 4.5)?
- How can hyperupcalls enhance not only the performance (§4.3, 4.2) but also the security (§4.5) and debuggability (§4.4) of virtualized environments?

Testbed. Our testbed consists of a 48 core dual-socket Dell PowerEdge R630 server with Intel E5-2670 CPUs, a Seagate ST1200 disk, which runs Ubuntu 17.04 with Linux kernel v4.8. The benchmarks are run on guests with 16 VCPUs and 8GB of RAM. Each measurement was performed 5 times and the average result is reported.

Hyperupcall prototype. We implemented a prototype for hyperupcall support on Linux v4.8 and KVM, the hypervisor which is integrated in Linux. Hyperupcalls are compiled through a patched LLVM 4, and are verified through the Linux kernel eBPF verifier with the patches we described in §3. We enable the Linux eBPF “JIT” engine , which compiles the eBPF code to native machine code after verification. The correctness of the BPF JIT

	h-visor	runtime (cycles)		eBPF	C
use case	event	h-upcall	native	instr.	SLoC
discard § 4.3	reclaim	185	147	357	32
tracing § 4.4	exit	568	336	3308	889
TLB § 4.2	interrupt	395	530	111	112
protect § 4.5	exit	43	25	119	74
	map	108	92	170	52

Table 5: Evaluated hyperupcall use cases, comparison of runtime, eBPF instructions and number of lines of code.

engine has been studied and can be verified [74].

Use cases. We evaluate four hyperupcall use cases as listed in Table 5. Each use case demonstrates the use of hyperupcalls on different hypervisor events, and uses hyperupcalls of varying complexity.

4.1 Hyperupcall overheads

We evaluate the overheads of using verified code to service hypervisor requests by comparing the runtime of a hyperupcall versus native code with the same function (Table 5). Overall, we find that the absolute overhead of the verified code relative to native is small (< 250 cycles). For the TLB use case which handles TLB shootdown to inactive cores, our hyperupcall runs faster than native code since the TLB flush is deferred. The overhead of verifying a hyperupcall is minimal. For the longest hyperupcall (tracing), verification took 67ms.

4.2 TLB Shootdown

While interrupt delivery to VCPUs can usually be done efficiently, there is a significant penalty if the target VCPU is not running. This can occur if CPUs are overcommitted and scheduling the target VCPU requires preempting another VCPU. With synchronous interprocessor interrupts (IPIs), the sender resumes execution only after the receiver indicates the IPI was delivered and handled, resulting in prohibitive overheads.

The overhead of IPI delivery is most notable in the case of translation lookaside buffer (TLB) shootdowns, a software protocol that OSs use to keep TLBs—caches of virtual to physical address mapping—coherent. As common CPU architectures (e.g., x86) do not keep TLBs coherent in hardware, an OS thread that modifies a mapping sends an IPI to other CPUs that may cache the mapping, and these CPUs then flush their TLBs.

We use hyperupcalls to handle this scenario by registering a hyperupcall which handles TLB shootdowns when interrupts are delivered to a VCPU. The hypervisor provides that hyperupcall with the interrupt vector and the target VCPU after ensuring it is in quiescent state. Our hyperupcall checks whether this vector is the "remote function invocation" vector and whether the function pointer equals to the OS TLB flush function. If it does, it runs this function with few minor modifications: (1) instead of flushing the TLB using native instruction, the TLB flush is performed using a helper function, which defers it to the next VCPU re-entry; (2) TLB flush is performed even when the VCPU interrupts are disabled, as experimentally it improves performance.

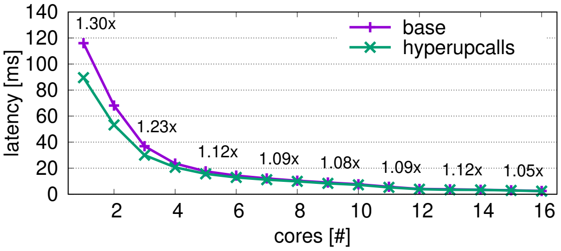

Figure 2: The latency of Apache when CPUs are overcommitted, with and without a hyperupcall that handle interrupts to preempted VCPUs. Numbers above data points indicate speedup over base.

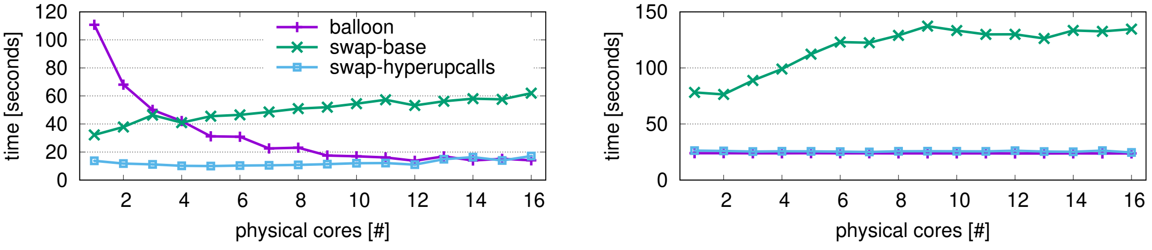
Admittedly, an alternative solution is available: introducing a hypercall that delegates TLB flushes to the hypervisor [52]. Although this solution can prevent TLB flushes, it requires a different code path, which may introduce hidden bugs [43], complicate the integration with OS code or introduce additional overheads [44]. This solution is also limited to TLB flushes, and cannot deal with other interrupts, for example, rescheduling IPIs.

Evaluation We run Apache Web server [23] in a guest using the default `mpm_event` module, which runs multithreaded workers to handle incoming requests. To measure performance, we use ApacheBench, an Apache HTTP server benchmarking tool, generating 10k requests using 16 connections, and measuring the request latency. The results, which are shown in Figure 2, show hyperupcalls reduce the latency by up to 1.3×. It might appear surprising that performance improves even when the physical CPUs are not oversubscribed. However, as VCPUs are often momentarily idle in this benchmark, they can also trigger an exit to the hypervisor.

4.3 Discarding Free Memory

Free memory, by definition, holds no needed data and can be discarded. If the hypervisor knows what memory is free in the guest, it can discard it during memory reclamation, snapshotting, live migration or lock-step execution [20] and avoid I/O operations for saving and restoring their content. Information on which memory pages are free, however, is held by the guest and unavailable to the hypervisor due to the semantic gap.

Throughout the years several mechanisms have been proposed to inform the hypervisor which memory pages



(a) reclaim

(b) refault

Figure 3: Time of guest memory reclaim of 7GB and refault, when reading a 4GB file, when CPUs are overcommitted. The x-axis shows the number of physical cores available. (a) As the number of physical cores decrease (and overcommitment increases), the time to reclaim memory increases. (b) refaulting free memory incurs a significant penalty for uncooperative swapping (swap-base) on its own because it swaps out active and free pages.

are free using paravirtualization. These solutions, however, either couple the guest and hypervisor [60]; induce overheads due to frequent hypercalls [41] or are limited to live migration [73]. All of these mechanisms suffer for an inherent limitation: without coupling the guest and the hypervisor, the guest needs to communicate to the hypervisor which pages are free.

In contrast, a hypervisor that supports hyperupcalls does not need to be notified about free pages. Instead, the guest sets a hyperupcall that describes whether a page is discardable based on the page metadata (Linux's `struct page`) and is based in Linux on the `is_free_buddy_page` function. When the hypervisor performs an operation that can benefit from discarding a free guest memory page such as reclaiming a page, the hypervisor invokes this hyperupcall to check whether the page is discardable. The hyperupcall is also called when the page is already unmapped, preventing a race in which it is discarded when it is no longer free.

Checking whether a page can be discarded must be done through a global hyperupcall, since the answer must be provided in a bounded and short time. As a result, the guest can only register part of its memory to be used by the hyperupcall, since this memory is never paged out to ensure timely execution of the hyperupcall. Our Linux guest registers the memory of the pages' metadata, which accounts to about 1.6% of the guest's physical memory.

Evaluation. To evaluate the performance of the "memory discard" hyperupcall, we measure its impact on a guest whose memory is reclaimed due to memory pressure. When memory is scarce, hypervisors can perform "uncooperative swapping"—directly reclaim guest memory and swap it out to disk. This approach, however, often leads to suboptimal reclamation decisions. Alternatively, hypervisors can use *memory ballooning*, a paravirtual mechanism in which a guest module is informed on host memory pressures and causes the guest to reclaim memory directly [71]. The guest can then make knowledgeable reclamation decisions and discard free pages. Although memory ballooning usually performs well, performance suffers when memory needs to be abruptly reclaimed [4, 6] or when the guest disk is set on a network attached storage [68], and it is therefore not used under high memory pressure [21].

To evaluate memory ballooning, uncooperative swapping and swapping with hyperupcalls we run a scenario in which memory and physical CPU need to be abruptly reclaimed, such as to accommodate a new guest. In the guest, we start and exit "memhog", making 4GB available to be reclaimed in the guest. Next, we make the guest busy by running a CPU intensive task with low memory footprint - the SysBench CPU benchmark, which computes primes using all VCPUs [39].

Now, with the the system busy, we simulate the need to reclaim resources to start a new guest by increasing memory and CPU overcommitment. We lower the number of physical CPUs available to the guest and restrict it to only 1GB of memory. We measure the time it takes to reclaim memory against the number of physical CPUs that were allocated for the guest (Figure 3a). This simulates a new guest starting up. Then, we stop increasing memory pressure and measure the time to run a guest application with a large memory footprint using the SysBench file read benchmark on 4GB (Figure 3b). This simulates the guest reusing pages that have been reclaimed by the hypervisor.

Ballooning reclaims memory slowly (up to 110 seconds) when physical CPUs are overcommitted, as the memory reclamation operations compete with the CPU intensive tasks on CPU time. Uncooperative swapping (swap-base) can reclaim faster (32 seconds), but as it is oblivious to whether memory pages are free, it incurs higher overhead in refaulting guest free pages. In contrast, when hyperupcalls are used, the hypervisor can promote free pages' reclamation and discard them, thereby reclaiming memory up to 8 times faster than balloon, with only 10% slowdown in refaulting the memory.

CPU overcommitment, of course, is not the only scenario where ballooning is non-responsive or unusable. Hypervisors refrain from ballooning when memory pressure is very high, and use host-level swapping instead [67]. It is possible for hyperupcalls to operate synergistically with ballooning: the hypervisor may use the balloon normally and use hyperupcalls when resource pressures are high or the balloon is not responding.

4.4 Tracing

Event tracing is an important tool for debugging correctness and performance issues. However, collecting traces for virtualized workloads is somewhat limited. Traces collected inside a guest do not show hypervisor events, such as when a VM-exit is forced, which can have significant effect on performance. For traces that are collected in the hypervisor to be informative, they require knowledge about guest OS symbols [15]. Such traces cannot be collected in cloud environments. In addition, each trace collects only part of the events and does not show how guest and hypervisor events interleave.

To address this issue, we run the Linux kernel tracing tool, `ftrace` [57], inside a hyperupcall. `Ftrace` is well suited to run in a hyperupcall. It is simple, lockless, and built to enable concurrent tracing in multiple contexts: non-maskable interrupt (NMI), hard and soft interrupt handlers and user processes. As a result, it was easily be adapted to trace hypervisor events concurrently with guest events. Using the `ftrace` hyperupcall, the guest can trace both hypervisor and guest events in one unified log, easing debugging. Since tracing all events use only guest logic, new OS versions can change the tracing logic, without requiring hypervisor changes.

Evaluation. Tracing is efficient, despite the hyperupcallcomplexity (3308 eBPF instructions), as most of the code deals with infrequent events that handles situations in which trace pages fill up. Tracing using hyperupcalls is slower than using native code by 232 cycles, which is still considerably shorter time than the time a context switch between the hypervisor and the guest takes.

Tracing is a useful tool for performance debugging, which can expose various overheads [79]. For example, by registering the `ftrace` on the VM-exit event, we see that many processes, including short-lived ones, trigger multiple VM exits due to the execution of the `CPUID` instruction, which enumerates the CPU features and must be emulated by the hypervisor. We find that the GNU C Library, which is used by most Linux applications, uses `CPUID` to determine the supported CPU features. This overhead could be prevented by extending Linux virtual dynamic shared object (vDSO) for applications to query the supported CPU features without triggering an exit.

4.5 Kernel Self-Protection

One common security hardening mechanisms that OSs employ is “self-protection”: OS code and immutable data write protection. However, this protection is done using page tables, allowing malware to circumvent it by modifying page table entries. To prevent such attacks, the use of nested page tables has been suggested, as these tables are inaccessible from the guest [50].

However, nesting can only provide a limited number of policies and for example, cannot whitelist guest code that is allowed to access protected memory. Hyperupcalls are much more expressive, allowing the guest to specify memory protection in a flexible manner.

We use hyperupcalls to provide hypervisor-level guest kernel self-protection, which can be easily modified to accommodate complex policies. In our implementation the guest sets a bitmap which marks protected pages, and registers hyperupcall on exit events, which checks the exit reason, whether a memory access occurred and if the guest attempted to write to protected memory according to the bitmap. If there is an attempt to access protected memory, a VM shutdown is triggered. The guest sets an additional hyperupcall on the “page map” event, which queries the required protection of the guest page frames. This hyperupcall prevents situations in which the hypervisor proactively prefaults guest memory.

Evaluation. This hyperupcall code is simple, yet incurs overhead of 43 cycles per exit. Arguably, only workloads which already experience very high number of context switches would be affected by the additional overheads. Modern CPUs prevent such frequent switches.

5 Conclusion

Bridging the semantic gap is critical performance and for the hypervisor to provide advanced services to guests. Hypercalls and upcalls are now used to bridge the gap, but they have several drawbacks: hypercalls cannot be initiated by the hypervisor, upcalls do not have a bounded runtime, and both incur the penalty of context switches. Introspection, an alternative which avoids context switches can be unreliable as it relies on observations instead of an explicit interface. Hyperupcalls overcome these limitations by allowing the guest to expose its *logic* to the hypervisor, avoiding a context switch by enabling the hyperupcall to safely execute guest logic directly.

We have built a complete infrastructure for developing hyperupcalls which allow developers to easily add new paravirtual features using the codebase of the OS. We have written and evaluated several hyperupcalls and show hyperupcalls improve virtualized performance by up to 2×, ease debugging of virtualized workloads and improve VM security.

Abstract

The need for countering Advanced Persistent Threat (APT) attacks has led to the solutions that ubiquitously monitor system activities in each host, and perform timely attack investigation over the monitoring data for analyzing attack provenance. However, existing query systems based on relational databases and graph databases lack language constructs to express key properties of major attack behaviors, and often execute queries inefficiently since their semantics-agnostic design cannot exploit the properties of system monitoring data to speed up query execution.

To address this problem, we propose a novel query system built on top of existing monitoring tools and databases, which is designed with novel types of optimizations to support timely attack investigation. Our system provides (1) domain-specific *data model and storage* for scaling the storage, (2) a domain-specific query language, *Attack Investigation Query Language (*AIQL*)* that integrates critical primitives for attack investigation, and (3) an optimized query engine based on the characteristics of the data and the semantics of the queries to efficiently schedule the query execution. We deployed our system in NEC Labs America comprising 150 hosts and evaluated it using 857 GB of real system monitoring data (containing 2.5 billion events). Our evaluations on a real-world APT attack and a broad set of attack behaviors show that our system surpasses existing systems in both efficiency (124x over PostgreSQL, 157x over Neo4j, and 16x over Greenplum) and conciseness (SQL, Neo4j Cypher, and Splunk SPL contain at least 2.4x more constraints than AIQL).

1 Introduction

Advanced Persistent Threat (APT) attacks are sophisticated (involving many individual attack steps across many hosts and exploiting various vulnerabilities) and stealthy (each individual step is not suspicious enough), plaguing many well-protected businesses [9, 11, 15, 18, 27, 30]. A recent massive Equifax data breach [11] has exposed the sensitive personal information of 143 million US customers. In order for enterprises to counter advanced attacks, recent approaches based on *ubiquitous system monitoring* have emerged as an important solution for monitoring system activities and performing attack investigation [37,42,47–49,54,57,58]. System monitoring observes *system calls* at the kernel level to collect system-level events about system activities. Collection of system monitoring data enables security analysts to investigate these attacks by *querying risky system behaviors* over the historical data [71].

Although attack investigation is performed after the attacks compromise enterprises' security, it is a considerably time-sensitive task due to two major reasons. First, advanced attacks include a sequence of steps and are performed in multiple stages. A timely attack investigation can help understand all attack behaviors and prevent the further damage of the attacks. Second, understanding the attack sequence is crucial to correctly patch the systems. A timely attack investigation can pinpoint the vulnerable components of the systems and protect the enterprises from future attacks of the same types.

Challenges: However, there are two major challenges for building a query system to support security analysts in efficient and timely attack investigation.

Attack Behavior Specification: The system needs to provide a query language with specialized constructs for expressing various types of attack behaviors using system monitoring data: (1) **Multi-Step Attacks**: risky behaviors in advanced attacks typically involve activities that are related to each other based on either specific attributes (e.g., the same process reads a sensitive file and accesses the network) or temporal relationships (e.g., file read happens before network access), which requires language constructs to easily specify *relationships among activities*. In Fig. 1, the attacker runs `osql`

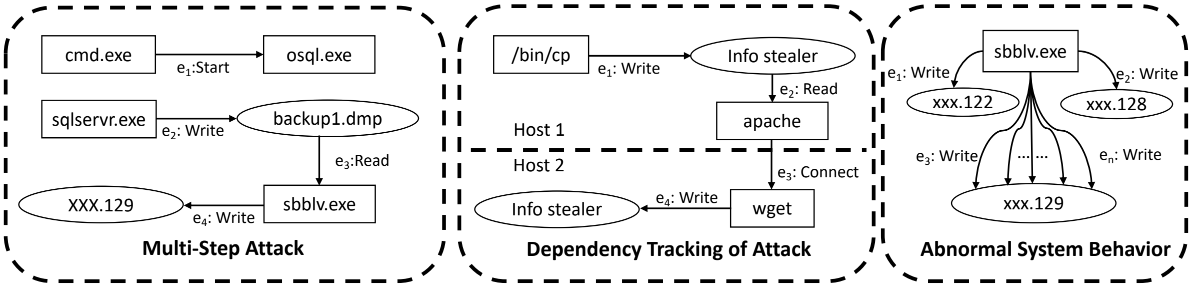

Figure 1: Major types of attack behaviors (events $e_1,\ldots,e_n$ are shown in ascending temporal order)

`.exe` to cause the database `sqlservr.exe` to dump its data into a file `backup1.dmp`. Later (i.e., `e3` happens after `e2`; temporal relationship), a malicious script `sbblv.exe` reads from the dump `backup1.dmp` (i.e., the same dump file in `e2` and `e3`; attribute relationship) and sends the data back to the attacker. (2) **Dependency Tracking of Attacks**: dependency analysis is often applied to track causality of data for discovering the "attack entry" (i.e., provenance) [48,49,61], which requires language constructs to *chain constraints among activities*. In Fig. 1, a malicious script `info_strealer` in Host 1 infects Host 2 via *network communications between* `apache` *and* `wget`. (3) **Abnormal System Behaviors**: frequency-based behavioral models are often required to express abnormal system behaviors, such as network access spikes [20, 29]. Investigating such spikes requires the system to support *sliding windows and statistical aggregation* of system activities, and compare the aggregate results with either *fixed thresholds (in absolute sense)* or the *historical results (in relative sense)*. In Fig. 1, a malicious script `sbblv.exe` sends a *large* amount of data to a particular destination `xxx.129`.[1]

Big-Data Security Analysis: System monitoring produces a huge amount of daily logs [55,69] (∼ 50 GB per day for 100 hosts), and the investigation of these attacks typically requires enterprises to keep at least a 0.5 ∼ 1 year worth of data [32]. Such *a big amount of security data* poses challenges for the system to meet the requirements of *timely* attack investigation.

Limitations of Existing Systems: Unfortunately, existing query systems do not address both of these inherent challenges in attack investigation. First, existing query languages in relational databases based on SQL and SPARQL [19,22,25] lack constructs for easily chaining constraints among relations. Graph databases such as Neo4j [16] and NoSQL tools such as MongoDB [38], Splunk [23], and ElasticSearch [10] are ineffective in expressing event relationships where two events have no common entities (e.g., e_1 and e_2 in Fig. 1). More importantly, none of these languages provide language constructs to express behavioral models with historical results. Second, system monitoring data is generated with a timestamp on a specific host in the enterprise, exhibiting strong *spatial and temporal properties*. However, none of these systems provide optimizations that exploit the domain specific characteristics of the data, missing opportunities to optimize the system for supporting timely attack investigation and often causing queries to run for hours (e.g., performance evaluation results in Sec. 6.2.2).

Contributions: We design and build a novel system for efficient attack investigation from system monitoring data. We build our system (∼ 50,000 lines of Java code) on top of existing system-level monitoring tools (i.e., auditd [28] and ETW [13]) for data collection and relational databases (i.e., PostgreSQL [19] and Greenplum [14]) for data storage and query. This enables our system to leverage the services provided by these mature infrastructures, such as data management, indexing mechanisms, recovery, and security. In particular, our system is designed with three novel types of optimizations. First, our system provides a domain-specific query language, *Attack Investigation Query Language (*AIQL*)*, which is optimized to express the three aforementioned types of attack behaviors. Second, our system provides domain-specific *data model and storage* for scaling the storage. Third, our system optimizes the query engine based on the characteristics of the monitoring data and the semantics of the queries to efficiently schedule the query execution. To the best of our knowledge, we are *the first to accelerate attack investigation via optimizing storage and query of system monitoring data.*

```
agentid = 1 // host id; spatial constraints
(at "01/01/2017") // temporal constraints
proc p1 start proc p2["%telnet%"] as evt1
proc p3 start ip ipp[dstport = 4444] as evt2
proc p4["%apache%"] read file f1["/var/www%"] as evt3
with p2 = p3,  // attribute relationship
evt1 before evt2, evt3 after evt2 // temporal
     relationships
return p1, p2, p4, f1
```

Query 1: AIQL Query for CVE-2010-2075 [5]

Domain-Specific Query Language (Sec. 4): Our AIQL language is designed for specifying the attack behaviors shown in Fig. 1 (i.e., Query 7 in Sec. 6.2.1, Query 3 in Sec. 4.2, and Query 5 in Sec. 6.2.1, respectively). Specifically, AIQL provides language constructs to specify re-

[1] While existing complex event processing systems [3, 12, 21] support similar features, they operate over stream rather than historical data stored in databases.

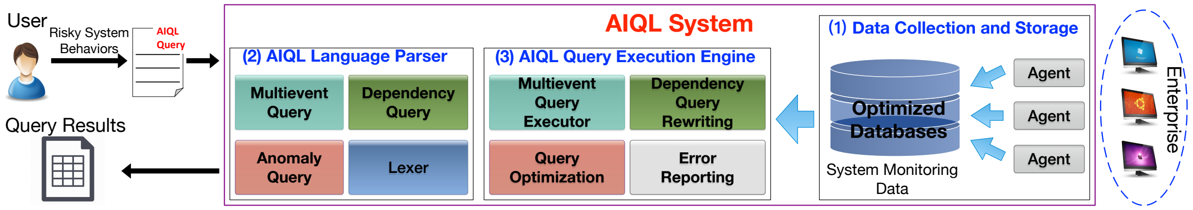

Figure 2: The AIQL system architecture

lationships among system activities (Sec. 4.1), chain constraints among activities (Sec. 4.2), and compute aggregate results in sliding time windows (Sec. 4.3). AIQL adopts the {*subject-operation-object*} syntax to represent system behavior patterns as events (e.g., `proc p1 write file f1`) and supports *attribute relationships* and *temporal relationships* of multiple events, as well as syntax shortcuts based on context-aware inference (Sec. 4.1). As shown in Query 1, AIQL can relate multiple system activities using spatial/temporal constraints and attribute/temporal relationships.

Data Model and Storage (Sec. 3.2): Our system models system monitoring data as a sequence of events, where each event describes how a process interacts with a system resource, such as writing to a file. More importantly, our system clearly identifies the spatial and temporal properties of the events, and leverages these properties to partition the data storage in both *spatial and temporal dimensions*. Such partitioning presents opportunities for parallel processing of query execution (Sec. 5.2).

Query Scheduling (Sec. 5): Our system identifies both *spatial* and *temporal* constraints in AIQL queries, and optimizes the query execution in two aspects: (1) for AIQL queries that involve multiple event patterns, our system prioritizes the search of event patterns with high pruning power, maximizing the reduction of irrelevant events as early as possible; (2) our system breaks down the query into independent sub-queries along temporal and spatial dimensions and executes them in parallel.

Evaluation: We deployed the AIQL system in NEC Labs America comprising 150 hosts. We performed a broad set of attack behaviors in the deployed environment, and evaluated the query performance and conciseness of AIQL against existing systems using 857 GB of real system monitoring data (16 days; 2.5 billion events): (1) our end-to-end efficiency evaluations on an APT attack case study (27 queries) show that AIQL surpasses both PostgreSQL (124x) and Neo4j (157x); (2) our performance evaluations show that the query scheduling employed by AIQL is efficient in both single-node databases (40x over PostgreSQL scheduling) and parallel databases (16x over Greenplum scheduling); (3) our conciseness evaluations on four major types of attack behaviors (19 queries) show that SQL, Neo4j Cypher, and Splunk SPL contain at least 2.4x more constraints, 3.1x more words, and 4.7x more characters than AIQL. All queries and a demo video are available on our *project website [1]*.

2 System Overview and Threat Model

Fig. 2 shows the AIQL system architecture: (1) we deploy monitoring agents across servers, desktops and laptops in the enterprise to monitor system activities by collecting information about system calls from kernels. The collected system monitoring data is then sent to the central server and stored in our optimized data storage (Sec. 3); (2) the language parser, implemented using ANTLR 4 [2], analyzes input queries and generates query contexts. A query context is an object abstraction of the input query that contains all the required information for the query execution. Multievent syntax, dependency syntax, and anomaly syntax are supported (Sec. 4); (3) the query execution engine executes the generated query contexts to search for the desired attack behaviors. Based on the data storage and the query semantics, domain-specific optimizations, such as relationship-based scheduling and temporal & spatial parallelization, are adopted to speedup the query execution (Sec. 5).

Threat Model: Our thread model follows the threat model of previous work [34, 48, 49, 54, 55]. We assume that kernel is trusted, and the system monitoring data collected from kernel is not tampered with [13, 28]. Any kernel-level attack that deliberately compromises security auditing systems is beyond the scope of this work.

3 Data Model and Storage

3.1 Data Model and Collection

System monitoring data records the interactions among system resources as system events [48]. Each of the recorded event occurs on a particular host at a particular time, thus exhibiting strong spatial and temporal properties. Existing works have indicated that on most modern operating systems (Windows, Linux and OS X), system resources (system entities) in most cases are files, processes, and network connections [42, 45, 48, 49]. Thus, in our data model, we consider system *entities* as *files*, *processes*, and *network connections*. We define a system event as the interaction among two system entities represented using the triple ⟨*subject, operation, object*⟩, which consists of the initiator of the interaction, the type

Table 1: Representative attributes of system entities

Entity	Attributes
File	Name, Owner/Group, VolID, DataID, etc.
Process	PID, Name, User, Cmd, Binary Signature, etc.
Network Connection	IP, Port, Protocol

of the interaction, and the target of the interaction. Subjects are processes originating from software applications such as Firefox, and objects can be files, processes and network connections. We categorize system events into three types according to their object entities, namely *file events*, *process events*, and *network events*.

Both entities and events have critical security-related attributes (Tables 1 and 2). The attributes of entities include the properties to support various security analyses (e.g., file name, process name, and IP addresses), and the unique identifiers to distinguish entities (e.g., file data ID and process ID). The attributes of events include event origins (i.e., agent ID and start time/end time), operations (e.g., file read/write), and other security-related properties (e.g., failure code). Agent ID refers to the unique ID of the host where the entity/event is observed.

Data Collection: We implement data collection agents for Windows and Linux based on ETW event tracing [13] and the Linux Audit Framework [28]. Tables 1 and 2 show representative attributes of our collected data.

3.2 Data Storage

After the modeling, we store the data in relational databases powered by PostgreSQL [19]. Relational databases come with mature indexing mechanisms and are scalable to massive data. However, even with indexes for speeding up queries, relational databases still face challenges in handling high ingest rates of massive system monitoring data. We next describe how we address these challenges to optimize the database storage.

Time and Space Partitioning: System monitoring data exhibits strong *temporal and spatial properties*: the data collected from different agents is independent from each other, and the timestamps of the collected data increase monotonically. Queries of the data are often specified with a specific time range or a host, or across many hosts within some time interval. Therefore, when storing the data, we partition the data in both the time and the space dimensions: separating groups of agents into table partitions and generating one database per day for the data collected on that day. We build various types of indexes on the attributes that will be queried frequently, such as executable name of process, name of file, source/destination IP of network connection.

Hypertable: For large organizations with hundreds or thousands of machines, we scale the data storage using MPP (massively parallel processing) databases Greenplum [14]. These databases intelligently distribute the storage and search of events and entities based on the spatial and temporal properties of our data model.

Table 2: Representative attributes of system events

Operation	Read/Write, Execute, Start/End, Rename/Delete
Time/Sequence	Start Time/End Time, Event Sequence
Misc.	Subject ID, Object ID, Failure Code

Time Synchronization: We correct potential time drifting of events on agents by applying synchronization protocols like Network Time Protocol (NTP) [17] at the client side, and checking with the clock at the server side.

4 Query Language Design

AIQL is designed to specify three types of attack behaviors: multi-step attacks, dependency tracking of attacks, and abnormal system behaviors. In contrast to previous query languages [7, 22, 23, 25] that focus on the specification of relation joins or graph paths, AIQL uniquely integrates the critical primitives for attack investigation, providing explicit constructs for spatial/temporal constraints, relationship specifications, constraint chaining among system events, and the access to aggregate and historical results in sliding time windows. Grammar 1 shows the representative rules of AIQL.

4.1 Multievent AIQL Query

For multievent queries, AIQL provides explicit language constructs for system events (in a natural format of $\{$*subject-operation-object*$\}$), spatial/temporal constraints, and event relationships.

A Running Example: Query 2 specifies an example system behavior that probes user command history files. Multiple context-aware syntax shortcuts (illustrated in comments) are used, such as attribute inference and omitting unreferenced entity IDs (details are given later).

```
agentid = 1 // unique id of the enterprise host
(at "01/01/2017") // time window
proc p2 start proc p1 as evt1
proc p3 read file[".viminfo" || ".bash_history"] as
     evt2 // .viminfo -> name=.viminfo; omit file ID
with p1 = p3, evt1 before evt2
return p2, p1 //p2 -> p2.exe_name, p1 -> p1.exe_name
sort by p2, p1
```

Query 2: Command history probing

Global Constraints: The global constraint rule ($\langle$*global_cstr*$\rangle$) specifies the constraints for all event patterns (e.g., *agentid* and *time window* in Query 2).

Event Pattern: The event pattern rule ($\langle$*evt_patt*$\rangle$) specifies an event pattern that consists of the subject/object entity ($\langle$*entity*$\rangle$), operation ($\langle$*op_exp*$\rangle$), and optional event ID ($\langle$*evt*$\rangle$). The entity rule ($\langle$*entity*$\rangle$) consists of entity type, optional entity ID, and optional attribute constraints ($\langle$*attr_cstr*$\rangle$). Logical operators ("&&" for AND,

"||" for OR, "!" for NOT) can be used in ⟨*op_exp*⟩ and ⟨*attr_cstr*⟩ to form complex expressions. The optional time window rule (⟨*twind*⟩) further narrows down the search for the event pattern. Common time formats (US formats and ISO 8601) and granularities are supported.

```
⟨aiql⟩          ::= ⟨multievent⟩ | ⟨dependency⟩
⟨multievent⟩    ::= (⟨global_cstr⟩)* (⟨m_query⟩)+
⟨dependency⟩    ::= (⟨global_cstr⟩)* ⟨d_query⟩
⟨global_cstr⟩   ::= ⟨cstr⟩ | '(' ⟨twind⟩ ')' | ⟨slide_wind⟩
⟨twind⟩         ::= 'from' ⟨datetime⟩ 'to' ⟨datetime⟩ | ...
⟨slide_wind⟩    ::= ⟨wind_length⟩ ⟨wind_step⟩
Multi-event query:
⟨m_query⟩       ::= ⟨evt_patt⟩+ ⟨evt_rel⟩? ⟨return⟩ ⟨filter⟩?
⟨evt_patt⟩      ::= ⟨entity⟩ ⟨op_exp⟩ ⟨entity⟩ ⟨evt⟩? ('(' ⟨twind⟩ ')')?
⟨entity⟩        ::= ⟨entity_type⟩ ⟨e_id⟩ ? ('[' ⟨attr_cstr⟩']')?
⟨attr_cstr⟩     ::= ⟨cstr⟩
                 |  '!'⟨attr_cstr⟩
                 |  ⟨attr_cstr⟩ ('&&' | '||') ⟨attr_cstr⟩
                 |  '(' ⟨attr_cstr⟩ ')'
⟨cstr⟩          ::= ⟨attr⟩ ⟨bop⟩ ⟨val⟩
                 |  '!'? ⟨val⟩
                 |  ⟨attr⟩ 'not'? 'in' '(' ⟨val⟩ (',' ⟨val⟩)* ')'
⟨op_exp⟩        ::= ⟨op⟩
                 |  '!'⟨op_exp⟩
                 |  ⟨op_exp⟩ ('&&' | '||') ⟨op_exp⟩
                 |  '(' ⟨op_exp⟩ ')'
⟨evt⟩           ::= 'as' ⟨evt_id⟩ ('[' ⟨attr_cstr⟩']')?
⟨evt_rel⟩       ::= 'with' ⟨rel⟩ (',' ⟨rel⟩)*
⟨rel⟩           ::= ⟨attr_rel⟩ | ⟨temp_rel⟩
⟨attr_rel⟩      ::= ⟨e_id⟩'.'⟨attr⟩ ⟨bop⟩ ⟨e_id⟩'.'⟨attr⟩
                 |  ⟨e_id⟩ ⟨bop⟩ ⟨e_id⟩
⟨temp_rel⟩      ::= ⟨evt_id⟩ ('before' | 'after' | 'within') ('[' ⟨val⟩'–'⟨val⟩ ⟨timeunit⟩']')? ⟨evt_id⟩
⟨return⟩        ::= 'return' 'count'? 'distinct'? ⟨res⟩ (',' ⟨res⟩)*
⟨res⟩           ::= ⟨e_id⟩('.'⟨attr⟩)?
                 |  ⟨agg_func⟩'(' ⟨res⟩ ')'
                 |  'as' ⟨rename_id⟩
⟨group_by⟩      ::= 'group by' ⟨res⟩ (',' ⟨res⟩)*
⟨filter⟩        ::= 'having' ⟨expr⟩
                 |  'sort by' ⟨attr⟩ (',' ⟨attr⟩)* ('asc' | 'desc')?
                 |  'top' ⟨int⟩
Dependency query:
⟨d_query⟩       ::= (('forward' | 'backward') ':')? (⟨entity⟩ ⟨op_edge⟩)+ ⟨entity⟩ ⟨return⟩ ⟨filter⟩?
⟨op_edge⟩       ::= ('->' | '<-') '[' ⟨op_exp⟩ ']'
```

Grammar 1: Representative BNF grammar of AIQL

Event Attribute and Temporal Relationships: The event relationship rule (⟨*evt_rel*⟩) specifies how multiple event patterns are related. The attribute relationship rule (⟨*attr_rel*⟩) uses attribute values of event patterns to specify their relationships. In Query 2, `p1=p3` (inferred as `p1.id=p3.id`) indicates that two event patterns `evt1` and `evt2` are linked by the same entity. The temporal relationship rule (⟨*temporal_rel*⟩) specifies temporal order ("before", "after", "within") of event patterns. For example, `evt1 before[1-2 minutes] evt2` specifies that `evt1` occurred 1 to 2 minutes before `evt2`.

Event Return and Filters: The event return rule (⟨*return*⟩) retrieves the attributes of the matched events. Constructs such as "count", "distinct", "top", "having", and "sort by" are provided for result manipulation and filtering.

Context-Aware Syntax Shortcuts: AIQL includes language syntax shortcuts to make queries more concise.

- *Attribute inference*: (1) default attribute names will be inferred if users specify only attribute values in an event pattern, or specify only entity IDs in the return clause. We select the most commonly used attributes in security analysis as the default attributes: `name` for files, `exe_name` for processes, and `dst_ip` for networks; (2) `id` will be used as the default attribute if users specify only entity IDs in attribute relationships.
- *Optional ID*: the ID of entity/event can be omitted if it is not referenced in the event relationship clause or the event return clause.
- *Entity ID reuse*: reusing entity IDs in multiple event patterns implicitly means that these event patterns share the same entity.

For example, in Query 2, `".viminfo"`, `return p2`, and `p1 = p3` will be inferred as `name = ".viminfo"`, `return p2.exe_name`, and `p1.id = p3.id`, respectively. Query 2 also omits the file ID in *evt2* since it is not referenced. We can also replace *p3* with *p1* in *evt2* and omit `p1 = p3`.

4.2 Dependency AIQL Query

AIQL provides the dependency syntax that chains constraints and specifies temporal relationships among event patterns, facilitating the specification of dependency tracking of attacks. The syntax specifies a sequence of event patterns in the form of a path, where nodes in the path represent system entities and edges represent operations. The `forward` and `backward` keywords can be used to specify the temporal order of the events on the path: `forward` (`backward`) means the events found by the left-most event pattern occurred earliest (latest).

```
1 (at "01/01/2017")
2 forward: proc p1["%/bin/cp%", agentid = 2] ->[write]
      file f1["/var/www/%info_stealer%"]
3 <-[read] proc p2["%apache%"]
4 ->[connect] proc p3[agentid=3] // tracking across
      host
5 ->[write] file f2["%info_stealer%"]
6 return f1, p1, p2, p3, f2
```

Query 3: Forward tracking for malware ramification

Query 3 shows a forward dependency query in AIQL that investigates the ramification of malware (`info_stealer`), which originates from host h_a (`agentid = 2`) and affects host h_b (`agentid = 3`) through an Apache web server. Lines 2-3 specify that `p1` writes to `f1`, and then `f1` is read by `p2`. Such syntax eliminates the need to repetitively specify the shared entity (i.e., `f1`) in each event pattern. An example result may show that `p3` is the `wget` process that downloads the malicious script from host h_b. The operation `->[connect]` at Line 4 indicates the search will track dependencies of events across hosts.

4.3 Anomaly AIQL Query

AIQL provides the constructs of *sliding time window* with common aggregation functions (e.g., `count`, `avg`, `sum`) to facilitate the specification of frequency-based system behavioral models. Besides, AIQL provides the construct of *history states*, allowing queries to compare frequencies using historical information.

```
1 (at "01/01/2017")
2 window = 1 min
3 step = 10 sec
4 proc p read ip ipp
5 return p, count(distinct ipp) as freq
6 group by p
7 having freq > 2 * (freq + freq[1] + freq[2]) / 3
```

Query 4: Simple moving average for network frequency

Query 4 shows an anomaly query that specifies a 1-minute sliding time window and computes the moving average [44] to detect network spikes (Line 7). AIQL supports the common types of moving averages through built-in functions (SMA, CMA, WMA, EWMA [44]). For example, the computation of EWMA for network frequency with normalized deviation can be expressed as: `(freq - EWMA(freq, 0.9)) / EWMA(freq, 0.9) > 0.2`.

5 Query Execution Engine

The AIQL query execution engine executes the query context generated by the parser and optimizes the query execution by leveraging domain-specific properties of system monitoring data. Optimizing a query with many constraints is a difficult task due to the complexities of joins and constraints [8]. AIQL addresses these challenges by providing explicit language constructs for spatial/temporal constraints and temporal relationships, so that the query engine can directly optimize the query execution by: (1) using event patterns as a basic unit for generating data queries and leveraging attribute/temporal relationships to optimize the search strategy; (2) leveraging the spatial and temporal properties of system monitoring data to partition the data and executing the search in parallel based on the spatial/temporal constraints.

5.1 Query Execution Pipeline

Fig. 3 shows the execution pipeline of a multievent query. Based on the query semantics, for every event pattern, the engine synthesizes a *SQL data query*, which searches the optimized relational databases (Sec. 3.2) for the matched events. The data query scheduler prioritizes the execution of data queries to optimize execution performance (Sec. 5.2). Execution results of each data query are further processed by the executor to perform joins and filtering to obtain the desired results. Note that by weaving all these join and filtering constraints together, the engine could generate a large SQL with many constraints mixed together. Such strategy suffers from indeterministic optimizations due to the large number of constraints and often causes the execution to last for minutes or even hours (Sec 6.2.2). For an input dependency query, the engine compiles it to an equivalent multievent query for execution. For an anomaly query, the engine maintains the aggregate results as historical states and performs the filtering based on the historical states.

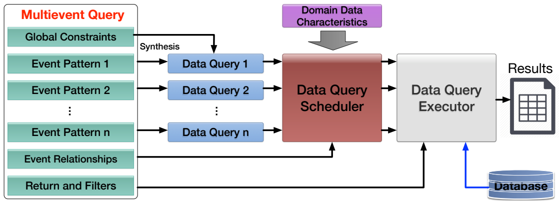

Figure 3: Execution of a multievent AIQL query

5.2 Data Query Scheduler

The data query scheduler in Fig. 3 schedules the execution of data queries. A straightforward scheduling strategy (*fetch-and-filter*) is to: (1) execute data queries separately and store the results of each query in memory; (2) leverage event relationships to filter out results that do not satisfy the constraints. However, this strategy incurs non-trivial computation costs and memory space if some data queries return a large number of results.

Relationship-Based Scheduling: To optimize the execution scheduling of data queries, we leverage two insights based on event relationships: (1) event patterns have different levels of pruning power, and the query engine can prioritize event patterns with more pruning power to narrow the search; (2) if two event patterns are associated with an event relationship, the query engine can execute the data query for the pattern that has more constraints first (likely having more pruning power), and use the execution results to constrain the execution of the other data query.

Algorithm 1 gives the *relationship-based* scheduling:

1. A pruning score is computed for every event pattern based on the number of constraints specified.
2. Event relationships are sorted based on the relationship type (process events and network events are sorted in front of file events) and the sum of the involved event patterns' pruning scores.
3. The main loop processes event relationships returned from the sorted list, executes data queries, and gener-

ates result tuples. The engine executes the data query whose associated event pattern has a higher pruning score first, and leverages existing results to narrow the search scope. To facilitate tuple management, we maintain a map M that stores the mapping from the event pattern ID to the set of event ID tuples that its execution results belong to. As the loop continues, new tuple sets are created and put into M, and old tuple sets are updated, filtered, or merged.

4. After analyzing all event relationships, if there remain unexecuted data queries, these queries are executed and the corresponding results are put into M.
5. The last step is to merge tuple sets in M, so that all event patterns are mapped to the same tuple set that satisfy all constraints.

Algorithm 1: Relationship-based scheduling

```
Input: $n$ data queries: $Q = \{q_i \mid i \leq n, i \in \mathbb{N}^+\}$
       $n$ event patterns: $E = \{e_i \mid i \leq n, i \in \mathbb{N}^+\}$
       $m$ event relationships: $R = \{rel(e_i, e_j)\}$
Output: Event ID tuples that satisfy all constraints
1. $\forall e_i \in E, score(e_i) \xleftarrow{compute} e_i$;
2. $R_{sorted} \xleftarrow{sort} R$;
3. Initialize empty set $Exec$, empty map $M$;
for $rel(e_i, e_j)$ in $R_{sorted}$ do
    if $e_i$ not in $Exec$ and $e_j$ not in $Exec$ then
        // Suppose $score(e_i) \geq score(e_j)$
        $S_i \xleftarrow{execute} q_i$; $Exec.add(e_i)$;        // $S_i$:event ID set
        $S_j \xleftarrow[S_i]{execute} q_j$; $Exec.add(e_j)$;
        $T \leftarrow S_i \times S_j |_{rel(e_i,e_j)}$;   // create tuple set from
        $S_i$ and $S_j$, then filter by $rel(e_i,e_j)$
        $M.put(e_i, T)$; $M.put(e_j, T)$;
    else if Either of $\{e_i, e_j\}$ in $Exec$ then
        // Suppose $e_i$ in $Exec$
        $S_j \xleftarrow[S_i]{execute} q_j$; $Exec.add(e_j)$;
        $T \leftarrow M.get(e_i)$; $T' \leftarrow T \times S_j |_{rel(e_i,e_j)}$;        // update
        tuple set using $S_j$ and $rel(e_i,e_j)$
        $replaceVals(M, T, T')$; $M.put(e_j, T')$;
    else
        $T_i \leftarrow M.get(e_i)$; $T_j \leftarrow M.get(e_j)$;
        if $T_i = T_j$ then
            $T' \leftarrow T_i |_{rel(e_i,e_j)}$;           // filter tuple set
            $replaceVals(M, T_i, T')$;
        else
            $T' \leftarrow T_i \times T_j |_{rel(e_i,e_j)}$;     // merge tuple sets
            $replaceVals(M, T_i, T')$; $replaceVals(M, T_j, T')$;
4. for $e_i \in E$ and $e_i$ not in $Exec$ do
    $S_i \xleftarrow{execute} q_i$; $Exec.add(e_i)$; $M.put(e_i, S_i)$;
5. while $unique(M.values()) > 1$ do
    Pick $T_i$, $T_j$ from $M.values()$, such that $T_i \neq T_j$;
    $T' \leftarrow T_i \times T_j$;                         // merge tuple sets
    $replaceVals(M, T_i, T')$; $replaceVals(M, T_j, T')$;
6. Return $unique(M.values())$;

Function replaceVals (M, T, T')
    Replace all values $T$ stored in $M$ with $T'$;
```

Our empirical results (Sec. 6.3.2 and 6.3.3) demonstrate that the number of constraints work well in approximating the pruning power of event patterns in a broad set of queries, even though they may not accurately represent the size of the results returned by event patterns.

Time Window Partition: The AIQL query engine leverages temporal properties of the data to further speed up the execution of synthesized data queries: the engine partitions the time window of a data query into sub-queries with smaller time windows, and executes them in parallel. Currently, our system splits the time window into days for a query over a multi-day time window.

6 Deployment and Evaluation

We deployed the AIQL system in NEC Labs America comprising 150 hosts (10 servers, 140 employee stations). We performed a series of attacks based on known exploits in the deployed environment and constructed 46 AIQL queries to investigate these attacks, demonstrating the expressiveness of AIQL. To evaluate the effectiveness of AIQL in supporting timely attack investigation, we evaluate the query *efficiency* and *conciseness* against existing systems: PostgreSQL [19], Neo4j [16], Splunk [23]. We also evaluate the efficiency offered by our data query scheduler (Sec. 5.2) in both storage settings: PostgreSQL and Greenplum. In total, our evaluations use 857GB of real system monitoring data (16 days; 2.5 billion events).

6.1 Evaluation Setup

The evaluations are conducted on a database server with an Intel(R) Xeon(R) CPU E5-2660 (2.20GHz), 64GB RAM, and a RAID that supports four concurrent reads/writes. Neo4j databases are configured by importing system entities as nodes and system events as relationships. Greenplum databases are configured to have 5 segment nodes that can effectively leverage the concurrent reads/writes of RAID. For each AIQL query (except anomaly queries), we construct semantically equivalent SQL, Cypher, and Splunk SPL queries. We measure the execution time and the conciseness of each query. Note that we omit the performance evaluation of Splunk since the community version is limited to 500MB per day and the enterprise version is prohibitively expensive ($1,900 per GB). Nevertheless, Splunk's limited support for joins [24] makes it inappropriate for investigating multi-step attack behaviors. Due to the limited expressiveness of SQL and Cypher, we cannot compare the anomaly queries (e.g., Query 5). All queries are available on our *project website [1].*

6.2 Case Study: APT Attack Investigation

We conduct a case study by asking white hat hackers to perform an APT attack in the deployed environment, as

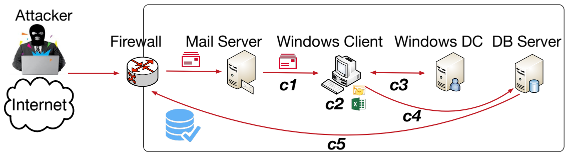

Figure 4: Environmental setup for the APT attack

shown in Fig. 4. Below are the attack steps:

c1 Initial Compromise: The attacker sends a crafted email to the victim. The email contains an Excel file with a malicious macro embedded.

c2 Malware Infection: The victim opens the Excel file through the Outlook mail client and runs the macro, which downloads and executes a malware (CVE-2008-0081 [4]) to open the backdoor to the attacker.

c3 Privilege Escalation: The attacker enters the victim's machine through the backdoor, scans the network ports to discover the IP address of the database, and runs the database cracking tool (`gsecdump.exe`) to obtain the credentials of the user database.

c4 Penetration into Database Server: Using the credentials, the attacker penetrates into the database server and delivers a VBScript to drop another malware, which creates another backdoor to the attacker.

c5 Data Exfiltration: With the access to the database server, the attacker dumps the database content using `osql.exe` and sends the data dump back.

Anomaly Detectors: We deployed two anomaly detectors based on existing solutions [36,52,66]. The first detector is deployed on the database server, which monitors network data transfer and emits alerts when the transfer amount is abnormally large. The second detector is deployed on the Windows client, which monitors process creation and emits alerts when a process starts an unexpected child process. These detectors may produce false positives, and we need tools like AIQL to investigate the alerts before taking any further action.

6.2.1 Attack Investigation Procedure

Our investigation assumes no prior knowledge of the detailed attack steps but merely the detector alerts. We start with these alerts and iteratively compose AIQL queries to investigate the entire attack sequence.

Step c5: We first examine the alerts reported by the database server detector, and identify a suspicious external IP "XXX.129" (obfuscated for privacy). Existing network traffic detectors usually cannot capture the precise process information [50,64]. Thus, we first compose an anomaly AIQL query that computes moving average (SMA3) to find processes which transfer a large amount of data to this suspicious IP.

```
(at "mm/dd/2017") // date (obfuscated)
agentid = xxx // SQL database server (obfuscated)
window = 1 min, step = 10 sec
proc p write ip i[dstip="XXX.129"] as evt
return p, avg(evt.amount) as amt
group by p
having (amt > 2 * (amt + amt[1] + amt[2]) / 3)
```

Query 5: AIQL anomaly query for large file transfer

Query 5 finishes execution within 4 seconds and identifies a suspicious process "sbblv.exe". We then compose a multievent AIQL query to find the data sources for this process (Query 6).

```
(at "mm/dd/2017")
agentid = xx // SQL database server (obfuscated)
proc p1["%sbblv.exe"] read || write file f1 as evt1
proc p1 read || write ip i1[dstip="XXX.129"] as evt2
with evt1 before evt2
return distinct p1, f1, i1, evt1.optype, evt1.access
```

Query 6: Starter AIQL query for *c5*

We identify a suspicious file "BACKUP1.DMP" for `f1` out of the other normal DLL files. We investigate its creation process and find "sqlservr.exe", which is a standard SQL server process with verified signature. Thus, we speculate that the attacker penetrates into the SQL server, dumps the data ("BACKUP1.DMP"), and sends the data back to his host ("XXX.129"). We verify this by checking that "osql.exe" process is started by "cmd.exe" (OSQL utility is often involved in many SQL database attacks). Query 7 gives the complete query for investigating the step *c5*.

```
(at "mm/dd/2017")
agentid = xxx // SQL database server (obfuscated)
proc p1["%cmd.exe"] start proc p2["%osql.exe"] as
     evt1
proc p3["%sqlservr.exe"] write file f1["%backup1.dmp"
     ] as evt2
proc p4["%sbblv.exe"] read file f1 as evt3
proc p4 read || write ip i1[dstip="XXX.129"] as evt4
with evt1 before evt2, evt2 before evt3, evt3 before
     evt4
return distinct p1, p2, p3, f1, p4, i1
```

Query 7: Complete AIQL query for *c5*

Steps c4-c1: The investigation for *c4-c1* is similar to *c5*, including iterative query execution and editing. In total, we constructed 26 multievent queries and 1 anomaly query to successfully investigate the APT attack, touching 119GB of data/422 million events.

6.2.2 Evaluation Results

As we can see, attack investigation is an iterative process that revises queries: (1) latter iterations add more event patterns based on the selected results from the former queries, and (2) 4-5 iterations are needed before finding a complete query with 5-7 event patterns. Thus, *slow response* and *verbose specification* could greatly impede the effectiveness and efficiency of the investigation.

End-to-End Execution Efficiency: Fig. 5 shows the execution time of AIQL queries, SQL queries in PostgreSQL, and Cypher queries in Neo4j. For evaluation

Table 3: Aggregate statistics for case study

Attack Step	# of Queries	# of Evt Patterns	AIQL (s)	PostgreSQL (s)	Neo4j (s)
c1	1	3	3.8	3.1	10.8
c2	8	27	31.0	8038.7	10981.7
c3	2	4	15.9	15.3	3615.6
c4	8	35	61.0	10906.7	8150.6
c5	7	18	58.8	2166.5	4285.4
All	26	87	170.5	21130.3	27044.1

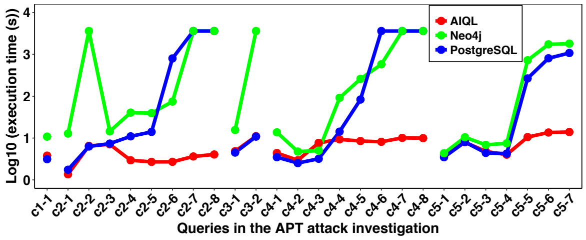

Figure 5: Log10-transformed query execution time

fairness, PostgreSQL and Neo4j databases store the same copies of data and employ the same schema and index designs as AIQL, but they do not employ our domain-specific data storage optimizations such as spatial and temporal partitioning, nor our scheduling optimizations.[2] Table 3 shows aggregate statistics for investigating each attack step, including the number of queries, the number of event patterns, and the total investigation time (second). We observe that: (1) Neo4j generally runs slower than PostgreSQL, due to the lack of support for efficient joins; (2) PostgreSQL and Neo4j become very slow when the query becomes complex and the number of event patterns (hence the required table joins) becomes large. Many large queries in PostgreSQL and Neo4j cannot finish within 1 hour (e.g., c2-7, c2-8, c4-7, c4-8); (3) all AIQL queries finish within 15 seconds, and the performance of the queries grows linearly with the number of event patterns (rather than the exponential growth in PostgreSQL and Neo4j), demonstrating the effectiveness of our domain-specific storage optimizations and query scheduling. (4) the total investigation time is ~5.9 hours for PostgreSQL and ~7.5 hours for Neo4j, which is a significant bottleneck for a timely attack investigation. In contrast, the total investigation time for AIQL is within 3 minutes (124x speedup over PostgreSQL and 157x speedup over Neo4j).

Conciseness: The largest AIQL query is c4-8 with 7 event patterns, 25 query constraints, 109 words, and 463 characters (excluding spaces). The corresponding SQL query contains 77 constraints (3.1x larger), 432 words (4.0x larger), and 2792 characters (6.0x larger). The corresponding Cypher query contains 63 constraints (2.5x larger), 361 words (3.3x larger), and 2570 characters (5.6x larger). As the attack behaviors become more complex, SQL and Cypher queries become verbose with many joins and constraints, posing challenges for constructing the queries for timely attack investigation.

Table 4: Selected malware samples from Virussign

ID	Name	Category
v1	7dd95111e9e100b6243ca96b9b322120	Trojan.Sysbot
v2	425327783e88bb6492753849bc43b7a0	Trojan.Hooker
v3	ee111901739531d6963ab1ee3ecaf280	Virus.Autorun
v4	4e720458c357310da684018f4a254dd0	Virus.Sysbot
v5	7dd95111e9e100b6243ca96b9b322120	Trojan.Hooker

6.3 Performance Evaluation

We evaluate the performance of AIQL in both storage settings (PostgreSQL and Greenplum) by constructing 19 AIQL queries for a broad set of attack behaviors, touching 738GB/2.1 billion events. Particularly, we are interested in the efficiency speedup provided by the AIQL scheduling (Sec. 5.2) in comparison with PostgreSQL scheduling and Greenplum scheduling.

6.3.1 Attack Behaviors

Multi-Step Attack Behaviors: We asked white hat hackers to launch another APT attack using different exploits (details available on [1]). We then constructed 5 AIQL queries for investigating the attack steps (*a1*-*a5*).

Dependency Tracking Behaviors: We performed causal dependency tracking of origins of Chrome update executables (*d1*) and Java update executables (*d2*). We performed forward dependency tracking of the ramification malware `info_stealer` (*d3*).

Real-World Malware Behaviors: We obtained a dataset of free malware samples from VirusSign [33]. We then randomly selected 5 malware samples (Table 4) from the 3 largest categories: *Autorun*, *Sysbot*, and *Hooker*. We executed the 5 selected samples in the deployed environment and constructed AIQL queries by analyzing the accompanied behavior reports [33] (*v1*-*v5*).

Abnormal System Behaviors: We evaluated 6 abnormal system behaviors based on security experts' knowledge: (1) *s1*: command history probing; (2) *s2*: suspicious web service; (3) *s3*: frequent network access; (4) *s4*: erasing traces from system files; (5) *s5*: network access spike; (6) *s6*: abnormal file access. Note that for *s5* and *s6*, we did not construct SQL, Cypher, or Splunk queries, due to their lack of support for sliding window and history state comparison.

6.3.2 Efficiency in PostgreSQL

We select two baselines: (1) PostgreSQL databases that *employ our data storage optimizations (Sec. 3.2)*. Note that this setting is different from the end-to-end efficiency evaluation in Sec. 6.2.2, because here we want to rule out the speedup offered by the data storage component; (2) AIQL with fetch-and-filter scheduling (denoted as AIQL_FF; Sec. 5.2). We measure the execution time of the 19 queries in Sec. 6.3.1.

[2] Fine-grained evaluations of the AIQL scheduling are in Sec. 6.3.

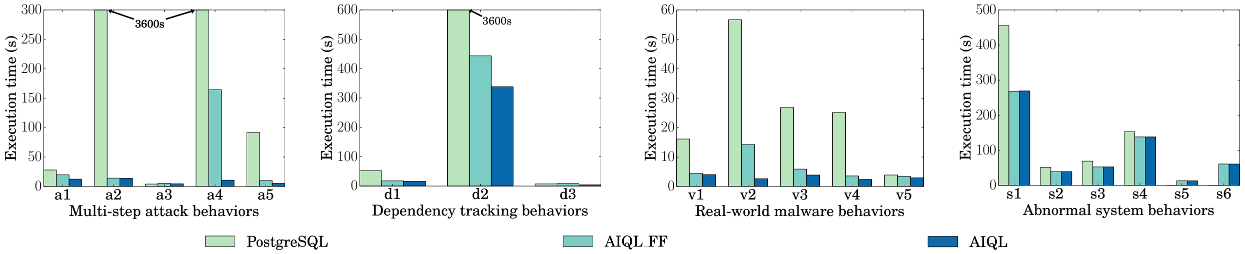

Figure 6: Query execution time of the scheduling employed by PostgreSQL, AIQL_FF, and AIQL (single-node)

Table 5: Conciseness improvement statistics

Metrics	AIQL/SQL	AIQL/ Cypher	AIQL/Splunk SPL
# of constraints	3.0x	2.4x	4.2x
# of words	3.9x	3.1x	3.8x
# of characters	5.3x	4.7x	4.7x

Evaluation Results: Fig. 6 shows the execution time of queries in PostgreSQL, AIQL_FF, and AIQL. We observe that: (1) the scheduling employed by PostgreSQL is inefficient in executing complex queries. In particular, PostgreSQL cannot finish executing *a2*, *a4*, and *d2* within 1 hour; (2) the scheduling employed by AIQL_FF and AIQL is more efficient than PostgreSQL, with 19x and 40x speedup, respectively; (3) the relationship-based scheduling employed by AIQL is more efficient than the fetch-and-filter scheduling employed by AIQL_FF.

6.3.3 Efficiency in Parallel Databases

We compare the performance of AIQL scheduling in the Greenplum storage with the Greenplum scheduling (i.e., running SQLs). As in Sec. 6.3.2, the Greenplum databases also *employ our data storage optimizations*.

Evaluation Results: Fig. 7 shows the execution time of queries in Greenplum and AIQL. We observe that: (1) in most cases, our scheduling in parallel settings achieves a comparable performance as Greenplum scheduling; (2) in certain cases (e.g., *a4*, *d3*), our scheduling is significantly more efficient than Greenplum scheduling; (3) the average speedup over Greenplum is 16x. The results show that without our semantics-aware model, Greenplum distributes the storage of events based on their incoming orders (which is arbitrary). On the contrary, our data model allows Greenplum to evenly distribute events in a host, and achieves more efficient parallel search.

6.4 Conciseness Evaluation

We evaluate the conciseness of queries that express the 19 attack behaviors in Sec. 6.3.1 in three metrics: the number of query constraints, the number of words, and the number of characters (excluding spaces).

Evaluation Results: Fig. 8 shows the conciseness metrics of AIQL, SQL, Neo4j Cypher, and Splunk SPL queries. Table 5 shows the average improvement of AIQL queries over other queries. We observe that AIQL *is the most concise query language* in terms of all three metrics and all attack behaviors: SQL, Neo4j Cypher, and Splunk SPL contain at least 2.4x more constraints, 3.1x more words, and 4.7x more characters than AIQL. In contrast to SQL, Cypher, and SPL which employ lots of joins on tables or nodes, AIQL provides high-level constructs for spatial/temporal constraints, relationship specifications, constraints chaining, and context-aware syntax shortcuts, making the queries much more concise.

7 Discussion

Query Scheduler: Our data query scheduler estimates the pruning score of an event pattern based on its number of constraints. This can be improved by (1) considering the number of records in different hosts and different time periods and (2) constructing a statistical model of constraint pruning power. Additionally, the query scheduler may partition the time window uniformly based on the data volume. Such strategies require further analysis of the domain data statistics to infer the proper data volume for splitting, which we leave for future work.

System Entities and Data Reduction: In the future work, we plan to add registry entries in Windows and pipes in Linux to expand the monitoring scope. We also plan to incorporate more finer granularity system monitoring, such as execution partition [58, 59] and in-memory data manipulations [40, 43]. To handle the increase of data size, we plan to explore more aggressive data reduction techniques in addition to existing solutions [55, 69] to make the system more scalable.

8 Related Work

Security-Related Languages: There also exist domain-specific languages in a variety of security fields that have a well-established corpus of low level algorithms, such as threat descriptions [6, 26, 31], secure overlay networks [46, 56], and network intrusions [35, 39, 65, 68]. These languages provide specialized constructs for their particular problem domain. In contrast to these languages, the novelty of AIQL focuses on querying attack behaviors, including (a) providing specialized constructs

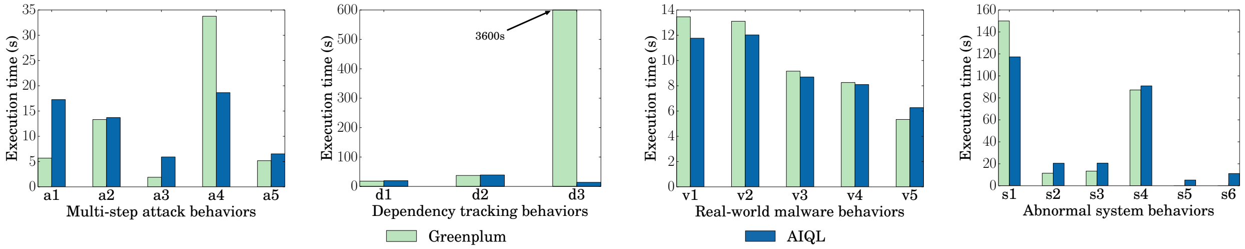

Figure 7: Query execution time of the scheduling employed by Greenplum and AIQL (parallel)

Figure 8: Conciseness evaluation of queries written in AIQL, SQL, Neo4j Cypher, and Splunk SPL

for system interaction patterns/relationships and abnormal behaviors; (b) optimizing query execution over system monitoring data. Splunk [23] and Elasticsearch [10] are distributed search and analytics engine for application logs, which provide search languages based on keywords and shell-like piping. However, these systems lack efficient supports for joins and their languages cannot express abnormal behaviors with history states as AIQL. Furthermore, our AIQL can be used to investigate the real-time anomalies detected on the stream of system monitoring data, complementing the stream-based anomaly detection systems [41] for better defense.

Database Query Languages: Relational databases based on SQL [19, 25] and SPARQL [22] provide language constructs for joins, facilitating the specification of relationships among events, but these languages lack constructs for easily chaining constraints among relations (i.e., tables). Graph databases [16] provide language constructs for chaining constraints among nodes in graphs, but these databases lack efficient support for joins. Similarly, NoSQL tools [38] lack efficient supports for joins. Temporal expressions are also introduced to databases [62], and various time-oriented applications are explored [63]. Currently, AIQL focuses on the set of temporal expressions that are frequently used in expressing attack behaviors, which is a subset of the temporal expressions proposed in [62]. More importantly, none of these languages provide constructs to express frequency-based behavioral models with historical results.

System Defense Based on Behavioral Analytics: Existing malware detection has looked at various ways to build behavioral models to capture malware, such as sequences of system calls [67], system call patterns based on data flow dependencies [51], and interactions between benign programs and the operating system [53]. Behavioral analytics have also shown promising results for network intrusion [70, 72] and internal threat detection [60]. These works learn models to detect anomaly or predict attacks, but they do not provide mechanisms for users to perform attack investigation. Our AIQL system fills such gap by allowing security analysts to query historical events for investigating the reported anomalies.

9 Conclusion

We have presented a novel system for collecting attack provenance using system monitoring and assisting timely attack investigation. Our system provides (1) domain-specific data model and storage for scaling the storage and the search of system monitoring data, (2) a domain-specific query language, *Attack Investigation Query Language (*AIQL*)* that integrates critical primitives for attack investigation, and (3) an optimized query engine based on the characteristics of the data and the queries to better schedule the query execution. Compared with existing systems, our AIQL system greatly reduces the cycle time for iterative and interactive attack investigation.

Abstract

The proliferation of applications that handle sensitive user data on wearable platforms generates a critical need for embedded systems that offer strong security without sacrificing flexibility and long battery life. To secure sensitive information, such as health data, ultra-low-power wearables must isolate applications from each other and protect the underlying system from errant or malicious application code. These platforms typically use microcontrollers that lack sophisticated Memory Management Units (MMU). Some include a Memory Protection Unit (MPU), but current MPUs are inadequate to the task, leading platform developers to software-based memory-protection solutions. In this paper, we present our memory isolation technique, which leverages compiler inserted code and MPU-hardware support to achieve better run-time performance than software-only counterparts.

1 Introduction

Smart watches and smart bands offer novel opportunities for individuals to monitor and control their health, manage a chronic disease, pursue athletic excellence, recover from surgery, or steer their lifestyle toward healthier behaviors. Smart watches can run a variety of apps, including third-party apps installed by the user. However, the battery life for a typical smart watch is about one day, far shorter than the weeks-long battery life typical of single-purpose fitness bands. To balance these trade-offs, some devices (such as the Amulet [10]) seek to achieve the battery life of a closed-source fitness band (like a Fitbit) and the capability to run multiple third-party apps, while retaining strong security properties. These low-energy multi-app wearable platforms employ ultra-low-power microcontrollers (MCUs), with tiny RAM, limited secondary storage, and which lack the hardware-based memory-protection mechanisms – such as Memory Management Units (MMU) – needed to ensure that applications cannot interfere with each other. This makes it difficult to provide long battery life *and* strong security properties that allow multiple third-party apps to coexist.

This work focuses on a fundamental security property: *memory isolation*, which ensures that no application can read, write, or execute memory locations outside its own allocated region, or call functions outside a designated system API. In this paper, we present a novel memory isolation technique, which leverages compiler inserted code and a low-sophistication Memory Protection Unit (MPU) found in many microcontrollers, to achieve better performance than software-only counterparts.

We use the open-source Amulet platform [10] to implement the following isolation methods for comparison: (1) compiler-enforced language limitations (no pointers, no recursion), (2) compiler-inserted run-time memory isolation (address-space bounds verification), and (3) MPU-supported memory isolation (hardware enforced failure). The first option is the approach taken by the Amulet team, which limits the programmer to a subset of C. Pointers are disallowed, and the compiler inserts code for run-time bounds-checking on arrays. In the second approach, we modify the Amulet implementation to allow for pointers and recursion, but our custom compiler inserts code to validate each pointer dereference to ensure the application stays within its bounds. In the third approach we implement a novel combination, in which the OS and compiler coordinate the dynamic assignment of the MPU's limited functionality – and limited compiler-inserted pointer checking – to enable the desired isolation. Finally, we automate this process through an extension to the Amulet Build System. We make the following **contributions**:

1. an analysis of design considerations, including security issues, that enable multiple applications on ultra-low-power wearables, with minimal burden on the programmer or the user;
2. a novel technique, using the limited-function hardware memory protection unit (MPU) found in commodity ultra-low-power microcontrollers, combined

with compile-time analysis of application code, to sandbox application code and memory;

3. a prototype implementation as a refinement of the open-source Amulet platform;
4. an evaluation that compares the performance of the Amulet platform's limited language-based memory-isolation mechanism, a full-featured software-only approach, and a full-featured MPU-assisted mechanism.

2 Background and Related Work

Early operating systems for wireless sensors like TinyOS [14] and others [1, 6, 9] reduced complexity [13], enabled dynamic reprogramming [15], and provided interfaces for concurrent execution [7]. These platforms did not provide memory isolation, nor did they allow installation of multiple third-party applications. As the application space grows, security mechanisms that enable multiprogramming of multi-tenant microcontroller units (MCUs) must be developed. Recent work has explored approaches for memory isolation on microcontrollers.

Some approaches change the language: AmuletOS [10] uses a dialect of ANSI C, termed AmuletC, which disallows pointers and recursion. TockOS [16] writes kernel code in Rust, a type-safe and memory-safe language, and isolates their apps using an MPU. While language modifications can make compile-time analysis easier [17], they tend to limit expressiveness and are rarely enough to ensure complete application isolation.

Language features are often coupled with compiler checks, binary-code rewriting, or system-implemented dynamic checks. For example, AmuletOS has a compiler that inserts run-time bounds-checking code around all array accesses [10]. Deputy [4, 5] enforces type safety at compile time; Harbor [12], built on top of SOS [9], rewrites binary code to check any pointer reference and function call. T-Kernel [8] modifies code at load time to secure application memory. Each of these compile and run-time techniques come with limitations: compile-time techniques depend on language features (or modifications) and clear OS rules, while dynamic checking requires expensive run-time overhead to check memory accesses.

Other systems virtualize the single memory space to isolate applications, like Maté [13], or rely on novel hardware mechanisms such as a Secure Loader hardware unit between the CPU, peripherals, and RAM [11].

Many ultra-low-power MCUs like the MSP430 FRAM series [18] are equipped with a basic Memory Protection Unit, but they have some or all of the following shortcomings: (1) they support too few distinct regions, not enough to sandbox each application; (2) they leave certain segments of memory, like hardware registers or RAM, unprotected; and (3) they have arcane protection boundary rules, because they depend on opaque hardware implementations.

Given all these prior techniques, we see the potential for a *new* approach that leverages the meager capabilities of the new class of MPU, and the lessons learned from years of isolation techniques using software approaches. In this paper, we evaluate the performance of our memory-isolation technique, which leverages compiler-inserted code and MPU-hardware support, against: a language-limited software-based approach (the native Amulet approach [10]), and a full-featured compiler-inserted-check approach.

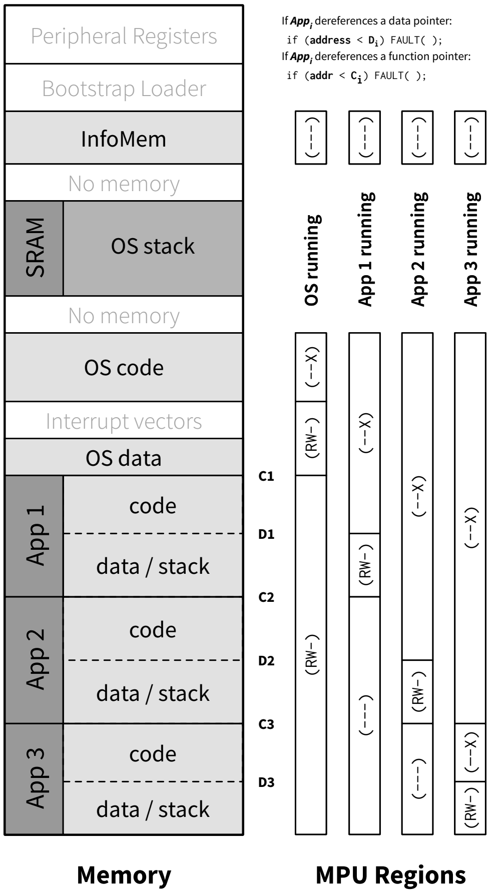
3 System Design

We apply our memory-isolation technique to the latest open-source build of Amulet[1]. Amulet implements memory isolation through compiler-enforced language limitations (no pointers, no recursion, no goto statements and no inline assembly). We remove the most burdensome restrictions by allowing app programmers to use recursion and C pointers (including function pointers) in their code, which reduces the effort to port code to the Amulet and allows developers to write new apps in a customary fashion. In our approach we implement two methods to allow these language features and still ensure memory isolation – use of the memory protection unit (MPU) and compiler-inserted run-time memory isolation.

The Amulet system allows an Amulet user to select a customized mix of applications to run on her Amulet wristband, from a suite of applications developed independently by separate app developers. The Amulet system consists of three core parts – AmuletOS, Amulet Runtime, and the Amulet Firmware Toolchain (AFT). AmuletOS provides the core system services and an event-based scheduler that drives the apps' state machines, delivering events by calling the appropriate event-handler function with parameters representing the details of the event. Amulet Runtime provides a state-machine environment in which all applications run. The Amulet Firmware Toolchain (AFT) [10], analyzes, transforms, merges, and compiles the user's desired applications with the AmuletOS to construct a firmware image for installation on the user's Amulet device.

Amulet devices use a TI MSP430FR5969 MCU, which have a memory protection unit (MPU), with limited capabilities as described in Section 2. The MPU is not a memory-management unit (MMU), nor does it provide full memory protection: it cannot protect all regions of memory (the MPU will not prevent instructions from reading or writing the peripheral registers, InfoMem, SRAM,

[1] The latest open-source release of the Amulet platform can be found at `https://github.com/AmuletGroup/amulet-project`



If *App_i* dereferences a data pointer:

```

If *App_i* dereferences a function pointer:

```
if (addr < C_i) FAULT( );
```

Figure 1: Memory diagram of our approach, and MPU regions per application.

or interrupt vectors), and its limited selection of three MPU-controlled segments does not allow us to subdivide memory into the four regions we desire (app code, app data/stack, off-limits memory below the app, and off-limits memory above the app). The MPU only has the ability to protect accesses to memory above the higher app bound but not below the lower app bound. To protect lower memory the compiler inserts a lower bound check. Thus, the MPU memory isolation method consists of configuring the MPU for an app and inserting lower-bound checks, while the compiler inserted (software-only) method mentioned earlier consists of not using the MPU and inserting both an upper and lower memory bound check. Although the MSP430's MPU itself is not sufficient to protect the system and other applications from pointer misuse by a buggy (or malicious) app, it is useful: in our approach, we strategically leverage both the MPU and the compiler to accomplish the necessary protections. This section details the memory map used for MPU, as well as how we handle memory accesses and context switches.

Memory Map: Use of the MPU requires a different memory mapping than in the original Amulet implementation. Figure 1 diagrams our approach. We leverage the SRAM for the AmuletOS stack, the low FRAM for AmuletOS code and data, and the high FRAM for app code and data, grouped by app.[2] Each app's code and data are separated, with its code in lower addresses than its data. The MPU has four segments, of which we can make good use of three.[3]InfoMem, the first segment, is fixed to a certain address range and its configuration can be changed any time by any code. Furthermore, only two boundaries are adjustable: the boundary between segment 1 and 2 and the boundary between segment 2 and 3.

To allow application developers to use C pointers, we leverage previously described MPU hardware. While an app is running, we configure the MPU segments as follows: 0: InfoMem (unused; no access); 1: OS, lower-memory apps, and current-running app's code (execute-only); 2: current-running app's data and stack (read-write only); 3: higher-memory apps (no access).

Consider, as an example, Application 2 in Figure 1. All of the app's code is gathered in one region, all of its data and stack in another region. The MPU configuration triggers a fault if a stray pointer references anything in higher regions (shown as Application 3 in the figure), but the MPU cannot fully protect regions in addresses below the application's code segment.

While the OS is running, we configure the MPU segments as follows: 0: InfoMem (unused; no access); 1: OS code (execute-only); 2: interrupt vectors and OS data (read-write only); 3: apps (read-write only). This configuration allows the AmuletOS to run its own code and, as needed, to manipulate data in both the app and OS regions.

It's important to note an important design change from Amulet as it was originally introduced. The Amulet system uses a single stack – shared by both the OS and the current application. This approach is possible because at most one app runs at any time, so there is no need to retain a stack for non-running apps. It is also possible because app code cannot use pointers, and thus cannot read any memory outside its statically allocated global variables, or outside its current stack frame. If we were to stick with the same single-stack model, we would need to `bzero` the stack region every time we switched apps, lest the new app glean information from the stack tailings left behind by the prior app. We chose instead to allocate a distinct region of memory for each app's stack, removing this cost (and other costs to ensure stack references remain

[2] If the AmuletOS is too large to fit in the low FRAM, it could span the interrupt vectors, but for simplicity we do not show it as such in the diagram.

[3] MPU segment 0 is pinned to the InfoMem, which is only 512 bytes and which we currently do not use. We anticipate using the InfoMem in future revisions, for a return-address stack that protects the return address from stack overflow bugs and attacks.

in-bounds) at the cost of increased memory usage.

That brings us to another important design decision related to security and the application stack. Languages such as C traditionally place a function's return address on the stack, and jump indirectly through that address as part of the function-return instruction. Stack overflows in buggy or malicious code can overwrite that entry on the stack, however, causing the function to return to a different address. We leverage the compiler to insert code to bounds-check the return address before every function return. Furthermore, we place the top of the app stack below the app's data in the app's data/stack segment, and allow the stack to grow downward. The compiler and linker can compute the size of the app's data region, and estimate the maximum stack depth, to ensure the data/stack segment is large enough for the app's needs. If the app overflows its stack, for example by too-deep recursive calls, it will cross an MPU boundary into an execute-only code region and trigger a fault.

Memory accesses: An important role for the runtime system is to handle application faults; when the app attempts an invalid memory access, it jumps to a `FAULT` function to log app-specific information about the fault. At compile time, the AFT uses its transformation tools to verify that the app only calls approved API functions and reads approved system global variables, and to insert code that verifies (at run-time) every pointer dereference before it occurs. Notice that every one of these checks is a simple comparison against a constant, followed by a conditional branch (jump) to the fault-handling code. Because all app code is processed by the AFT, and the app cannot inline any of its own assembly code, the resulting code is guaranteed to check every pointer used by the app.

Context Switches: The AmuletOS provides an API for applications to access utilities and system services. We need to swap MPU configurations and change stacks on each transition, and we need to carefully handle application-provided pointers passed through API calls to the OS. Furthermore, because each app, and the OS, has a separate stack segment, we need to change the stack pointer on every transition between the OS and an app.

AFT Implementation: We extend the AFT to implement the MPU and software-only method checks previously mentioned. These tasks are accomplished by the AFT in a four-phase code analysis. In the first phase, the AFT checks for any still unsupported language features – such as inline assembly and GOTO statements. In addition, the AFT enumerates each memory access and OS API call on an app by app basis. Examination of the application call graph and the stack frame for each function determines the maximum stack size for each app. In the event of recursion, the maximum stack size cannot be determined and the AFT cannot guarantee a large enough stack to prevent overflow. During the second phase, the MPU configuration code and the previously mentioned memory access checks (with placeholder values for app boundaries) are injected into the code. The third phase marks apps with memory section attributes for the linker, as well as injecting the assembly code needed to manipulate the stack pointer. The last phase involves determining the code size of each app, updating the linker script to place each app in high memory (as detailed in Figure 1), and updating the memory access checks from phase two with the correct app boundaries. The AFT completes by recompiling the modified code into the final firmware image.

Operation	No Isolation	Feature Limited	MPU	Software Only
Memory Access	23	41	29	32
Context Switch	90	90	142	98

Table 1: Average cycle count for basic memory isolation operations.

4 Evaluation

In this section we evaluate the costs of application isolation. Our proposed system allows developers to write pure C, instead of a constrained Amulet C, enabling them to more easily write (or port) application code to the Amulet platform. We look at the isolation overhead of a large set of Amulet applications for three methods in Section 4.1, and see that while the overhead of our isolation method is higher than a feature-limited Amulet C, the impact of the overhead on battery lifetime is negligible. In Section 4.2 we describe three benchmark applications, and the tradeoffs they display between computation-intensive and OS-intensive applications.

4.1 Isolation Overhead

We use the Amulet Resource Profiler (ARP) and the ARP-view tool to count the number of memory accesses and context switches per state and transition, per application. Using ARP-view, we can account for the rate of environmental, user, and timer events set by the developer, combine this information with the counted number of memory accesses and context switches, and extrapolate the number of cycles of overhead for isolating applications. We can then convert the estimated cycles into energy cost (in Joules) to estimate the negative impact of isolation on battery lifetime. The results of this experiment are shown in Figure 2 for nine applications that are part of the Amulet platform. These applications comprise thousands of lines of code, and many have been deployed in user studies [2, 3]. **For all applications, isolation using either the MPU or Software Only methods has less than a 0.5% impact on battery lifetime.**

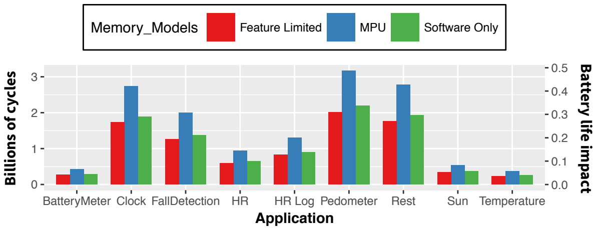

Figure 2: Isolation overhead in billions of cycles per week, and battery lifetime impact percentage for a variety of applications. Gathered using the Amulet Resource Profiler infrastructure.

4.2 Benchmark Applications

We further explore the system overhead of application isolation through several benchmark applications with varying levels of memory accesses. We designed a **Synthetic App** a simple application whose purpose is to test the two fundamental actions that incur memory-protection overheads: *memory accesses* and *context switches*. We then investigate two major functions in our **Activity Detection App**, which correspond to *Activity Case 1* and *Activity Case 2* in Figure 3. These functions have a high number of memory accesses compared to context switches. Finally, we design a **Quicksort App:** an application that runs the quicksort algorithm with a high number of memory accesses and no context switches. Each application was run 200 times and a hardware timer on the MSP430FR5969 MCU was used to measure the time of each iteration (with a precision of 16 cycles).

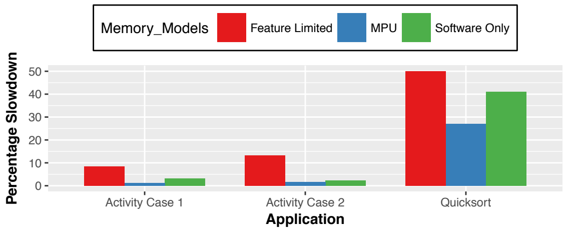

Figure 3: Percentage slowdown for each memory isolation method calculated by comparing them to running apps with no isolation method.

The results from the synthetic app test in Table 1 show that our MPU method had the fastest memory accesses, but the slowest context switches. This result was expected, and validates the simulation results, as our method only requires half the number of bounds checks as the Software Only approach, but incurs extra overhead for reconfiguring the MPU during context switches. Figure 3 further confirms the results from Table 1, which is that our method is the most effective when used for computationally heavy applications.

5 Discussion and Conclusion

In this paper we explore the challenge of memory isolation on ultra-low-power microcontrollers, which offer primitive hardware support for memory protection. Traditional approaches use a range of language limitations, compiler analysis, or dynamic checks (inserted by compiler or other tools); few have leveraged the capabilities of emerging MPUs.

Our solution employs MPU hardware to protect most regions of memory from inappropriate access by application code. Our proof-of-concept implementation (on an Amulet) is limited by the capabilities of the MSP430 MPU, which cannot protect the region below the current app's allocation; thus, the compiler still needs to insert some code for bounds checks – albeit half as many as in the software-only solution. We envision extending our approach to work with more advanced MPUs to further reduce our runtime overheads; MPUs that can protect *all* of memory and support 4 or more regions would negate the need for our compiler-inserted bounds checks. We may also explore more robust error handling techniques, such as restart policies for applications that trigger a memory access fault, or the use of a shadow return-address stack to prevent applications from jumping outside their code bounds.

In conclusion, our exploration shows that (1) it is possible to efficiently support memory isolation without resorting to language limitations, as in the original Amulet approach, and (2) a hybrid approach that leverages compiler-inserted code and MPU-hardware support can provide performance benefits over a software-only approach. While our approach leveraging the MPU was not effective for apps that make frequent API calls, our MPU isolation approach had, for all applications, less than 0.5% impact on battery lifetime.

Peeking Behind the Curtains of Serverless Platforms

Liang Wang [1], Mengyuan Li [2], Yinqian Zhang [2], Thomas Ristenpart[3], Michael Swift[1]

[1]UW-Madison, [2]Ohio State University, [3]Cornell Tech

Abstract

Serverless computing is an emerging paradigm in which an application's resource provisioning and scaling are managed by third-party services. Examples include AWS Lambda, Azure Functions, and Google Cloud Functions. Behind these services' easy-to-use APIs are opaque, complex infrastructure and management ecosystems. Taking on the viewpoint of a serverless customer, we conduct the largest measurement study to date, launching more than 50,000 function instances across these three services, in order to characterize their architectures, performance, and resource management efficiency. We explain how the platforms isolate the functions of different accounts, using either virtual machines or containers, which has important security implications. We characterize performance in terms of scalability, coldstart latency, and resource efficiency, with highlights including that AWS Lambda adopts a bin-packing-like strategy to maximize VM memory utilization, that severe contention between functions can arise in AWS and Azure, and that Google had bugs that allow customers to use resources for free.

1 Introduction

Cloud computing has allowed backend infrastructure maintenance to become increasingly decoupled from application development. Serverless computing (or function-as-a-service, FaaS) is an emerging application deployment architecture that completely hides server management from tenants (hence the name). Tenants receive minimal access to an application's runtime configuration. This allows tenants to focus on developing their functions — small applications dedicated to specific tasks. A function usually executes in a dedicated *function instance* (a container or other kind of sandbox) with restricted resources such as CPU time and memory. Unlike virtual machines (VMs) in more traditional infrastructure-as-a-service (IaaS) platforms, a function instance will be launched only when the function is invoked and is put to sleep immediately after handling a request. Tenants are charged on a per-invocation basis, without paying for unused and idle resources.

Serverless computing originated as a design pattern for handling low duty-cycle workloads, such as processing in response to infrequent changes to files stored on the cloud. Now it is used as a simple programming model for a variety of applications [14, 22, 42]. Hiding resource management from tenants enables this programming model, but the resulting opacity hinders adoption for many potential users, who have expressed concerns about: security in terms of the quality of isolation, DDoS resistance, and more [23, 35, 37, 40]; the need to understand resource management to improve application performance [4, 19, 24, 27, 28, 40]; and the ability of platforms to deliver on performance [10–12, 29–31]. While attempts have been made to shed light on platforms' resource management and security [33, 34], known measurement techniques, as we will show, fail to provide accurate results.

We therefore perform the most in-depth study of resource management and performance isolation to date in three popular serverless computing providers: AWS Lambda, Azure Functions, and Google Cloud Functions (GCF). We first use measurement-driven approaches to partially reverse-engineer the architectures of Lambda and Azure Functions, uncovering many undocumented details. Then, we systematically examine a series of issues related to resource management: how quickly function instances can be launched, function instance placement strategies, function instance reuse, and more. Several security issues are identified and discussed.[1] We further explore how CPU, I/O and network bandwidth are allocated among functions and the ensuing performance implications. Last but not least, we explore whether all resources are properly accounted for, and report on two resource accounting bugs that allow tenants to use extra resources for free. Some highlights of our results include:

- AWS Lambda achieved the best scalability and the lowest coldstart latency (the time to provision a new function instance), followed by GCF. But

[1] We responsibly disclosed our findings to related parties before this paper was made public.

the lack of performance isolation in AWS between function instances from the same account caused up to a 19x decrease in I/O, networking, or coldstart performance.

- Azure Functions used different types of VMs as hosts: 55% of the time a function instance runs on a VM with debased performance.
- Azure had exploitable placement vulnerabilities [36]: a tenant can arrange for function instances to run on the same VM as another tenant's, which is a stepping stone towards cross-function side-channel attacks.
- An accounting issue in GCF enabled one to use a function instance to achieve the same computing resources as a small VM instance at almost no cost.

Many more results are given in the body. We have repeated several measurements in May 2018 and highlight in the paper the improvements the providers have made. We noticed that serverless platforms are evolving quickly; nevertheless, our findings serve as a snapshot of the resource management mechanisms and efficiency of popular serverless platforms, provide performance baselines and design options for developers to build more reliable platforms, and help tenants improve their use of serverless platforms. More generally, our study provides new measurement techniques that are useful for other researchers. Towards facilitating this, we will make our measurement code public and open source.[2]

2 Background

Serverless computing platforms. In serverless computing, an application usually consists of one or more ***functions*** — standalone, small, stateless components dedicated to handle specific tasks. A function is most often specified by a small piece of code written in some scripting language. Serverless computing providers manage the execution environments and backend servers of functions, and allocate resources dynamically to ensure their scalability and availability.

In recent years, many serverless computing platforms have been developed and deployed by cloud providers, including Amazon, Azure, Google, and IBM. We focus on Amazon AWS Lambda, Azure Functions and Google Cloud Functions.[3] In these services, a function is executed in a dedicated container or other type of sandbox with limited resources. We use ***function instance*** to refer to the container/sandbox a function runs on. The resources advertised as available to a function instance varies across platforms, as shown in Table 1. When the function is invoked by requests, one or more function instances (depending on the request volume) will be launched to execute the function. After the function instance(s) have processed the requests and exited or reached the maximum execution time (see "Timeout" in Table 1), the function instance(s) becomes idle. They may be reused to handle subsequent requests to avoid the delay of launching new instances. However, idle function instances can also be suddenly terminated [32]. Each function instance is associated with a non-persistent local disk for temporarily storing data, which will be erased when the function instance is destroyed.

	AWS	**Azure**	**Google**
Memory (MB)	64 * k (k = 2, 3, ..., 24)	1536	128 * k (k = 1, 2, 4, 8, 16)
CPU	Proportional to Memory	Unknown	Proportional to Memory
Language	Python 2.7/3.6 Nodejs 4.3.2/6.10.3 Java 8, and others	Nodejs 6.11.5, Python 2.7, and others	Nodejs 6.5.0
Runtime OS	Amazon Linux	Windows 10	Debian 8*
Local disk (MB)	512	500	> 512
Run native code	Yes	Yes	Yes
Timeout (second)	300	600	540
Billing factor	Execution time Allocated memory	Execution time Consumed memory	Execution time Allocated memory Allocated CPU

Table 1: A comparison of function configuration and billing in three services. (*: We infer the OS version of GCF by checking the help information and version of several Linux tools such as `APT`.)

One benefit of using serverless services is that tenants do not pay for resources consumed when function instances are idle. Tenants are billed based on resource consumption only during execution.[4] In common across platforms is charging for aggregated function execution time across all invocations. Additionally, the price varies depending on the pre-configured function memory (AWS, Google) or the actual consumed memory during invocations (Azure). Google further charges different rates based on CPU speed.

Related work. Many serverless application developers have conducted their own experiments to measure coldstart latency, function instance lifetime, maximum idle time before shut down, and CPU usage in AWS Lambda [10–12, 19, 27, 28, 40]. Unfortunately, their experiments were ad-hoc, and the results may be misleading because they did not control for contention by other instances. A few research papers report on measured performance in AWS. Hendrickson et al. [18] measured request latency and found it had higher latency than AWS Elastic Beanstalk (a platform-as-a-service system). McGrath et al. [34] conducted preliminary measurements on four serverless platforms, and found

[2] `https://github.com/liangw89/faas_measure`

[3] We use AWS, Azure and Google to refer to these services.

[4] Azure Functions offers two types of function hosting plans. *Consumption Plan* manages resources in a serverless-like way while *App Service Plan* is more like "container-as-a-service". We only consider Consumption Plan in this paper.

that AWS achieved better scalability, coldstart latency, and throughput than Azure and Google.

A concurrent study from Lloyd et al. [33] investigated the factors that affect application performance in AWS and Azure. The authors developed a heuristic to identify the VM a function runs on in AWS based on the VM uptime in `/proc/stat`. Our experimental evaluation suggests that their heuristic is unreliable (see §4.5), and that the conclusions they made using it are mostly inaccurate.

In our work, we design a reliable method for identifying instance hosts, and use systematic experiments to inspect resource scheduling and utilization.

3 Methodology

We take the viewpoint of a serverless user to characterize serverless platforms' architectures, performance, and resource management efficiency. We set up vantage points in the same cloud provider region to manage and invoke functions from one or more accounts via official APIs, and leverage the information available to functions to determine important characteristics. We repeated the same experiment under various settings by adjusting function configuration and workloads to determine the key factors that could affect measurement results. In the rest of the paper, we only report on the relevant factors affecting the experiment results.

We integrate all the necessary functionalities and subroutines into a single function that we call a *measurement function*. A measurement function performs two tasks: (1) collect invocation timing and function instance runtime information, and (2) run specified subroutines (e.g., measuring local disk I/O throughput, network throughput) based on received messages. The measurement function collects runtime information via the proc filesystem on Linux (`procfs`), environment variables, and system commands. It also reports on execution start and end time, invocation ID (a random 16-byte ASCII string generated by the function that uniquely identify an invocation), and function configurations to facilitate further analysis.

The measurement function checks the existence of a file named *InstanceID* on the local disk, and if it does not exist, creates this file with a random 16-byte ASCII string that serves as the function instance ID. Since the local disk is non-persistent and has the same lifetime as the associated function instance, the *InstanceID* file will not exist for a fresh function instance, and will not be modified or deleted during the function instance lifetime once created.

The regions for functions were us-east-1, us-central-1, "EAST US" in AWS, Google and Azure (respectively). The vantage points were VMs with at least 4 GB RAM and 2 vCPUs. We used the software recommended by the providers and follow the official instructions to configure the time synchronization service in the vantage points. [5]

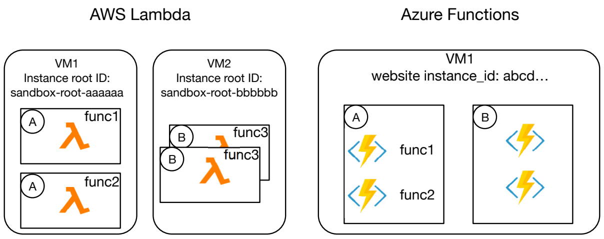

Figure 2: VM and function instance organization in AWS Lambda and Azure Functions. A rectangle represents a function instance. A or B indicates different tenants.

We implemented the measurement function in various languages, but most experiments used Python 2.7 and Nodejs 6.* as the language runtime (the top 2 most popular languages in AWS according to Newrelic [25]). We invoked the functions via synchronous HTTP requests. Most of our measurements were done from July–Dec 2017.

Ethical considerations. We built our measurement functions in a way that should not cause undue burden on platforms or other tenants. In most experiments, the function did no more than collecting necessary information and sleeping for a certain amount of time. Once we discovered performance issues we limited our tests to not DoS other tenants. We only conducted small-scale tests to inspect the security issues but did not further exploit them.

4 Serverless Architectures Demystified

We combine two approaches to infer the architectures of AWS Lambda, Google Cloud Functions, and Azure Functions: (1) reviewing official documents, related online articles and discussions, and (2) measurements — analyzing the data collected from running our measurement functions many times ($>$ 50,000) under varying conditions. This data enables partially reverse engineering the architectures of AWS, Azure, and Google.

4.1 Overview

AWS. A function executes in a dedicated function instance. Our measurements suggest different versions of a function will be treated as distinct and executed in different function instances (we discuss outliers in §5.5). The `procfs` file system exposes global statistics of the underlying VM host, not just a function instance, and contains useful information for profiling runtime,

[5] AWS: `http://docs.aws.amazon.com/AWSEC2/latest/UserGuide/set-time.html`; Google: `https://developers.google.com/time/`; Azure does not offer instructions so we use the default NTP servers at `http://www.pool.ntp.org/en/use.html`

(1) Set up N distinct functions $f_1, ..., f_N$ that run the following task upon receiving a `RUN` message: record `/proc/diskstats`, write 20 K – 30 K times to a file (1 byte each time), and record `/proc/diskstats` again.

(2) Invoke each function once without `RUN` message to launch N function instances.

(3) Assuming the instances of $f_1, ..., f_k$ (k instances) share the same instance root ID, invoke $f_1, ..., f_k$ once each with the `RUN` message and examine I/O statistics of each function instance.

Figure 3: I/O-based coresidency test in **AWS**.

identifying host VMs, and more. From `procfs`, we found host VMs mostly have 2 vCPUs and 3.75 GB physical RAM (same as EC2 c4.large instances).

Azure. Azure Functions uses *Function Apps* to organize functions. A function app, corresponding to one function instance, is a container that contains the execution environments for individual functions [5]. The environment variables in the function instance contain some global information about the host VM. The environment variables collected suggest the host VMs can have 1, 2 or 4 vCPUs.

One can create multiple functions in a function app and run them concurrently. In our experiments, we assume that a function app has only one function.

Google. Google isolates and filters information that can be accessed from `procfs`. The files under `procfs` only report usage statistics of the current function instance. Also, many system files and syscalls are obscured or disabled so we cannot get much information about runtime. The `/proc/meminfo` and `/proc/cpuinfo` files suggest a function instance has 2 GB RAM and 8 vCPUs, which we suspect is the configuration for VMs.

4.2 VM identification

Associating function instances with VMs enables us to perform richer analysis. The heuristic for identifying VMs in AWS Lambda proposed by Lloyd et al., though theoretically possible, has never been evaluated experimentally [33]. Therefore, we looked for a more robust method.

AWS. The `/proc/self/cgroup` file has a special entry that we call *instance root ID*. It starts with "sandbox-root-" followed by a 6-byte random string. We found it can be used to reliably identity a host VM. Using the I/O-based coresidency tests (shown in Figure 3), we confirmed that the instances sharing the same instance root ID are on the same VM, as the difference in the total bytes written between two consecutive invocations, for f_i and f_{i+1} respectively, is almost the same as the number of bytes written by f_i. Moreover, we can get the same kernel uptime (or memory usage statistics) from the instances when reading `/proc/uptime` (`/proc/meminfo`) at the same time.

We call the IP obtained via querying IP address lookup tools from an instance *VM public IP*, and the IP obtained from running `uname` command *VM private IP*. Function instances that share the same instance root ID have the same VM public IP and VM private IP.

Azure. The `WEBSITE_INSTANCE_ID` environment variable serves as the VM identifier, according to official documents [6]. We refer to it as *Azure VM ID*. We used Flush-Reload via shared DLLs to verify coresidency of instances sharing the same Azure VM ID [43]. The results suggest Azure VM ID is a robust VM identifier.

Google. We could not find any information enabling us to identify a host. Using I/O-based coresidency did not work as `procfs` contains no global usage statistics. We tried to use performance as a covert-channel (e.g., performing patterned I/O operations in one function instance and detecting the pattern from I/O throughput variation in another) but found this is not reliable, as performance varied greatly (See §6.2).

4.3 Tenant isolation

Prior studies showed that co-located VMs in AWS EC2 allow attacks [36, 38, 41]. With the knowledge of instance-VM relationship, we examined how well tenants' primary resources — function instances — are isolated. We assume that one tenant corresponds to one user account, and only consider VM-level coresidency.

AWS. The functions created by the same tenant will share the same set of VMs, regardless of their configurations and code. The detailed instance placement algorithm will be discussed in §5.1. AWS assigns different VMs to each tenant, since we have never seen function instances from different tenants in the same VM. We conducted a cross-tenant coresidency test to confirm this assumption. The basic principle is similar to Figure 3: in each round, we create a new function under each of the two accounts at the same time, write a random number of bytes in one function, and check the disk usage statistics in another function. We ran this test for 1 week, but found no VM-coresidency of cross-tenant function instances.

Azure. Azure Functions are a part of the Azure App service, in which all tenants share the same set of VMs according to Azure [2]. Hence, tenants in Azure Functions should also share VM resources. A simple test confirmed this assumption: we invoked 500 functions in each of two accounts and found that 30% of function instances were coresident with a function instance from the other account, executing in a total of 120 VMs. Note that as of May 2018, different tenants no longer share the same VMs in Azure. See §5.1 for more details.

4.4 Heterogeneous infrastructure

We found the VMs in all the considered services had a variety of configurations. The variety, likely resulting from infrastructure upgrades, can cause inconsistent function performance. To estimate the fraction of different types of VM in a given service, we examined the configurations of the host VMs of 50,000 unique function instances in each service.

In AWS, we checked the *model_name* and the processor numbers in the `/proc/cpuinfo`, and the *MemTotal* in the `/proc/meminfo`, and found five types of VMs: two E5-2666 vCPUs (2.90 GHZ), two E5-2680 vCPUs (2.80 GHZ), two E5-2676 vCPUs (2.40 GHZ), two E5-2686 vCPUs (2.30 GHZ), and **one** E5-2676 vCPUs. These types account for 59.3%, 37.5%, 3.1%, 0.09% and 0.01% of 20,447 distinct VMs.

Azure shows a greater diversity of VM configurations. The instances in Azure report various vCPU counts: of 4,104 unique VMs, 54.1% use 1 vCPU, 24.6% use 2 vCPUs, and 21.3% use 4 vCPUs. For a given vCPU count, there are three CPU models: two Intel and one AMD. Thus, nine (at least) different types of VMs are being used in Azure. Performance may vary substantially based on what kind of host (more specifically, the number of vCPUs) runs the function. See §6 for more details.

In Google, the *model_name* is always "unknown", but there are 4 unique model versions (79, 85, 63, 45), corresponding to 47.1%, 44.7%, 4.2%, and 4.0% of selected function instances.

4.5 Discussion

Being able to identify VMs in AWS is essential for our measurements. It helps to reduce noise in experiments and get more accurate results. For the sake of comparison, we evaluated the heuristic designed by Lloyd et al. [33]. The heuristic assumes that different VMs have distinct boot times, which can be obtained from `/proc/stat`, and group function instances based on the boot time. We sent 10 – 50 concurrent requests at a time to 1536 MB functions for 100 rounds, used our methodology (instance root ID + IP) to label the VMs, and compared against the heuristic. The heuristic identified 940 VMs as 600 VMs, so 340 (36%) VMs were incorrectly labeled. So, we conclude this heuristic is not reliable.

None of these serverless providers completely hide runtime information from tenants. More knowledge of instance runtime and the backend infrastructure could make finding vulnerabilities in function instances easier for an adversary. In prior studies, `procfs` has been used as a side-channel [9, 21, 46]. In the serverless setting, one actually can use it to monitor the activity of coresident instances; while seemingly harmless, a dedicated adversary might use it as a steppingstone to more sophisticated attacks. Overall, accesses to runtime information, unless necessary, should be restricted for security purposes. Additionally, providers should expose such information in an auditable way, i.e., via API calls, so they are able to detect and block suspicious behaviors.

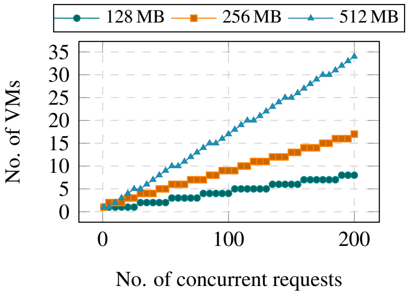

Figure 4: The total number of VMs being used after sending a given number of concurrent requests in **AWS**.

5 Resource Scheduling

We examine how instances and VMs are scheduled in the three serverless platforms in terms of instance coldstart latency, lifetime, scalability, and more.

5.1 Scalability and instance placement

Elastic, automatic scaling in response to changes in demand is a main advertised benefit of the serverless model. We measure how well platforms scale up.

We created 40 measurement functions of the same memory size $f_1, f_2, \ldots, f_{40}$ and invoked each f_i with $5i$ concurrent requests. We paused for 10 seconds between batches of invocations to cope with rate limits in the platforms. All measurement functions simply sleep for 15 seconds and then return. For each configuration we performed 50 rounds of measurements.

AWS. AWS is the best among the three services with regard to supporting concurrent execution. In our measurements, N concurrent invocations always produced N concurrently running function instances. AWS could easily scale up to 200 (the maximum measured concurrency level) fresh function instances.

We observed that **3,328 MB** was the maximum aggregate memory that can be allocated across all function instances on any VM in AWS Lambda. AWS Lambda appears to treat instance placement as a bin-packing problem, and tries to place a new function instance on an existing active VM to maximize *VM memory utilization rates*, i.e., the sum of instance memory sizes divided by 3,328. We invoked a single function with sets of concurrent requests, increasing from 5 to 200 with a step of 5, and recorded the total number of VMs being used after each number of requests. A few examples are shown in Figure 4.

#vCPU	Total	1	2	3	4	>4
1	61.3	16.6	24.6	13.7	4.9	1.5
2	19.5	7.3	7.1	3.3	1.4	0.4
4	19.2	7.6	6.2	3.9	1.3	0.2
All	100	31.5	37.9	20.9	7.6	2.1

Table 5: The average (over 10 runs) probabilities (as percentages) of getting N-way single-account coresidency (for $N \in \{1,2,3,4,\}$ and $N > 4$, when launching 1,000 function instances in **Azure**. Here $N = 1$ indicates no coresidency among the functions.

The number of active VMs are close to the "expected" number if AWS maximizes VM memory utilization. Quantitatively speaking, more than 89% of VMs we got in the test achieved 100% memory utilization. Sending concurrent requests to different functions resulted in the same pattern, indicating placement is agnostic to function code.

In a further test we sent 10 sets of random numbers of concurrent requests to randomly-chosen functions of varied memory sizes over 50 runs. AWS's placement still worked efficiently: the average VM memory utilization rate across VMs in the same run ranged from 84.6% to 100%, with a median of 96.2%.

Azure. Azure documentation states that it will automatically scale up to at most 200 instances for a single Nodejs-based function and at most one new function instance can be launched every 10 seconds [7]. However, in our tests of Nodejs-based functions, we saw at most 10 function instances running concurrently for a single function, no matter how we changed the interval between invocations. All the requests were handled by a small set of function instances. None of the concurrently running instances were on the same VM. So, it appears that Azure does not try to co-locate function instances of the same function on the same VMs.

We conducted a single-account coresidency test to examine how function instances are placed on VMs of different numbers of vCPUs. We invoked 100 different functions from one account at a time until we had 1,000 concurrent, distinct function instances running. We then checked for co-residency, and repeated the entire test 10 times.

We observed at most 8 instances on a single 1/2/4-vCPU VM. Co-resident instances tend to be on 1-vCPU VMs (presumably because there are more 1-vCPU VMs for Azure Functions). We show the breakdown of co-residency results in Table 5. In general, co-residency is undesirable for users wanting many function instances, as contention between instances on low-end VMs will exacerbate performance issues.

We further conducted a cross-account coresidency test in a more realistic scenario where an attacker wants to place her function instances on the same VM with the instances of a target victim. In each round of this test, we launched either 5 or 100 function instances from one account (the *victim*) and 500 simultaneous function instances from another account (the *attacker*). On average, 0.12% (3.82%) of the 500 attacker instances were coresident with the 5 (100) victim instances in each round (10 rounds in total). So, it was possible to achieve cross-tenant coresidency even for a few targets. In the test with 100 victim instances, we were able to obtain up to 5 attacker instances on the same VM. Security implications will be discussed in §5.6.

We repeated the coresidency tests in May 2018 but could not find any cross-tenant coresident instances, even in the test in which we tired 500 victim instances. Therefore, we believe that Azure has fixed the cross-tenant coresidency issue.

Google. Google failed to provide our desired scalability, even though Google claims HTTP-triggered functions will scale to the desired invocation rate quickly [13]. In general, only about half of the expected number of instances, even for a low concurrency level (e.g., 10), could be launched at the same time, while the remainder of the requests were queued.

5.2 Coldstart and VM provisioning

We use *coldstart* to refer to the process of launching a new function instance. For the platform, a coldstart may involve launching a new container, setting up the runtime environment, and deploying a function, which will take more time to handle a request than reusing an existing function instance (*warmstart*). Thus, coldstarts can significantly affect application responsiveness and, in turn, user experience.

For each platform, we created 1,000 distinct functions of the same memory and language and sequentially invoked each of them twice to collect its coldstart and warmstart latency. We use the difference of invocation send time (recorded by the vantage point) and function execution start time (recorded by the function) as an estimation of its coldstart/warmstart latency. As baselines, the median warmstart latency in AWS, Google, and Azure were about 25, 79 and 320 ms (respectively) across all invocations.

AWS. We examine two types of coldstart events: a function instance is launched (1) on a new VM that we have never seen before and (2) on an existing VM. Intuitively, case (1) should have significantly longer coldstart latency than (2) because case (1) may involve starting a new VM. However, we found case (1) was only slightly longer than (2) in general. The median coldstart latency in case (1) was only 39 ms longer than (2) (across all settings). Plus, the smallest VM kernel uptime (from `/proc/uptime`) we found was 132 seconds, indicating that the VM has been launched before the invocation.

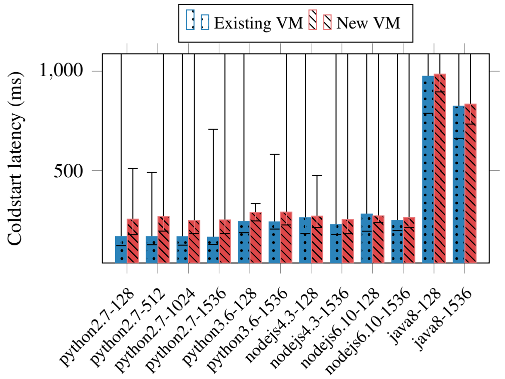

Figure 6: Median coldstart latency with min-max error bars (across 1,000 rounds) under different combinations of function languages and memory sizes in **AWS**. Y-axis is truncated at 1,000 ms.

So, AWS has a pool of ready VMs. The extra delays in case (1) are more likely introduced by scheduling (e.g., selecting a VM) rather than launching a VM.

Our results are consistent with prior observations: function memory and language affect coldstart latency [10], as shown in Figure 6. Python 2.7 achieves the lowest median coldstart latencies (167–171 ms) while Java functions have significantly higher latencies than other languages (824–974 ms). Coldstart latency generally decreases as function memory increases. One possible explanation is that AWS allocates CPU power proportionally to the memory size; with more CPU power, environment set up becomes faster (see §6.1).

A number of function instances may be launched on the same VM concurrently, due to AWS's instance placement strategy. In this case, the coldstart latency increases as more instances are launched simultaneously. For example, launching 20 function instances of a Python 2.7-based function with 128 MB memory on a given VM took 1,321 ms on average, which is about 7 times slower than launching 1 function instance on the same VM (186 ms).

Azure and Google. The median coldstart latency in Google ranged from 110 ms to 493 ms (see Table 7). Google also allocates CPU proportionally to memory, but in Google memory size has greater impact on coldstart latency than in AWS. It took much longer to launch a function instance in Azure, though their instances are always assigned 1.5 GB memory. The median coldstart latency was 3,640 ms in Azure. Anecdotes online [3] suggest that the long latency is caused by design and engineering issues in the platform that Azure is both aware of and working to improve.

Latency variance. We collected the coldstart latencies of 128 MB, Python 2.7 (AWS) or Nodejs 6.* (Google and Azure) based functions every 10 seconds for over 168 hours (7 days), and calculated the median of the coldstart latencies collected in a given hour. The changes of coldstart latency are shown in Figure 8. The coldstart latencies in AWS were relatively stable, as were those in Google (except for a few spikes). Azure had the highest network variation over time, ranging from about 1.5 seconds up to 16 seconds.

Provider-Memory	Median	Min	Max	STD
AWS-128	265.21	189.87	7048.42	354.43
AWS-1536	250.07	187.97	5368.31	273.63
Google-128	493.04	268.5	2803.8	345.8
Google-2048	110.77	52.66	1407.76	124.3
Azure	3640.02	431.58	45772.06	5110.12

Table 7: Coldstart latencies (in ms) in AWS, Google, and Azure using Nodejs 6.* based functions for comparison.

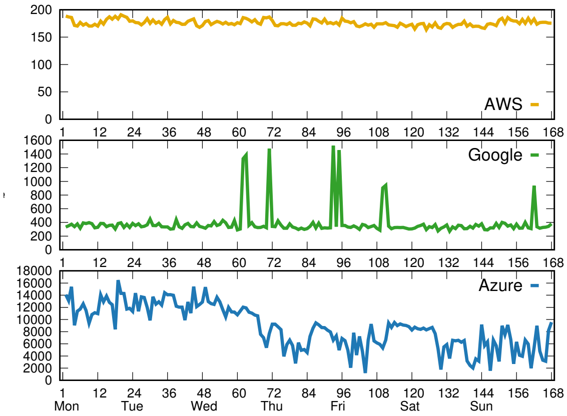

Figure 8: Coldstart latency (in ms) over 168 hours. All the measurements were started at right after midnight on a Sunday. Each data point is the median of all coldstart latencies collected in a given hour. For clarity, the y-axes use different ranges for each service.

We repeated our coldstart measurements in May 2018. We did not find significant changes in coldstart latency in AWS. But, the coldstart latencies became 4x slower on average in Google, probably due to its infrastructure update in February 2018 [15], and 15x better in Azure. This result demonstrates the importance of developing a measurement platform for serverless systems (similar to [39] for IaaS) to do continuous measurements for better performance characterization.

5.3 Instance lifetime

A serverless provider may terminate a function instance even if still in active use. We define the longest time a function instance stays active as *instance lifetime*. Tenants prefer long lifetimes because their applications will be able to maintain in-memory state (e.g., database connections) longer and suffer less from coldstarts.

To estimate instance lifetime, we set up functions of different memory sizes and languages, and invoked

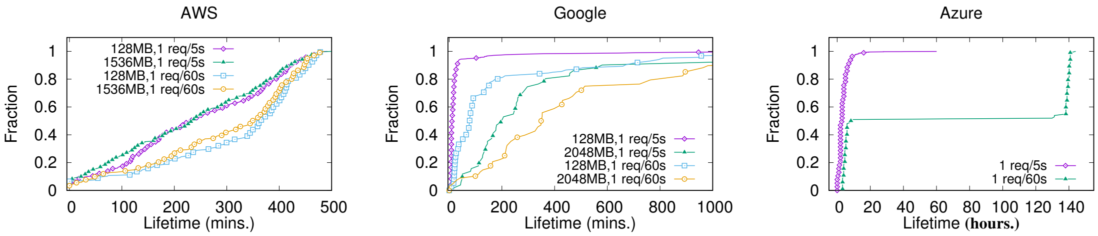

Figure 9: The CDFs of instance lifetime in AWS, Google, and Azure under different memory and request frequency.

them at different frequencies (one request per 5/30/60 seconds). The lifetime of a function instance is the difference between the first time and the last time we saw the instance. We ran the experiment for 7 days (AWS and Google) or longer (Azure) so that we could collect at least 50 lifetimes under a given setting.

In general, Azure function instances have significantly longer lifetimes than AWS and Google as shown in Figure 9. In AWS, the median instance lifetime across all settings was 6.2 hours, with the maximum being 8.3 hours. The host VMs in AWS usually lives longer: the longest observed VM kernel uptime was 9.2 hours. When request frequency increases instance lifetime tends to become shorter. Other factors have little effect on lifetime except in Google, where instances of larger memory tend to have longer lifetimes. For example, when being invoked every five seconds, the lifetimes were 3–31 minutes and 19–580 minutes for 90% of the instances of 128 MB and 2,048 MB memory in Google, respectively. So, for functions with small memory under a heavy workload, Google seems to launch new instances aggressively rather than reusing existing instances. This can increase the performance penalty from coldstarts

5.4 Idle instance recycling

To efficiently use resources, Serverless providers shutdown idle instances to recycle allocated resources (see, e.g., [32]). We define the longest time an instance can stay idle before getting shut down as *instance maximum idle time*. There is a trade-off between long and short idle time, as maintaining more idle instances is a waste of VM memory resources, while fewer ready-to-serve instances cause more coldstarts.

We performed a binary search on the minimum delay t_{idle} between two invocations of the function that resulted in distinct function instances. We created a function, invoked it twice with some delay between 1 and 120 minutes, and determined whether the two requests used the same function instance. We repeated until we identified t_{idle}. We confirmed t_{idle} (to minute granularity) by repeating the measurement 100 times for delays close to t_{idle}.

AWS. An instance could usually stay inactive for at most 27 minutes. In fact, in 80% of the rounds instances were shut down after 26 minutes. When their host VM is "idle", i.e., no active instances on that VM, idle function instances will be recycled the following way: Assuming that the function instances of N functions $f_1, \ldots, f_N$ are coresident on a VM, and k_{f_i} instances are from f_i. For a given function f_i, AWS will shut down $\lfloor k_{f_i}/2 \rfloor$ of the idle instances of f_i every 300 (more or less) seconds until there are two or three instances left, and eventually shut down the remaining instances after 27 minutes (we have tested with $k_{f_i} = 5, 10, 15, 20$). AWS performs these operations to $f_1, \ldots, f_N$ on a given VM independently, and also on individual VMs independently. Function memory or language does not affect maximum idle time.

If there are active instances on the VM, instances can stay inactive for a longer time. We kept one instance active on a given VM by sending a request every 10 seconds and found: (1) AWS still adopted the same strategy to recycle the idle instances of the same function, but (2) somehow idle time was reset for other coresident instances. We observed some idle instances could stay idle in such cases for 1–3 hours.

Azure and Google. In Azure, we could not find a consistent maximum instance idle time. We repeated the experiment several times on different days and found the maximum idle times of 22, 40, and more than 120 minutes. In Google, the idle time of instances could be more than 120 minutes. After 120 minutes, instances remained active in 18% of our experiments.

5.5 Inconsistent function usage

Tenants expect the requests following a function update should be handled by the new function code, especially if the update is security-critical. However, we found in AWS there was a small chance that requests could be handled by an old version of the function. We call such cases *inconsistent function usage*. In the experiment, we sent $k = 1$ or $k = 50$ concurrent requests to a function, and did this again without delay after updating one of the following aspects of the function: IAM role, memory size, environment variables, or function code. For a given setting, we performed these operations for 100 rounds. When $k = 1$, 1%–4% of the tests used an inconsistent function. When there were more associated instances before the update ($k = 50$), 80% of our rounds had at least one inconsistent function. Looking across all tests from all rounds, we found that 3.8% of instances ran an inconsistent function. Examining the cases, we found two situations: (1) AWS launched new instances of the outdated function (2% of all the cases), and (2) AWS reused existing instances of the outdated function. Inconsistent instances never handle more than one request before terminating (note that max execution time is 300 s in AWS), but still, a considerable faction of requests may fail to get desired results.

As we waited for a longer time after the function update to send requests, we found fewer inconsistent cases, and eventually zero cases with a 6-second waiting time. So, we suspect that the inconsistency issues are caused by race conditions in the instance scheduler. The results suggest coordinating function update among multiple function instances is challenging as the scheduler cannot do an atomic update.

5.6 Discussion

We believe our results motivate further study on designing more efficient instance scheduling algorithms and robust schedulers to further improve VM resource utilization, i.e., to maximize VM memory usage, reduce scheduling latency, and promptly propagate function updates while guaranteeing consistency.

Loading modules or libraries could introduce high latency during coldstart [1, 3]. To reduce coldstart latency, providers might need to adopt more sophisticated library loading mechanisms, for example, using library caching to speed up this process, and resolving the library dependence before deployment and only loading required libraries.

Cross-tenant VM sharing in Azure plus the ability to run arbitrary binaries in the function instance could make applications vulnerable to many kinds of side-channel attacks [16, 17, 20, 45]. We did not examine how well Azure can tackle the potential threats resulting from cross-tenant VM sharing, and leave the actual security vulnerable as an open question.

AWS's bin-packing placement may bring security issues to an application, depending on its design. When a multi-tenant application in Lambda uses IAM roles to isolate its tenants, function instances from different application tenants still share the same VMs. We found two real services that use this pattern: Backand [8] and Zapier [44]. Both allow their tenants to deploy functions in Lambda in some way. We successfully achieved cross-account function coresidency in Backand in just a few tries, while failing in Zapier due to its rate limits and large user base (1 M+). Nevertheless, we could still observe the changes of `procfs` caused by other Zapier tenants' applications, which may admit side-channels [9, 21, 46]. For these multi-tenant applications to isolate their tenants and achieve better security and privacy, AWS may need to provide a finer-grained VM isolation mechanism, i.e., allocating a set of VMs to each IAM role instead of to each account.

Figure 11: (a) CDFs of CPU utilization rates of instances (1,000 for each type) and (b) the median CPU utilization rates across a given number of coresident instances (50 rounds) in Azure, with min-max error bars.

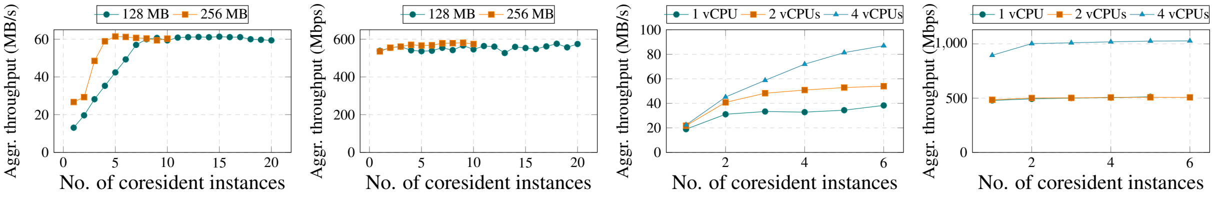
6 Performance Isolation

In this section, we investigate performance isolation. We mainly focus on AWS and Azure, where our ability to achieve coresidency allows more refined measurements. We also present some basic performance statistics for instances in Google that surface seeming contention with other tenants.

6.1 CPU utilization

To measure CPU utilization, our measurement function continuously records timestamps using `time.time()` (Python) or `Date.now()` (Nodejs) for 1,000 ms. The metric *instance CPU utilization rate* is defined as the fraction of the 1,000 ms for which a timestamp was recorded.

AWS. According to AWS, a function instance's CPU power is proportional its pre-configured memory [26]. However, AWS does not give details of how exactly CPU time is allocated to instances. We measured the CPU utilization rates on 1,000 distinct function instances and show the median rate for a given memory size in



(a) AWS: I/O (b) AWS: Network (c) Azure: I/O (d) Azure: Network

Figure 12: Aggregate I/O and network throughput across coresident instances as concurrency level increases. The coresident instances perform the same task simultaneously. The values are the median values across 50 rounds.

Figure 10a. Instances with higher memory get more CPU cycles. The median instance CPU utilization rate increased from 7.7% to 92.3% as memory increased from 128 to 1,536 MB, and the corresponding standard deviations (SD) were 0.7% and 8.7%. When there is no contention from other coresident instances, the CPU utilization rate of an instance can vary significantly, resulting in inconsistent application performance. That said, an upper bound on CPU share is approximated by $2 * m/3328$, where m is the memory size.

We further examine how CPU time is allocated among coresident instances. We let colevel be the number of coresident instances and a colevel of 1 indicates only a single instance on the VM. For memory size m, we selected a colevel in the range 2 to $\lfloor 3328/m \rfloor$. We then measured the CPU utilization rate in each of the coresident instances. Examining the results over 20 rounds of tests, we found that the currently running instances share CPU fairly, since they had nearly the same CPU utilization rate (SD <0.5%). With more coresident instances, each instance's CPU share becomes slightly less than, but still close to $2 * m/3328$ (SD <2.5% in any setting).

The above results indicate that AWS tries to allocate a fixed amount of CPU cycles to an instance based only on function memory.

Azure and Google. Google adopts the same mechanism as AWS to allocate CPU cycles based on function memory [13]. In Google, the median instance CPU utilization rates ranged from 11.1% to 100% as function memory increased. For a given memory size, the standard deviations of the rates across different instances are very low (Figure 10b), ranging from 0.62% to 2.30%.

Azure has a relatively high variance in the CPU utilization rates (14.1%–90%), while the median was 66.9% and the SD was 16%. This is true even though the instances are allocated the same amount of memory. The breakdown by vCPU number shows that the instances on 4-vCPU VMs tend to gain higher CPU shares, ranging from 47% to 90% (Figure 11a). The distributions of utilization rates of instances on 1-vCPU VMs and 2-vCPU VMs are in fact similar; however, when colevel increased, the CPU utilization of instances on 1-vCPU VMs drops more dramatically, as shown in Figure 11b.

6.2 I/O and network

To measure I/O throughput, our measurement functions in AWS and Google used the `dd` command to write 512 KB of data to the local disk 1,000 times (with `fdatasync` and `dsync` flags to ensure the data is written to disk). In Azure, we performed the same operations using a Python script (which used `os.fsync` to ensure data is written to disk). For network throughput measurement, the function used `iperf 3.13` with default configurations to run the throughput test for 10 seconds with different same-region iperf servers, so that iperf server-side bandwidth was not a bottleneck. The iperf servers used the same types of VMs as the vantage points.

AWS. Figure 12 shows aggregate I/O and network throughput across a given number of coresident instances, averaged across 50 rounds. All the coresident instances performed the same measurement concurrently. Though the aggregate I/O and network throughput remains relatively stable, each instance gets a smaller share of the I/O and network resources as colevel increases. When colevel increased from 1 to 20, the average I/O throughput per 128 MB instance dropped by 4x, from 13.1 Mbps to 2.9 Mbps, and network throughput by 19x, from 538.6 MB/s to 28.7 MB/s.

Coresident instances get less share of the network with more contention. We calculate the Coefficient of Variation (CV), which is defined as SD divided by the mean, for each colevel. A higher CV suggests the performance of instances differ more. For 128 MB instances, the CV of network throughput ranged from 9% to 83% across all colevels, suggesting significant performance variability due to contention with coresident instances. In contrast, the I/O performance was similar between instances (CV of 1% to 6% across all colevels). However, the I/O performance is affected by function memory (CPU) for small memory sizes ($\leq$ 512 MB), and therefore the I/O throughput of an instance could degrade more when competing with instances of higher memory.

Azure. In Azure, the I/O and network throughput of an instance also drops as colevel increases, and fluctuates due to contention from other coresident instances. Even more interestingly, resource allocation is differentiated based on what type of VM a function instance happens to be scheduled on. As shown in Figure 12, the 4-vCPU VMs could get 1.5x higher I/O and 2x higher network throughput than the other types of VMs. The 2-vCPU VMs have higher I/O throughput than 1-vCPU VMs, but similar network throughput.

Google. In Google, both the measured I/O and network throughput increase as function memory increases: the median I/O throughput ranged from 1.3 MB/s to 9.5 MB/s, and the median network throughput ranged from 24.5 Mbps to 172 Mbps. The network throughput measured from different instances with the same memory size can vary substantially. For instance, the network throughput measured in the 2,048 MB function instances fluctuated between 0.2 Mbps and 321.4 Mbps. We found two cases: (1) all instances throughputs' fluctuated during a given period of time, irrespective of memory sizes, or (2) a single instance temporarily suffered from degraded throughput. Case (1) may be due to changes in network conditions, while case (2) leads us to suspect that GCF tenants actually share hosts and suffer from resource contention.

6.3 Discussion

AWS and Azure fail to provide proper performance isolation between coresident instances, and so contention can cause considerable performance degradation. In AWS, the fact that they bin-pack function instances from the same account onto VMs means that scaling up a function places the same function on the same VM, resulting in resource contention and prolonged execution time (not to mention a longer coldstart latency). Azure has similar issues, with the additional issue that contention within VMs arises between accounts. The latter also opens up the possibility for cross-tenant degradation of service attacks.

We leave developing new, efficient isolation mechanisms that take the special characteristics of serverless (e.g., frequent instance creation, short-lived instances, and small memory-footprint functions) as considerations for future work.

7 Resource accounting

In the course of our study, we found several resource accounting issues that can be abused by tenants.

Background processes. We found in Google one could execute an external script in the background that continued to run even *after* the function invocation concluded. The script we ran posted a 10 M file every 10 seconds to a server under our control, and the longest time it stayed alive was 21 hours. We could not find any logs of the network activity performed by the background process and were not charged for its resource consumption.[6][7] In contrast, one could run such background script in Azure but Azure logged all the activity. Our observations suggest that: (1) In Azure and Google the function instance execution context will not be frozen after an invocation, as opposed to AWS; and (2) Google does resource accounting via monitoring the Node.js process rather than the entire function instance.

One can exploit the billing issue in Google to run sophisticated tasks at negligible cost. For a function instance with 2 GB memory and 2.4 GHz CPU, one only needs to pay for a few invocations ($0.0000029/100 ms, with 2 M free calls) to get the same computing resources as using a g1-small instance ($0.0257/hour) on Google Cloud Platform.

CPU accounting. In Google, we found there was an 80% chance that a just-launched function instance (of any memory size other than 2,048 MB) could temporally gain more CPU time than expected. Measuring the CPU utilization rates and the completion times of a CPU-intensive task, we confirmed that the instances that one expects to have 8%–58% of the CPU time (see §6) had near 100% of the CPU time, the same as that given to 2,048 MB instances. The instance can retain the CPU resources until the next invocation. Note that if one wants to conduct performance measurements in Google, this issue could introduce a lot of noise (we appropriately controlled for it in previously reported experiments).

8 Conclusion

In this paper, we provided insights into architectures, resource utilization, and the performance isolation efficiency of three modern serverless computing platforms. We discovered a number of issues, raised from either specific design decisions or engineering, with regard to security, performance, and resource accounting in the platforms. Our results surface opportunities for research on improving resource utilization and isolation in future serverless platform designs.

{zbc102,mcdaniel,gtan}@cse.psu.edu

Abstract

Broadly defined as the Internet of Things (IoT), the growth of commodity devices that integrate physical processes with digital systems have changed the way we live, play and work. Yet existing IoT platforms cannot evaluate whether an IoT app or environment is safe, secure, and operates correctly. In this paper, we present Soteria, a static analysis system for validating whether an IoT app or IoT environment (collection of apps working in concert) adheres to identified safety, security, and functional properties. Soteria operates in three phases; (a) translation of platform-specific IoT source code into an intermediate representation (IR), (b) extracting a state model from the IR, (c) applying model checking to verify desired properties. We evaluate Soteria on 65 SmartThings market apps through 35 properties and find nine (14%) individual apps violate ten (29%) properties. Further, our study of combined app environments uncovered eleven property violations not exhibited in the isolated apps. Lastly, we demonstrate Soteria on MalIoT, a novel open-source test suite containing 17 apps with 20 unique violations.

1 Introduction

The introduction of IoT devices into public and private spaces has changed the way we live. For example, home automation apps supporting smart devices of thermostats, locks, switches, surveillance systems, and Internet-connected appliances change the way we interact with our living spaces. While these systems have been widely embraced, IoT has also raised concerns about the security and safety of digitally augmented lives [18,21,24,34,36]. IoT apps have access to functions that may put the user or environment at risk, e.g., unlock doors when not at home or create unsafe or damaging conditions by turning off the heat in winter. There has been an increasing amount of recent research exploring IoT security and more broadly environmental safety.

One of the oft-discussed criticisms of IoT is that the software and hardware frameworks do not possess the capability to determine if an IoT device or environment is implemented in a way that is safe, secure, and operates correctly. The SmartThings [37], OpenHab [32], Apple's Homekit [1] provide guidelines and policies for regulating security [2, 31, 43], and related markets provide a degree of internal (hand) vetting of the apps prior to distribution [3,40]. Recent technical community efforts have explored vulnerability analysis within targeted IoT domains [21,30], while others focused on sensitive data leaks and correctness of IoT apps using a range of analyses [8, 17, 25, 45]. However, tools and algorithms for evaluating general safety and security properties within IoT apps and environments are at this time largely absent.

In this paper, we present Soteria[1], a static analysis system for validating whether an IoT app or IoT environment (collection of apps working in concert) adheres to identified safety, security, and functional properties. We exploit existing IoT platforms' sensor-computation-actuator program structures to translate source code of an IoT app into an intermediate representation (IR). Here, the Soteria IR models the app's lifecycle–including app entry points, event handler methods, and call graphs. From this, Soteria uses the IR to perform efficient static analysis extracting a state model of the app; the state model includes its states and transitions. A set of IoT properties is systematically developed, and model checking is used to check that the app (or collection of apps) conforms to those properties. In this work, we make the following contributions:

- We introduce Soteria, a system designed for model checking of IoT apps. Soteria automatically extracts a state model from a SmartThings IoT app and applies model checking to find property violations.
- We used Soteria on 65 different IoT apps (35 apps from the official SmartThings repository and 30 community-contributed third-party apps from the official SmartThings forum) and reveal how safety and security properties are violated.
- We develop an IoT-specific test corpus MalIoT, an open-source repository of 17 flawed apps that containing an array of safety and security violations.

[1] Soteria is the goddess in Greek mythology preserving from harm.

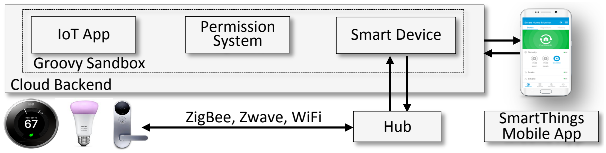

Figure 1: The architecture of SmartThings IoT platform.

2 Background

IoT platforms provide a software stack used to develop applications that monitor and control IoT devices.[2] For example, Fig. 1 shows the three components of the Samsung's SmartThings Platform: a hub, apps, and the cloud backend [40]. The hub controls the communication between connected devices, cloud back-end, and mobile apps. Apps are developed in the Groovy language (a dynamic, object-oriented language) and executed in a Kohsuke sandboxed environment. The cloud backend creates software proxies called SmartDevices that act as a conduit for physical devices, as well as run the apps.

The permission system in SmartThings allows a developer to specify devices and user inputs required for an app at install time. Devices in SmartThings have capabilities (i.e., permissions) that are composed of *actions* and *events*. Actions represent how to control or actuate device states and events are triggered when device states change. SmartThings apps control one or more devices. Apps subscribe to device events or other pre-defined events such as the icon-clicking event, and an event handler is invoked to handle it, which may lead to further events and actions.

Users can install SmartThings apps either from the market or proprietary system via SmartThings Mobile. In the former, publishing an app in the official market requires the developer to submit the source code of the app for review. Official apps appear in the market after the completion of a lengthy review process [40]. In the latter, organizations can develop an app and make it accessible using the Web IDE. These self-published apps do not receive any official review process and are often shared in the SmartThings official community forum [41].

3 Motivation and Assumptions

Example IoT Applications. We introduce three running examples used throughout for exposition and illustration:
The `Smoke-Alarm` app contains a smoke-detection alarm, a water valve (basement), and a light switch (living room). The app sounds the smoke alarm and turns on the light when smoke is detected; when smoke is detected and a heat level is reached, the app opens the water valve to activate fire sprinklers; finally, it turns off the alarm and closes water valve when smoke is clear. Also, it turns on the light switch when the smoke-detector battery is low.
The `Water-Leak-Detector` app detects a water leak with a moisture sensor and shuts off the main water supply valve in order to prevent any further water damage.

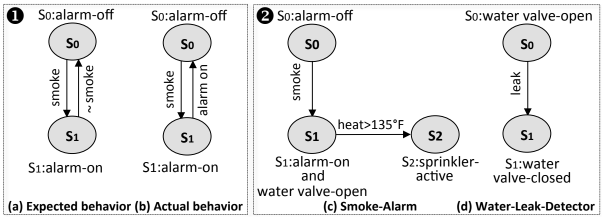

Figure 2: ❶ shows the state models of the expected and actual behavior of the `Smoke-Alarm` app. The app fails because of a bug which halts the alarm when smoke is present. ❷ shows the state models of the `Smoke-Alarm` and `Water-Leak-Detector` apps violating a property when they installed together. The environment fails when the apps interact–the `Water-Leak-Detector` app shuts off water valve when a fire is detected.

The `Thermostat-Energy-Control` app locks the front door and sets the heating thermostat temperature to a predefined value when the user-presence mode is changed (e.g., from the user-away mode to the user-home mode or vice versa). When the energy usage is above a pre-defined consumption threshold, it turns off the thermostat switch.
SOTERIA illustrated. Here we informally illustrate SOTERIA analysis through a single and multi-app example.

Consider the `Smoke-Alarm` app. We first model the app's source code as a transition system. Fig. 2(1a) presents the expected behavior of the smoke alarm; the alarm sounds when smoke is detected and not otherwise. The state model starts from an initial state S_0 and transits to state S_1 when smoke is detected. The state transitions are controlled by the output of the smoke sensor: "smoke-detected" (smoke) and "not detected" (~smoke). Fig. 2(1b) is the actual behavior extracted from the open-source implementation of a smoke alarm (that has a bug). We use SOTERIA to validate the above safety property–i.e., "does the alarm always sound when there is smoke?" To perform this analysis SOTERIA encodes the safety property in temporal logic and verifies it on the model with a symbolic model checker. Naturally, the analysis showed a violation; the actual behavior of the app stops the sound moments after the alarm sounds (the state transition from S_1 to S_0). In this case, users may not hear the short or intermittent alarm with potentially disastrous consequences.

Now consider the situation when both `Smoke-Alarm` and `Water-Leak-Detector` apps are co-located in an environment. Fig. 2(2c) and 2(2d) presents expected behavior of the `Smoke-Alarm` and `Water-Leak-Detector` apps, respectively. Here, we use SOTERIA to validate the property "does the sprinkler system activate when there is a fire?". The model checker revealed that there was a safety violation: the `Water-Leak-Detector` app shuts off the water valve and stops fire sprinklers when it detects water release from sprinklers. In this case, the joint behavior of the otherwise-safe apps leaves users are at risk from fire.

[2] While the SOTERIA approach is largely agnostic to the specific IoT software platform, we focus on Samsung's SmartThings Platform [37].

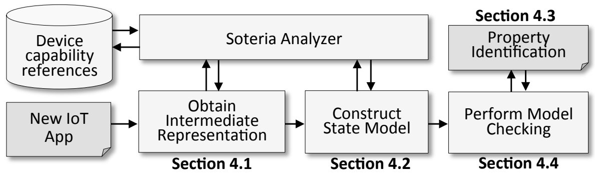

Figure 3: Overview of SOTERIA architecture.

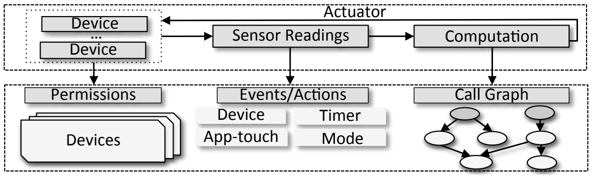

Figure 4: Components of the intermediate representation (IR).

Assumptions and Threat Model. We assume violations can be caused by design flaws or malicious intent. In the latter, the adversary may insert malicious code resulting in insecure or unsafe states, e.g., as seen in attacks on smart light bulbs [36] and home security systems [35]. We do not evaluate adversaries' ability to thwart security measures (e.g., crypto, forged inputs) or explore user privacy, but defer those investigations to future work.

4 SOTERIA

Fig. 3 provides an overview of the four stages of the SOTERIA system analysis. SOTERIA first extracts an intermediate representation (IR) from the source code of an IoT app (Sec. 4.1). The IR is used to model the lifecycle of an app including entry points, event handler methods, and call graphs. Second, SOTERIA uses the IR to extract a state model of the app; the state model includes its states and transitions (Sec. 4.2). Lastly, a set of IoT properties is developed (Sec. 4.3), and model checking is used to check that the app conforms to those properties when running independently or interacting with other apps (Sec. 4.4).

4.1 From Source Code to IR

The first step toward modeling an IoT app is to extract an IR from the app's source code. SOTERIA builds the IR from a framework-agnostic component model, which is comprised of the building blocks of IoT apps, shown in Fig. 4. A broad investigation of existing IoT environments showed that the programming environments could be generalized into three component types: (1) *Permissions* grant capabilities to devices used in an app; (2) *Events/Actions* reflect the association between events and actions: when an event is triggered, an associated action is performed; and (3) *Call graphs* represent the relationship between entry points and functions in an app. The IR has several benefits. First, it allows us to precisely model the app lifecycle as described above. Second, it is used to abstract away parts of the code that are not relevant to property analysis, e.g., `definition` blocks that specify app meta-data and `logger` logging code. Third, it allows efficiently extract the states and state transitions from the implementation (see below). Presented in Fig. 5, we use the `Smoke-Alarm` app to illustrate the use of the IR.

Permissions. When a SmartThings app gets installed or updated, the permissions for devices and user inputs are displayed to the user (and explicitly accepted). The permissions are read-only, and app logic is implemented using the permissions. SOTERIA visits permissions of an app to extract its devices and user inputs. Turning to the IR in Fig. 5, the permission block (lines 1–7) defines: (1) the devices; a smoke detector, a switch, an alarm, a valve, and a battery in the smoke detector; and (2) user input: "thrshld" is used to determine whether the battery level of the smoke detector is low. For each permission, the IR declares a triple following keyword "input". For a device, the triple associates an identifier for the device, called the *device handle*, to its platform-specific device name in order to determine the interface that the device may access. For instance, an app may associate identifier `the_switch` with a switch device, which is in either the "off" or the "on" state. For a user input, the triple in the IR contains the variable name storing the user input, its type, and a tag showing the kind of input such as the user-defined input. In this way, we obtain a complete list of devices and user inputs that an app might access.

Events/Actions. Similar to mobile applications, an IoT app does not have a main method due to its event-driven nature. Apps implicitly define entry points by subscribing events. The event/actions block in an IR is built by analyzing how an app subscribes to events. Each line in the block includes three pieces of information: a device handle, a device event to be subscribed, and an event handler method to be invoked when that event occurs (lines 9–10). Event handler methods are commonly used to take device actions. Therefore, an app may define multiple entry points by subscribing multiple events of a device or devices. Turning to our example, the event of "smoke-detected" state change is associated with an event handler method named `h1()` and the event of "battery" level state change with `h2()`. We also found that events are not limited to device events; we call these *abstract events*: (1) *Timer events*; event-handlers are scheduled to take actions within a particular time or at pre-defined times (e.g., an event-handler is invoked to take actions after a given number of minutes has elapsed or at specific times such as sunset); (2) *App touch events*; for example, some action can be performed when the user clicks on a button in an app; (3) what actions get generated may also depend on *mode events*, which are behavior filters automating device actions. For instance, an app running in "home" mode turns off the alarm and turns on the alarm when it is in the "away" mode. SOTERIA examines all event subscriptions and finds their corresponding event-handler methods; it creates a dummy main method for each entry point.

```
 1: // Permissions block
 2: input (smoke_detector, smokeDetector, type:device)
 3: input (the_switch, switch, type:device)
 4: input (the_alarm, alarm, type:device)
 5: input (the_valve, valve, type:device)
 6: input (the_battery, battery, type:device)
 7: input (thrshld, number, type:user_defined)
 8: // Events/Actions block
 9: subscribe(smoke_detector, "smoke", h1)
10: subscribe(the_battery, "battery", h2)
11: // Entry point
12: h1(){
13:   if(evt.value == "detected") {
14:       the_alarm.siren()
15:       the_valve.open()
16:   }
17:   if(evt.value=="clear"){
18:       the_alarm.off()
19:       the_valve.close()
20:   }
21: }
22: // Entry point
23: h2(){
24:   batteryLevel = p()
25:   if(batteryLevel < thrshld){
26:       the_switch.on()
27:   }
28: }
29: p(){
30:    return the_battery.currentValue("battery")
31: }
```

Figure 5: The IR of Smoke-Alarm app constructed with SOTERIA.

Asynchronously Executing Events. While each event corresponds to a unique event-handler, the sequence of event handler invocations cannot be decided in advance when multiple events happen at the same time. For instance, in our example, there could be a third subscription in the event/actions block that subscribes to the switch-off event to invoke another event handler method. We consider eventually consistent events, which means any time an event handler is invoked, it will finish execution before another event is handled, and the events are handled in the order they are received by an edge device (e.g., a hub). We base our implementation on path-sensitive analysis that analyzes an app's event handlers, which can run in arbitrary sequential order. This analysis is enabled by constructing a separate call graph for each entry point.

Call Graphs. We create a call graph for each entry point that defines an event handler method. Turning to the IR in Fig. 5, we define call graphs for two entry points `h1()` and `h2()` (line 12 and 23). `h1()` invokes `p()` to get the current battery level of the smoke detector. Addressed below, note that these initial graphs are sometimes incomplete because of dynamic method invocations (reflection).

4.2 State Model Extraction

SOTERIA next extracts a state model from the IR model.

Definition of State Models. An IoT app manages one or more devices. Each device has a set of attributes, which are the states of the device. For instance, in the Water-Leak-Detector app, the water sensor has a boolean-typed attribute, whose value signals the "water-detected" or "water-undetected" status. Hence, we naturally model the states in the model from the values of device attributes. IoT apps are event-driven: events such as state changes or user input trigger event handlers, which can in turn change device attributes by invoking device actions. Therefore, by analyzing an IoT app's code, we can add state transitions and label them with events that trigger the transitions (changes to attribute values).

More formally, we define the state model of an IoT app as a triple $(\mathtt{Q}, \Sigma, \delta)$, where Q is a set of states, Σ is a set of transition labels, and δ is a state-transition function that represents labeled transitions between states. We restrict our attention to deterministic state models, as we believe this is a condition for safe operation of IoT devices. In fact, after a state model extracted, SOTERIA reports nondeterministic state models as a safety violation.

Challenges in Extracting State Models. Although it may appear at first glance to be straightforward, extracting state models is fraught with challenges. First, extraction faces state-explosion problem. For instance, a thermostat device may have an integer-discrete or continuous temperature attribute would lead to many different states–adding a state for every possible value in such cases would result in state explosion. To address this, SOTERIA implements a form of property abstraction that collapses states by aggregating attribute values (see Sec. 4.2.1).

A second challenge concerns with model precision. A state model is an abstraction of an app's logic and necessarily has to over-approximate. A sound over-approximation can cause false positives during model checking. One such approximation that caused false positives for an earlier version of SOTERIA was that the labels on transitions were only events and thus too coarse-grained. It turns out that many IoT apps change device states *conditionally*; for example, an app may turn off a switch when the energy consumption is above some threshold and turn on the switch when the energy consumption is below another threshold. For precision, the current version of SOTERIA performs a path-sensitive analysis to extract predicates that guard state changes and adds the predicates as part of state-transition labels. We detail how state transitions are constructed in Sec. 4.2.2.

Finally, the SmartThings platform has a number of idiosyncrasies that SOTERIA's model extraction must address. For instance, SmartThings apps are written in Groovy, a dynamically typed language that supports call by reflection; as another example, SmartThings apps can use special objects for persistent data storage. We will discuss how these issues are addressed in Sec. 4.2.3.

4.2.1 Extracting States

As discussed, states in an app's state model should represent device attribute values. Turning to the Water-Leak-Detector app, this app has two devices: a water sensor and a valve, both of which are represented as Boolean attributes. Therefore, the app's state model has four states: water-detected and valve-closed; water-detected and valve-open; water-undetected and valve-closed; water-undetected and valve-open. The number of possible states of an app is determined by the Cartesian product of the attributes of its device. For instance, an app implementing two devices that have A and B attributes

Algorithm 1: Computing dependence from device's code

```
Input  : ICFG: Inter-procedural control flow graph
Input  : A numerical-valued attribute
Output : Dependence relation dep
$worklist \leftarrow \emptyset$; $done \leftarrow \emptyset$; $dep \leftarrow \emptyset$
for an id in a device action call that sets the attribute at node n do
    $worklist \leftarrow worklist \cup \{(n{:}\ id)\}$
end
while worklist is not empty do
    $(n{:}\ id) \leftarrow worklist.pop()$
    $done \leftarrow done \cup \{(n{:}\ id)\}$
    /* a def of (n: id) at node n′ means a path from n′
       to n exists and on the path there is no other
       assignment to id */
    for a def of (n: id) at node n′ of form id = e and e has only a
      single identifier id′ do
        $worklist \leftarrow worklist \cup (\{(n'{:}\ id')\} \setminus done)$
        $dep \leftarrow dep \cup \{(n{:}\ id, n'{:}\ id')\}$
    end
end
```

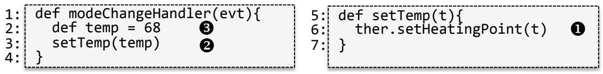
should have states of all pairs $(\mathtt{a},\mathtt{b})$, where $\mathtt{a}\in\mathtt{A}$ and $\mathtt{b}\in\mathtt{B}$.

Identification of Device Attributes. An IoT platform supports many physical devices. Sound model extraction requires identifying the complete set of device attributes. Prior work has used binary instrumentation to observe the runtime behavior of apps to infer the set of device operations used with a particular state [16]. However, this is not an option on some IoT platforms such as SmartThings where app execution is inside proprietary back-ends. Another option would be to use the built-in capability files, which come with devices. The capability file for a device identifies device permissions but not attribute values–and thus do not provide enough information for analysis.

Thus, to identify device attributes, Soteria uses platform-specific device handlers. A device handler is the representation of a physical device in an IoT platform and is responsible for communication between the device and the IoT platform (it is similar to a traditional device driver in an OS). For instance, the switch device handlers in SmartThings [44] and OpenHAB [32] IoT platforms support the "switch on" and "switch off" attributes, and allow apps to incorporate different kinds of switches in the same way. We developed a crawler script, which visits the `status` (for attributes) and `reply` (for actions) code blocks of SmartThings device handlers found in its official GitHub repository [44] and determines a complete set of attributes and actions for devices. We then created our own platform-specific *device capability reference file*, which includes for each device its complete set of attributes and actions. Soteria then uses this file to identify all attributes for those devices used in an app.

Numerical-Valued Device Attributes. Noted above, IoT devices may have attributes with integer or continuous values leading to many states. Returning to the previous `Thermostat-Energy-Control` app, a thermostat with 45 values (50-95 °F) and a power meter with 100 energy levels would lead to (clearly intractable) 4.5K states if a state is added for each combination of attribute values.

Soteria performs property abstraction [5] to reduce the state space. It first performs dependence analysis on an app's source code to identify possible sources for numerical-valued attributes, and then prunes sources using path- and context-sensitivity; the remaining sources are used to construct states in the state model. The Soteria dependence analysis is presented in Algorithm 1 as a worklist-based algorithm. The goal of the algorithm is to identify a set of possible sources that a numerical-valued attribute can take during the execution of an app. The worklist is initialized with identifiers that are used in the arguments of device action calls that change the attribute. The worklist also labels an identifier with node information to uniquely identify the use of an identifier, because the same identifier can be used in multiple locations. The algorithm then takes an entry (n, id) from the worklist and finds a definition for *id* according to the ICFG; if the right-hand side of the definition has a single identifier, the identifier is added to the worklist;[3] furthermore, the dependence between *id* and the right-hand side identifier is recorded in *dep*. For ease of presentation, the algorithm treats parameter passing as inter-procedural definitions.



```
1: def modeChangeHandler(evt){
2:   def temp = 68      ❸
3:   setTemp(temp)      ❷
4: }
```

```
5: def setTemp(t){
6:   ther.setHeatingPoint(t)   ❶
7: }
```

Figure 6: Property abstraction under backward flow analysis.

The dependence analysis is a form of backward taint analysis and produces a set of sources that can affect a change to a numerical-valued attribute. For those sources, Soteria makes them separate states in the state model and adds another state representing the rest of values.

To illustrate, we use a code block of the `Thermostat-Energy-Control` app as an example, shown in Fig. 6. There is a device action call that sets the thermostat to `t` at ❶; so the worklist is initialized to be (6:`t`); for presentation, we use line numbers instead of node numbers to label identifiers. Then, because of the function call at ❷, (3:`temp`) is added to the worklist and the dependence (6:`t`, 3:`temp`) is recorded in *dep*. With this dependence analysis, Soteria computes that the value for `t` has to be 68 °F since `temp` is initialized to be a constant value at ❸. Therefore, the state model has two states for the thermostat: a state when the temperature is equal to 68 °F, and a state when the temperature is not 68 °F; thus, the state space for temperature values is reduced from 45 to 2.

The backward dependence analysis also produces the *dep* relation, through which Soteria constructs paths from identifier initialization points to where device changes happen. For the example in Fig. 6, it produces the path

[3] We found that SmartThings IoT apps most often propagates a developer-defined constant or a user input to places that change device attributes. Occasionally, simple arithmetic is performed; for example, the user input is stored in y, followed by $x = y + 10$, followed by a device attribute change using x. In theory, an IoT app could perform operations like $x = y + z$, where both y and z are user input or defined to be constants; however, we have not encountered this in our evaluation.

❸→❷→❶. Some produced paths by dependence analysis, however, can be infeasible paths. As an optimization, SOTERIA prunes infeasible paths using path- and context-sensitivity. For a path calculated in dependence analysis, it collects the predicates at conditional branches and checks whether the conjunction of those predicates (i.e., the path condition) is always false; if so, the path is infeasible and discarded. This is similar to how symbolic execution prunes paths using path conditions. For instance, if a path goes through two conditional branches and the first branch evaluates $x > 1$ to true and the second evaluates $x < 0$ to true, then it is an infeasible path. SOTERIA does not use a general SMT solver to check path conditions. We found that the predicates used in IoT apps are extremely simple in the form of comparisons between variables and constants (such as $x = c$ and $x > c$); thus, SOTERIA implemented its simple custom checker for path conditions. Furthermore, SOTERIA throws away paths that do not match function calls and returns (using depth-one call-site sensitivity [39]). At the end of the pruning process, we get a set of feasible paths that propagate sources defined by the developer or by user input to device action calls that change the numerical-valued attribute; and then those sources are used to define the states in the model.

4.2.2 Extracting State Transitions

If an event handler changes a device's attributes by actuating the device, it leads to a state transition. By statically analyzing event handlers, SOTERIA computes state transitions and labels them with events. When a water-detected event is generated in the `Water-Leak-Detector` app a handler method closes the valve; by analyzing the handler method, SOTERIA adds a transition with the water-detected event label from state "water-undetected and valve-open" to "water-detected and valve-closed" state.

Labeling Transitions with Predicates. Many device state changes happen in conditional branches; as a result, those state changes occur only when the predicates in the conditional branches hold. To illustrate, consider the source code in Fig. 7 abstracted from the `Thermostat-Energy-Control` app. The app has a conditional branch turning off the switch when energy usage is above a consumption threshold (`above`=50); it turns on the switch when it is below the threshold (`below`=5).

SOTERIA implements a path-sensitive analysis to capture state transitions and predicates that guard transitions. Particularly, it uses *symbolic execution* to perform path exploration on source code and accumulates path conditions during exploration. In detail, it starts the analysis at the entry of an event handler with respect to some initial state, say S_0. Then it performs forward symbolic execution along all paths, and also smartly merges paths following the ESP algorithm [13] (as a way of avoiding path explosion). For a conditional branch with condition b, it evaluates both paths and labels the true path with b and the false path with $\neg b$. If the end states for the true and false branches are the same, then the two paths are merged [13]. On the other hand, if the end states are different for the two paths, they are kept separate for further symbolic execution. SOTERIA throws away infeasible paths in a way similar to that used during property abstraction. At the end of symbolic execution, SOTERIA obtains the set of paths, their end states, and path conditions. For each path, a state transition from the initial state to the end state is added to the state model, and the transition is labeled by the event triggering the event handler and path condition.

```
// Permission block
Input(switch, switch)
Input(power_meter, powerMeter)
// Event/Action block
subscribe(power_meter, power, handler)
// Entry point
handler(){
   above = 50
   below = 5
   power_val = get_power()
   if (power_val > above){
      switch.off()
   }
   if (power_val < below){
      switch.on()
   }
}
get_power(){
   latest_power = power_meter.currentValue("power")
   return latest_power
}
```

Figure 7: The impact of predicates on state transitions in the `Thermostat-Energy-Control` app.

We use the `Thermostat-Energy-Control` app with the initial state of "switch-on" as an illustration of this exploration. SOTERIA explores all paths, and there are two feasible paths at the end, with `currentValue("power")>50` as the path condition of the path that turns off the switch, and `currentValue("power")<5` as the path condition of the path that turns on the switch.

In addition, SOTERIA also tracks the sources of components in predicates that guard state transitions. For predicate `currentValue("power")>50` in the previous example, `currentValue("power")` is obtained from a device state and therefore is labeled as "device-state", while 50 is hardcoded by the developer and therefore is labeled as "developer-defined". In some cases, users can also define part of predicates at install time of an app. For instance, if the threshold value were entered by a user, then SOTERIA would label it as "user-defined". Labeling sources in predicates is useful for precisely stating properties used in model checking. For example, one property says that the alarm must siren when the main door is left open longer than a threshold entered by the user. In this case, there is no property violation if the threshold is not hard-coded into the app by the developer. We detail this in Sec. 4.3.

4.2.3 SmartThings Idiosyncrasies

Platform-specific Interfaces. The SmartThings platform implements a variety of programmer interfaces for an app to obtain device attribute values (for the same value). For instance, the temperature value of a thermostat can be read through the `currentState` or the `currentTemperature` interface (see Listing 1 (lines 1–8). Additionally, we found

Listing 1: Sample code blocks for SmartThings Idiosyncrasies

```
 1 /* A code block of an app using platform-specific interfaces */
 2 subscribe(theMotion, "motion", motionHandler)
 3 subscribe(theThermostat, "thermostat", thermostatHandler)
 4 // different interfaces to get device attribute values
 5 def thermostatHandler() {
 6     def tempAttr = theThermostat.currentState("temperature")
 7     def tempAttr2 = theThermostat.currentThermostat
 8 }
 9 // transitions without explicit event subscriptions
10 def motionHandler(evt) {
11     if (evt.value == "active") { ... }
12     else if (evt.value == "inactive") {...}
13 }
14 /* A code block of an app using call by reflection */
15 //initial state = S0
16 def getMethod(){
17   httpGet("http://url"){ resp ->
18       if(resp.status == 200){
19           name = resp.data.toString()
20       }
21   }
22   "$name"() // dynamic method invocation
23 }
24 // check state transition from S0 to next state in both methods
25 def foo() {...}
26 def bar() {...}
```

that some apps subscribe to all device events instead of specific device events; for example, the `subscribe` interface in Listing 1 (lines 9–13) is used to subscribe to all events of a motion sensor. The event handler then gets an event value as an argument that describes what event it is. We extract precise state models by parsing the event values passed in these interfaces and adding state transitions through those interfaces.

Call by Reflection. The Groovy language supports programming by reflection (using the `GString` feature) [44], which allows a method to be invoked by providing its name as a string. For instance, a Groovy method `foo()` can be invoked by declaring a string `name="foo"` requested from an external server via the `httpGet()` interface and thereafter called by reflection through `$name` (see Listing 1 (lines 14–26)). To handle calls by reflection, Soteria's call graph construction adds all methods in an app as possible call targets, as a safe over-approximation. For the example in Listing 1, Soteria adds both `foo()` and `bar()` to the targets of the call; then it searches for state changes in each method and extracts state transitions.

4.3 Identifying IoT Properties

As many have found in the security and safety communities, identifying the correct set of properties to validate for a given artifact is often a daunting task. In this work and as described below, we use established techniques adapted from other domains to systematically identify a set of properties that exercise Soteria and are representative of the real world needs of users and environments. That being said, we acknowledge in practice that properties are often more contextual and the methods to find them are often more art than science. Hence, we argue that many environments will need to tailor their property discovery process to their specific security and safety needs.

We refer to a property as a system artifact that can be formally expressed via specification and validated on the application model. We extend the use/misuse case requirements engineering [29, 33, 38, 47] to identify IoT properties. This approach derives requirements (properties) by evaluating the connections between 1) *assets* are artifacts that someone places value upon, e.g., a garage door, 2) *functional requirements* define how a system is supposed to operate in normal environment, e.g., when a garage door button is opened, the door opens, and 3) *functional constraints* restrict the use or operation of assets, e.g., the door must open only when an authorized garage-door opener device requests it. We used use/misuse case requirements engineering as a property discovery process on the IoT apps used in our evaluation (See Section 6) and identified 5 general properties (S.1-S.5, see Fig. 8) and 30 application-specific properties (P.1-P.30, see Table 1).

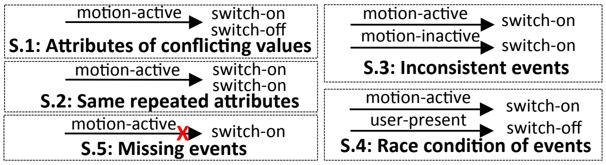


Figure 8: Illustration of general properties (S.1-S.5).

General Properties. General properties are constraints on state models that are independent of an app's semantics–intuitively, these are states and transitions that should never occur regardless of the app domain. We develop the properties based on the constraints on states and state transitions. To illustrate, property S.1 states that a handler must not change an attribute to conflicting values on the same control-flow path, e.g., the motion-active handler must not turn on and turn off a switch in the same branch of the handler. More subtly, property S.4 states that two or more non-complementary handlers must not change an attribute to conflicting values, e.g., a user-present handler turns on the switch while a timer turns off the switch–leading to a potential race condition.

App-specific Properties. App-specific properties are developed according to use cases of one or more devices–here we take a device-centric approach. For instance, P.1 says that the door must always be locked when the user is not at home (thus involving the smart door and presence detector). Similarly, P.30, states that the water valve must be shut off when there is a water leak (thus involving the water valve and moisture sensor). We evaluated all apps using this approach, but defer discussion to the extended paper. We check the app against a property if all of the devices in the property are included in the app.

4.4 Validating Properties

Validation begins by defining a temporal formula for each property to be verified. Thereafter, Soteria uses a general purpose model checker to validate the property with respect to the generated model of the target app (see next section for details). What the user does with a discovered violation is outside the scope of Soteria. However, in most cases, we expect that the results will be recorded

ID	Property Description
P.1	The door must always be locked when the user is not home.
P.10	The alarm must always go off when there is smoke.
P.12	The light must be off when the user is not home.
P.13	The devices (e.g., coffee machine, crock-pot) must always be on at the time set by the user.
P.14	The refrigerator and security system must always be on.
P.17	The AC and heater must not be on at the same time.
P.22	The battery of devices must not be below a specified threshold.
P.28	The sound system must not play music during the sleeping mode.
P.29	The flood sensor must always notify the user when there is water.
P.30	The water valve must be closed if a leak is detected.

Table 1: Examples of application-specific properties. A complete list of properties is available in the extended paper [9].

Algorithm 2: Creating the union of apps' state models

```
   Input   : $G = \{G_i\}_{i=1}^{n}$: State models of $n$ apps
   Output : $G'$ is the union of $\{G_i\}_{i=1}^{n}$
   /* Initialize G' */
1  states($G'$) ← {$v$ | $v$ is a tuple of attribute values in G}
   /* Construct union of apps' state models */
2  for $i \in (1{:}\ n)$ do
3      forall states $v \in G_i$ do
4          forall transitions $e = v \xrightarrow{l} u \in G_i$ do
5              $V'$ is a subset of states in $G'$ that contain $v$
6              $U'$ is a subset of states in $G'$ that contain $u$
7              forall $v' \in V'$ and $u' \in U'$ do
8                  add $e' = v' \xrightarrow{l} u'$ to $G'$ and label the edge with $i$
9              end
10         end
11     end
12 end
```

and the code hand-investigated to determine the cause(s) of the violation. If the violation is not acceptable for the domain or environment, the app can be rejected (from the market) or modified (by the developer) as needs dictate.

Validation of properties in multi-app environments is more challenging. Apps often interact through a common device or some common abstract event (such as the home or away modes). For illustration, consider two apps (App1 and App2) co-resident with the Smoke-Alarm and Thermostat-Energy-Control apps in a multi-device environment. App1 changes the mode from away to home when the light switch is turned on, and App2 turns off a light switch when the smoke is detected, as follows:

Smoke-Alarm: switch-off $\xrightarrow{\text{smoke-detected}}$ switch-on
App1: away-mode $\xrightarrow{\text{switch-on}}$ home-mode
Thermostat-Energy-Control: door-unlocked $\xrightarrow{\text{home-mode}}$ door-locked
App2: switch-on $\xrightarrow{\text{smoke-detected}}$ switch-off

The Smoke-Alarm app interacts with App1 through the switch, and interacts with App2 through the smoke detector and switch. The Thermostat-Energy-Control app interacts with App2 through the mode-change event.

To check general and app-specific properties in the setting of multiple apps, Soteria builds a state model that is the union of the apps' state models. The resulting state model G' represents the complete behavior when running the multiple apps together. The union algorithm is presented in Algorithm 2. Soteria first creates an empty-transition state model G' whose states are the Cartesian product of the states in the input apps (line 1); note that since the input apps' states encode device attributes, the Cartesian product should remove attributes of duplicate devices (i.e., those devices that appear in multiple apps). For instance, if we consider Smoke-Alarm and App1, G' should have four states, and each state encodes a pair of switch and mode attributes. The algorithm then iterates through all apps' transitions and adds appropriate transitions to the union model G'. Soteria's union algorithm is a modification of the multiple-graph union algorithm of igraph library [22], based on a set of constraints on transitions and states. It has a complexity of $O(|V|+|E|)$, $|V|$ and $|E|$ is the number of vertices and edges in G'.

With the union state model created, Soteria then performs model checking on the union model concerning properties we discussed earlier. As an example, Soteria reports that, when Smoke-Alarm and App2 are used together, there is a property violation of S.1: the smoke-detected event would make the Smoke-Alarm app turn on the switch, while it would also make App2 to turn off the switch. As another example, when Smoke-Alarm, App1 and Thermostat-Energy-Control are used together, there is a misuse case that violates property P.3: the door would be locked when there is smoke at home. The property violation is demonstrated as follows:

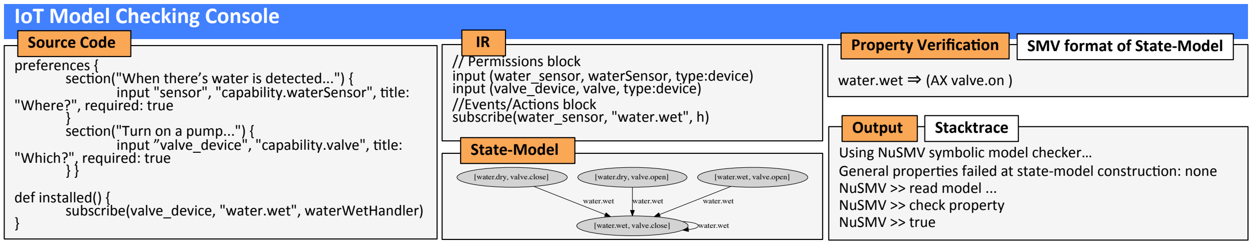
switch-off $\xrightarrow{\textbf{smoke-detected}}$ **switch-on** $\xrightarrow{\textbf{switch-on}}$ **home-mode** $\xrightarrow{\textbf{home-mode}}$ **door-locked**

P.3 is violated because switch-on attribute in the Smoke-Alarm app is used by App1, which changes the mode from away to home. The mode change then triggers locking the door in Thermostat-Energy-Control.

5 Implementation

IR and State Model Construction. Constructing an IR from the source code requires, among other things, the building of the app's ICFG. Here the Soteria IR-building algorithm directly works on the Abstract Syntax Tree (AST) representation of Groovy source code. The Groovy compiler supports customizing the compilation via compiler hooks, through which one can insert extra passes into the compiler (similar to the modular design of the LLVM compiler [27]). Soteria visits AST nodes at the compiler's semantic analysis phase where the Groovy compiler performs consistency and validity checks on the AST. Our implementation uses an ASTTransformation to hook into the compiler, GroovyClassVisitor to extract the entry points and the structure of the analyzed app, and GroovyCodeVisitor to extract method calls and expressions inside AST nodes. Here we AST visitors to analyze expressions and statements to construct the IR and model.

Soteria uses AST visitors for state model construction as well. We extend the ASTBrowser class implemented in the Groovy Swing console, which allows users to enter and run Groovy scripts [19]. The implementation hooks into the IR of an app in the console and dumps information to the TreeNodeMaker class; the information includes an AST node's children, parent, and all properties built during compilation. This includes the resolved classes,



```
preferences {
          section("When there's water is detected...") {
                    input "sensor", "capability.waterSensor", title:
"Where?", required: true
          }
          section("Turn on a pump...") {
                    input "valve_device", "capability.valve", title:
"Which?", required: true
          } }

def installed() {
          subscribe(valve_device, "water.wet", waterWetHandler)
}

NuSMV >> true
```

Figure 9: Our SOTERIA framework designed for IoT apps. The left region is the analysis frame; the middle region contains the IR and visual representation of the state model of an example IoT app, and the right region shows the output for a property violation.

static imports, the scope of variables, method calls, interfaces accessed in an app. We then use Groovy visitors to traverse the IR's ICFG and extract the state model.

Model Checking with NuSMV. We translate the state model of an IoT app into a Kripke structure [12]. A Kripke structure is an equivalent temporal structure of a state model and increases readability. We create a visual representation of a state model using open-source graph visualization software GraphViz [14]. We use the open-source symbolic model checker NuSMV [10] for its reliability and maturity. We express properties with temporal logic formulas [11]. NuSMV either confirms a property holds or presents a counter-example showing why the property is false. To address state explosion in apps that control a large number of devices or that have complex control logic, we use NuSMV options that combine binary decision diagrams (BDDs)-based model checking with SAT-based model checking [6]. This was successfully applied to verify models having more than 10^{20} states and hundreds of state variables [7].

Output of SOTERIA. Fig. 9 presents SOTERIA's analysis result on a sample app. It builds the app IR, extracts the state model, and displays a visual representation of the state model. For each property, SOTERIA either shows the property holds or presents a counter-example.

6 Evaluation

As a means of evaluating the SOTERIA framework, we performed an analysis on two large-scale data-sets–one market based and one synthetic. In these studies, we sought to validate the correctness, completeness, and performance of property analysis on the target datasets. We performed our experiments on a laptop computer with a 2.6GHz 2-core Intel i5 processor and 8GB RAM, using Oracle's Java Runtime version 1.8 (64 bit) in its default settings. We use NuSMV 2.6.0 for model checking and Graphviz 2.36 for visualization of a state model.

Datasets. For the market dataset, we obtained 35 official (vetted) apps (O1-O35) from the SmartThings GitHub repository [43] and 30 community-contributed third-party (non-vetted) apps (TP1-TP30) from the official SmartThings community forum [41] in late 2017 (see Table 2). The 65 apps were selected to include various devices and functionality that encompass diverse real-life use-cases.

	Nr.	Unique Devices	Avg/Max States‡	Avg/Max LOC	Func.†
Official	35	14	36/180	220/2633	All
Third-party	30	18	32/96	246/1360	All

‡ This is after applying SOTERIA's state-reduction algorithms.

† The apps cover all spectrum of functionality, including security and safety, green living, convenience, home automation, and personal care. We determined an app's functionality by checking definition blocks in its source code.

Table 2: Description of analyzed official and third-party apps.

For the synthetic dataset, we introduce MALIOT [23], an open source repository containing flawed IoT apps. Inspired by other security-relevant app test suites [4, 15, 28], MALIOT includes 17 hand-crafted flawed SmartThings apps (App1-App17) containing property violations in an individual app and multi-app environments. 14 apps have a single property violation, and three have multiple property violations, with a total of 20 property violations. The apps include various devices covering diverse real-life use-cases. The accurate identification of property violations requires program analysis including multiple entry points, numerical-valued device attributes, and transitions guarded by predicates. Each app in MALIOT also comes with ground truth of what properties are violated; this is provided in a comment block in the app's source code.

6.1 Market App Evaluation

We first report results of the verification of general (S.1-S.5) and app-specific (P.1-P.30) properties. The properties are checked for each app and collections of apps working in concert. SOTERIA flagged that nine individual apps and three multi-app groups violate at least one property. We manually checked the property violations and verified that all reported ones are true positives. The manual checking process was straightforward to perform since SmartThings apps are relatively small.

Individual App Analysis. Table 3 the results of our analysis on single apps. SOTERIA flagged one third-party app violating multiple properties, eight third-party apps violating a single property. None of the official apps were flagged as violating properties; we believe this is because of the strict manual vetting enforced on official apps, which takes a couple of months [40]. For third-party apps, we manually verified that all reported property violations are indeed problems with the implementation. For exam-

ID	Violation Description	Violated Pr.
TP1	The music player is turned on when user is not at home.	P.13
TP2	The switch turns on and blinks lights when no user is present.	P.12
TP3	The location is changed to the different modes when the switch is turned off and when the motion is inactive.	S.4
TP4	The flood sensor sounds alarm when there is no water.	P.29
TP5	The music player turns on when the user is sleeping.	P.28
TP6	The lights turn on and turn off when nobody is at home.	P.13 and S.1
TP7	The lights turn on and turn off when the icon of the app is tapped.	S.1
TP8	The door is unlocked on sunrise and locked on sunset.	P.1
TP9	The door is locked multiple times after it is closed.	S.2

Table 3: SOTERIA's results on individual apps.

ple, a property violation happens in an app (TP6) that turns off and on a light switch when there is nobody at home; another app (TP9) unlocks the door at sunset and locks the door at sunrise–and unintended action.

To assess whether the property violations are real bugs in analyzed apps, we opened a thread in official SmartThings community forum and asked users whether the functionality of the apps confirms their expectations [42]. We got eight answers from the users that are smart home enthusiasts. These apps may have subtle and surprising uses under the right conditions: a user for TP4, said that he used his flood sensor to let him know when there is no water so that he can add water to the trees during Christmas; another user stated that TP6 might simulate occupancy of his home at night by randomly turning on/off lights when nobody is home. To guard against malicious code, those users stated that they attempted to read and understand the source code of the apps before they installed them. However, since regular users cannot be expected to read and check the source code of apps manually, SOTERIA addresses this problem by analyzing apps and presenting their potential property violations to users, which allows them to determine whether a violation is actually harmful.

Multi-App Analysis. We found that multiple apps working in concert can lead to unsafe and undesired device states. SOTERIA flagged three group of apps violating multiple properties. We examined 28 groups and found three groups that have 17 apps violate 11 properties. Table 4 shows the app groups, events, and device attributes that constitute violations, and violated properties. In the following discussion, we will use app group IDs (G.1-G.3) in Table 4. Each group includes a set of apps that a user may install together and authorize to use the same devices.

In G.1, O3 and O4 violate S.1 by setting the switch attribute to conflicting values when the contact sensor is open; there is a similar violation between O4, O8 and TP12 when the contact sensor is closed. O8 and TP12 violates S.2 by turning on the switch multiple times with the "contact sensor close" event. In addition, O3 and O4 violate S.3 by turning on the switch with complement events of "contact sensor close" and "contact sensor open". In G.2, O9, O16, and TP3 violates S.2 by turning on the switch multiple times with the "motion active" event. Additionally, the interaction between O14, O9, O16 and TP3 violates S.4 by invoking "switch on" and "switch off" actions with different device events ("contact sensor open" and "motion active"). There is a similar violation between O14 and TP2 ("contact sensor open" and "app touch"). These events may occur at the same time, which leads to a race condition. In G.3, similar to the other groups, S.1 and S.2 are violated. In addition, multiple app-specific properties are violated. O7 and TP3 change the location mode when the switch is turned off and also when motion is inactive. O30 and TP21 turn off the switch of a set of devices including a security system, smoke detector, and heater when the location is changed; O31 and TP22 turns on devices such as TV, coffee machine, A/C, and heater when the location is changed; both cases violate multiple properties (P.12, P.13, P.14 and P.17) and cause security and safety risks for users. Lastly, O12 and TP19 sets the thermostat to user settings when the switched is turned off and when the motion is inactive. These result in an unauthorized control of thermostat heating and cooling temperature values.

Gr. ID	App ID	Events/Actions	Violated Pr.
G.1	O3	$\xrightarrow{\text{contact sensor open}}$switch on	S.1, S.2, S.3
	O4	$\xrightarrow{\text{contact sensor open}}$switch off	
		$\xrightarrow{\text{contact sensor close}}$switch on	
	O8, TP12	$\xrightarrow{\text{contact sensor close}}$switch off	
G.2	O14	$\xrightarrow{\text{contact sensor open}}$switch off	S.2, S.4
	O9, O16, TP3	$\xrightarrow{\text{motion active}}$switch on

Table 4: SOTERIA's results in multi-app environments.

6.2 MALIOT Evaluation

Our analysis of SOTERIA on MALIOT showed that it correctly identified the 17 of the 20 unique property violations in the 17 apps. SOTERIA produces a false warning for an app that uses call by reflection (App5). This app invokes a method via a string. It over-approximates the call graph by allowing the method invocation to target all methods in the app. Since one of the methods turns off the alarm when there is smoke, SOTERIA reports a violation. However, it turns out that the reflective call in this app would not call the property-violating method. Note this pattern did not appear in the 65 real IoT apps we discussed earlier. Additionally, SOTERIA did not report a violation for an app that leaks sensitive data (App10) and for an app that implements dynamic device permissions (App11) as they are outside the scope of SOTERIA analysis.

6.3 MicroBenchmarks

State Reduction Efficacy. Earlier we presented algorithms for performing property abstraction on numerical-valued device attributes. To evaluate its impact, we measured the number of states before and after the application of these algorithms, and the results are presented on the top of Fig. 10. We note that SOTERIA performs state reduction only for apps with devices that have numerical-valued

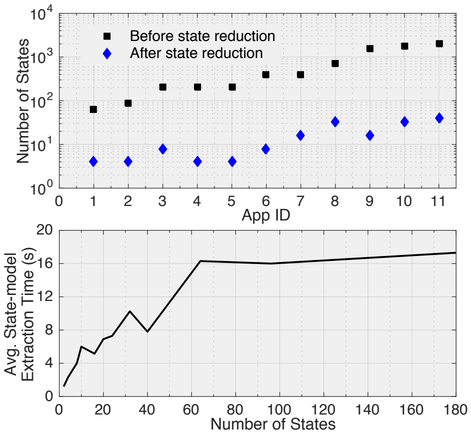

Figure 10: Soteria's state reduction efficacy (Top). Soteria's state model extraction overhead (Bottom).

attributes; examples include thermostats, batteries, and power meters. Among the devices we examine, there are ten such devices in analyzed apps, and 14 apps grant access to these devices, and the states of three apps have the same number before reduction and reduced to the same number. The figure shows that Soteria's state reduction often results in order of magnitude less number of states. **State Model Extraction Overhead.** We ran Soteria with apps that have varying numbers of states and recorded the state-model generation time; the result is shown on the bottom of Fig. 10. The time includes the time for IR extraction, generating a graphical representation of the model, obtaining the SMV code of a state model, and logging (required for general properties). The average run-time for an app with 180 states was 17.3±2 secs. We note that the total time depends on the time taken by the algorithms we have developed for state reduction. For instance, an app having 32 states took more time than an app having 40 states due to many branches used in the 32-state app. Note that overheads can be mitigated by eliminating non-essential processing and other optimization.

We also measured the time for constructing a state model in multi-app environments. The state model of multiple apps requires extraction of each app's state model. Soteria's graph-union algorithm then finds 30 interacting apps (which have on average 64 states and six state attributes) and 4±2.1 seconds for the union algorithm. **Property Verification Overhead.** We evaluated the verification time of a property on state models. The verification of a property took on the order of milliseconds to perform since the SmartThings apps have comparatively smaller state models than the large-scale ones found in other domains such as operating system kernels.

7 Limitations and Discussion

A limitation of Soteria is the treatment of call by reflection. As discussed in Sec. 4.2.3, Soteria constructs an imprecise call graph that allows a reflective call to target any method. This increases the size of state models and may lead to false positives during property checking. We plan to explore string analysis to statically identify possible values of strings and refine the target sets of method calls by reflection. Another limitation of Soteria is dynamic device permissions and app configurations. These may yield property violations because of the erroneous device and input configurations by users at install time. For instance, if a user enters an incorrect time value, the door may be left unlocked in the middle of the night.

Soteria's implementation and evaluation are based on the SmartThings programming platform designed for home automation. There are other IoT domains suitable for applying model checking for finding property violations, such as FarmBeats for agriculture [46], HealthSaaS for healthcare [20], and KaaIoT for the automobile industry [26]. We plan to extend our Soteria to these platforms by applying the IR-based analysis, as well as engage in large-scale analyses of IoT markets and industries.

8 Conclusions

We presented Soteria[4], a novel system that extracts state models from IoT code suitable for finding the security, safety, and functional errors. We evaluated Soteria in two studies; a study of apps on the SmartThings market, and a study on our novel MalIoT app corpus. These studies demonstrated that our approach can efficiently identify property violations and that many apps violate properties when used in isolation and when used together in multi-app environments. In future work, we will extend the kinds of analysis and provide a suite of tools for developers and researchers to evaluate implementations and study the complex interactions between users and IoT environments devices that they use to enhance their lives.

Scaling Guest OS Critical Sections with *e*CS

Sanidhya Kashyap   Changwoo Min[†]   Taesoo Kim
Georgia Institute of Technology   *Virginia Tech*[†]

Abstract

Multi-core virtual machines (VMs) are now a norm in data center environments. However, one of the well-known problems that VMs suffer from is the vCPU scheduling problem that causes poor scalability behaviors. More specifically, the symptoms of this problem appear as preemption problems in both under- and over-committed scenarios. Although prior research efforts attempted to alleviate these symptoms separately, they fail to address the common root cause of these problems: the missing semantic gap that occurs when a guest OS is preempted while executing its own critical section, thereby leading to degradation of application scalability.

In this work, we strive to address all preemption problems together by bridging the semantic gap between guest OSes and the hypervisor: the hypervisor now knows whether guest OSes are running in critical sections and a guest OS has hypervisor's scheduling context. We annotate all critical sections by using the *lightweight* para-virtualized APIs, so we called *enlightened critical sections (eCS)*, that provide scheduling hints to both the hypervisor and VMs. The hypervisor uses the hint to reschedule a vCPU to fundamentally overcome the *double scheduling* problem for these annotated critical sections and VMs use the hypervisor provided hints to further mitigate the blocked-waiter wake-up problem. Our evaluation results show that *e*CS guarantees the forward progress of a guest OS by 1) decreasing preemption counts by 85–100% while 2) improving the throughput of applications up to 2.5× in an over-committed scenario and 1.6× in an under-committed scenario for various real-world workloads on an 80-core machine.

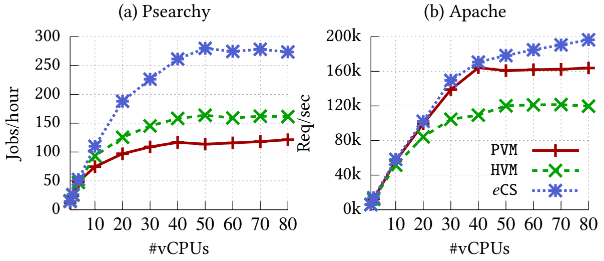

Figure 1: Impact of exposing some of the semantic information from the VM to the hypervisor and vice-versa, which leads to better scalability of Psearchy and Apache web server benchmark, in a scenario in which two VMs are running with the same benchmark. Here, PVM and HVM denote with and without para-virtualization support, while *e*CS represents our approach. Psearchy mostly suffers from LHP and BWW. Similarly, Apache suffers from LHP and ICP.

1 Introduction

Virtualization is now the backbone of every cloud-based organization to run and scale applications horizontally on demand. Recently, this scalability trend is also extending towards vertical scaling [2, 11], *i.e.*, a virtual machine (VM) has up to 128 virtual CPUs (vCPUs) and 3.8 TB of memory to run large in-memory databases [24, 35] and data processing engines [47]. At the same time, cloud providers strive to oversubscribe their resources to improve hardware utilization and reduce energy consumption, without imposing any permissible overhead on the application [38, 46]. However, over subscription requires multiplexing of physical CPUs among VMs to equally distribute physical CPU cycles. Thus, the multiplexing of these VMs introduces the *double scheduling problem* [40]: 1) the guest OS schedules processes on vCPUs and 2) the hypervisor schedules vCPUs on physical CPUs. Some of the prior works address this problem by adopting co-scheduling approaches [17, 41, 45], which can suffer from priority inversion, CPU fragmentation, and may mitigate the double scheduling symptoms [40]. Such symptoms, that have mostly been addressed individually, are lock-holder preemption (LHP) [8, 15, 42, 44], lock-waiter preemption (LWP) [44], and blocked-waiter wakeup (BWW) [5, 39], problems.

The root cause of this double scheduling phenomenon is a semantic gap between a hypervisor and guest OSes, in which the hypervisor is agnostic of not only the scheduling of VMs but also guest OS-specific critical code that deter the scalability of applications. Furthermore, LHP/LWP are not only limited to spinlocks [15, 19, 42], but are also possible in blocking primitives such as mutex and rwsem as well as readers of the rwsem. Moreover, because of their non work-conserving nature, these blocking primitives inherently suffer from the BWW problem (refer Psearchy in Figure 1 (a)). Besides these, none of the prior works have identified the preemption of an interrupt context that happens in interrupt-intensive applications such as Apache web-server (Figure 1 (b)). We define this problem as *interrupt context preemption* (ICP).

Our key observation is that these symptoms occur because 1) the hypervisor is scheduling out a vCPU at a time when the vCPU is executing a critical code, and 2) a vCPU, waiting to acquire a lock, is either uncooperative or sleeping [16], leading to LWP and BWW issues. Thus, we propose an alternative perspective, *i.e.*, instead of devising a solution for each symptom, we use four key ideas that allows a VM to hint the hypervisor for making an effective scheduling decision to allow its forward progress. First, we consider all of the locks and interrupt contexts as critical components. Second, we devise a set of para-virtualized APIs that annotate these critical components as *enlightened critical sections* (*e*CS). These APIs are lightweight in nature and notify a hypervisor from the VM and vice-versa with memory operations via shared memory, while avoiding the overhead of hypercall and interrupt injection. Third, the hypervisor now can figure out whether a vCPU is executing an *e*CS and can reschedule it. We empirically found that an extra schedule (one millisecond [27]) is sufficient as it decreases preemptions by 85–100%; and these critical sections are shorter (in μs [42]) than one schedule. However, by rescheduling a vCPU, we introduce unfairness in the system. We tackle this issue with the OS's fair scheduling policy [27], which compensates for that additional schedule by allowing other tasks to run for extra time, thereby maintaining the eventual fairness in the system. Lastly, we leverage our APIs to design a virtualized schedule-aware spinning strategy (*e*SchdSpin) that enables lock waiters to be work conserving as well as cooperative inside a VM. That is, a vCPU now cooperatively spins for the lock, if a physical CPU is under-committed, else it yields the vCPU.

Thus, our approach improves the scalability of real-world applications by 1.2–1.6× in an under-committed case. Moreover, our *e*CS annotation, combined with *e*SchdSpin, avoids preemption by 85–100% while improving the scalability of applications by 1.4–2.5× in an over-committed scenario on an 80-core machine.

In summary, we make the following contributions:

- We identify similarities among various subproblems that stem from the double scheduling phenomenon. Moreover, we identify three new problems: 1) LHP in blocking locks, 2) readers preemption (RP) in read-write locks and semaphores, and 3) vCPU preemption while processing an interrupt context (ICP).
- We address these subproblems with *e*CS, which we annotate with six new APIs that bridge the semantic gap between a hypervisor and a VM, and even among vCPUs inside a VM.
- Our annotation approach, along with *e*SchdSpin, improves the scalability of applications in both under- and over-committed scenarios up to 2.5× with only 0–15% preemptions, while maintaining eventual fairness with merely one extra schedule.

2 Background and Motivation

We first describe the problem of double scheduling and highlight its implications. Later, we summarize the prior attempts to solve this problem, and then motivate our approach.

2.1 Symptoms of Double Scheduling

In a virtualized environment, a hypervisor multiplexes the hardware resources for a VM, such as assigning vCPUs to physical CPUs (pCPUs). In particular, it runs a vCPU to execute by its fair share [27], which is a general policy of commodity OSes such as Linux, and preempts it because of either vCPUs of other VM or of the intermittent processes of the OS and bookkeeping tasks of the hypervisor such as I/O threads. Hence, there is a possibility that the hypervisor can preempt a vCPU while executing some critical task inside a VM that leads to an application performance anomaly, which we enumerate below:

Lock holder preemption (LHP) problem occurs when a vCPU holding a lock gets preempted and all waiters waste CPU cycles for the lock. Most of the prior works [8, 14, 42, 44] have focused on non-blocking primitives such as spinlocks.[1] On the other hand, LHP also occurs in blocking primitives such as mutex [28] and rwsem [26, 31], which the prior works have not identified. However, LHP accounts up to 90% preemptions for blocking primitives in some of the memory intensive applications that have short critical sections.

Lock waiter preemption (LWP) problem stems when the very next waiter is preempted just before acquiring the lock, which occurs due to the strict FIFO ordering of spinlocks [14, 42]. Fortunately, this problem has been mostly mitigated in existing spinlock design [19, 20], as the current implementation allows waiters to steal the lock before joining the waiter queue. We do not see such a problem in blocking primitives because the current implementation is based on the test-and-set (TAS) lock—an unfair lock, which inherently mitigates LWP.

Blocked-waiter wakeup (BWW) problem occurs mostly for blocking primitives in which the latency to wake up a waiter to pass the lock is quite high. This issue severely degrades the throughput of applications running on a high core count [16], even in a native environment. Moreover, it is evident in both under- and over-committed VM scenarios. For example, the BWW problem degrades the application scalability up to 1.6× (refer Figure 6).

Readers preemption (RP) problem is a new class of problem that occurs when a vCPU holding a read lock among multiple readers gets preempted. This problem impedes the forward progress of a VM and also increases the latency of the write lock. For instance, various memory-intensive workloads have sub-optimal throughput as RP accounts to at most 20% of preemptions. We observe this issue in various read-dominated memory-intensive workloads in which the readers are scheduled out.

RCU reader preemption (RRP) problem is a type of RP

[1] Non-blocking locks, both holders and waiters, do not schedule out. However, the para-virtualized interface converts spinlocks to blocking locks (only waiters) with hypercalls [6, 20] to overcome LHP/LWP issues.

problem that occurs when an RCU reader is preempted, while holding the RCU read lock [33]. Because of RRP, the guest OS suffers from an increased quiescence period. This issue can increase the memory footprint of the application, and is responsible for 5% of preemptions.

Interrupt context preemption (ICP) problem happens when a vCPU that is executing an interrupt context gets preempted. In particular, this problem is different from prior works that focus on interrupt delivery [12, 43] rather than interrupt handling. This issue occurs in cases such as TLB shootdowns, function call interrupts, rescheduling interrupts, IRQ work interrupts, etc. in every commodity OS. For example, we found that Apache web server, an interrupt-intensive workload, suffers from the ICP problem as it accounts to almost 18% of preemptions for evaluated workloads (refer Figure 3).

2.2 Prior Approaches

Some of the prior studies mitigate LHP and LWP problems by relaxed co-scheduling [45], balancing vCPUs to physical CPUs [41] with IPIs as a heuristic [17], or using hardware features [34]. Meanwhile, others designed a para-virtualized interface [8, 14, 42, 44] to only tackle the LHP and LWP problem for spinlocks. Besides these, one radical design focused on scheduling VM's processes than vCPUs by hot plugging vCPUs on the basis of load on the VM [3, 40]. Unfortunately, all of these prior works address the double scheduling problem either *partially* that misses other preemption problems, or take a radical path that is not only difficult to adopt in practice but can have significant overhead, in terms of scaling for machines with almost 100 physical cores. Because their approach involves 1) the detection of response to the double scheduling in the form of hypercalls and interrupt injection [3], and 2) explicit task migration from idle vCPUs to active vCPUs. On the contrary, our approach does simple memory operations and exploits the vCPU scheduling boundary to notify the hypervisor for scheduling decisions without any explicit task and vCPU migration: a lightweight approach even at high core count.

2.3 The Case for *An Extra Schedule*

As mentioned before, OS critical sections are the ones that define the forward progress of an application for which the OS is responsible. For instance, let us take an example of two threads competing to acquire a lock to update contents of a file. If the lock holder, which is updating the file, is preempted, the other waiter will waste CPU cycles. There are several critical operations that affect the application scalability [16, 25], and OS performs such operations either by acquiring a lock or executing an interrupt context (I/O processing, TLB shootdowns, etc.). In particular, a delay in processing of these critical sections can result in a severe performance anomaly such as a convoy effect [14, 16], or decreased network throughput for applications such as web servers (refer Figure 1). Hence, unlike prior approaches, we propose a simple and an intuitive approach, *i.e.*, now a VM hints the hypervisor about a critical section that enables the hypervisor to let a vCPU execute for a pre-defined time slot (schedule). This extra schedule is sufficient to complete a critical section because 1) most critical sections are very fine-grained, and have a time granularity of several microseconds [42], while 2) the granularity of a single schedule is in the order of milliseconds, which is sufficient enough to complete a critical section. For instance, an extra schedule decreases the preemption count by 85–100% (Figure 3). This approach is not only practical but also critical to apply on machines with large core count. However, the extra schedule introduces *unfairness* in the system, which we address by designing a simple, *zero-overhead schedule penalization algorithm* that tries to maintain the *eventual fairness* in the system by leveraging the CFS [27] that tries to maintain fairness in the system.

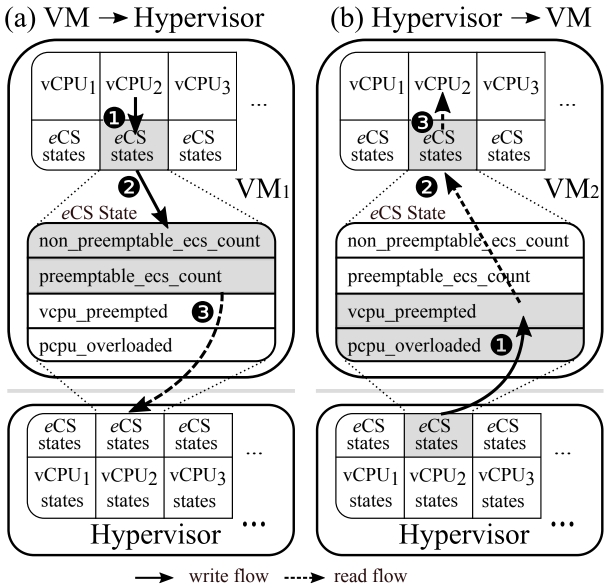

Figure 2: Overview of the information flow between a VM and a hypervisor. Each vCPU has a per-CPU state that is shared with the hypervisor, denoted as *e*CS state. Figure (a) shows how the vCPU$_2$ relays information about an *e*CS to the hypervisor. On entering a critical section or an interrupt context (❶), vCPU$_2$ updates the non_preemptable_ecs_count (❷). After a while, before scheduling out vCPU$_2$, the hypervisor reads its *e*CS state (❸), and allows it run for one more schedule to mitigate any of the double scheduling problems. Figure (b) shows how the hypervisor shares the information whether a vCPU is preempted or a physical CPU is overloaded, at the schedule boundary. For instance, the hypervisor marks vcpu_preempted, while scheduling out a vCPU; or updates pcpu_overloaded flag to one if the number of active tasks on that physical CPU is more than one. Both try to further mitigate LWP and BWW problems.

Hint	Lightweight Para-virtualized API	Description
VM → Hypervisor	`void activate_non_preemptable_ecs(cpu_id)`	Increase the *e*CS count for a `vCPU` with cpu_id by 1 for a non-preemptable task
	`void deactivate_non_preemptable_ecs(cpu_id)`	Decrease the *e*CS count for a `vCPU` with cpu_id by 1 for a non-preemptable task
	`void activate_preemptable_ecs(cpu_id)`	Increase the *e*CS count for a `vCPU` with cpu_id by 1 for a preemptable task
	`void deactivate_preemptable_ecs(cpu_id)`	Decrease the *e*CS count for a `vCPU` with cpu_id by 1 for a preemptable task
Hypervisor → VM	`bool is_vcpu_preempted(cpu_id)`†	Return whether a `vCPU` with cpu_id is preempted by the hypervisor
	`bool is_pcpu_overcommitted(cpu_id)`	Return whether a physical CPU, running a `vCPU` with cpu_id, is over-committed

Table 1: Set of para-virtualized APIs exposed by the hypervisor to a VM for providing hints to the hypervisor to mitigate double scheduling. These APIs provide hints to the hypervisor and VM via shared memory. A `vCPU` relies on the first four APIs to ask for an extra schedule to overcome `LHP`, `LWP`, `RP`, `RRP`, and `ICP`. Meanwhile, a `vCPU` gets hints from the hypervisor by using the last two APIs to mitigate `LWP` and `BWW` problems. The `cpu_id` is the core id that is used by tasks running inside a guest OS.
†Currently, `is_vcpu_preempted()` is already exposed to the VM in Linux.

3 Design

A hypervisor can mitigate various preemption problems, if it is aware of a `vCPU` executing a critical section. We denote such a hypervisor-aware critical section as an *enlightened critical section* (*e*CS), that can be executed for one more schedule. *e*CS is applicable to all synchronization primitives and mechanisms such as `RCU` and interrupt contexts. We now present our lightweight APIs that act as a cross-layer interface for annotating an *e*CS and later focus on our notion of an extra schedule and our approach to maintain eventual fairness in the system.

3.1 Lightweight Para-virtualized APIs

We propose a set of six *lightweight para-virtualized APIs* to bridge the semantic gap that both VM and hypervisor use for conveying information between them. These APIs rely on four variables (refer Figure 2) that are *local* to each `vCPU`. They are exposed via shared memory between the hypervisor and a VM and the notification happens via simple read and write memory operations. A simple memory read is sufficient for the hypervisor to decide on scheduling because 1) it tries to execute each `vCPU` on a separate `pCPU`, 2) and it requires knowing about an *e*CS only at the schedule boundary, thereby removing the cost of polling and other synchronous notifications [3]. To consider an OS critical section as an *e*CS, we mark the start and unmark the end of a critical section, which lets the hypervisor know about an *e*CS. However, a process in an OS can be of two types. First is the non-preemptable process that can never be scheduled out. Such a process is either an interrupt or a kernel thread running after acquiring a spinlock. Another one is the preemptable task such as a user process or a process with blocking lock. Hence, we introduce four APIs (VM → Hypervisor) to separately handle these two types of tasks. The last two APIs (Hypervisor → VM) provide the hypervisor context to the VM, which a lock waiter can use to mitigate the `LWP` problem or yield the `vCPU` to other hypervisor tasks or `vCPU`s in an over-committed scenario. Figure 2 illustrates those four states:

- **`non_preemptable_ecs_count`** maintains the count of active non-preemptable *e*CSs, such as non-blocking locks, `RCU` reader, and interrupt contexts. It is similar to the preemption count of the OS.
- **`preemptable_ecs_count`** is similar to the preemption count variable of the OS, but it only maintains the count of active preemptable *e*CSs, such as blocking primitives, namely, `mutex` and `rwsem`.
- **`vcpu_preempted`** denotes whether a `vCPU` is running. It is useful for handling the `BWW` problem in both under- and over-committed scenarios.
- **`pcpu_overloaded`** denotes whether a physical CPU, executing that particular `vCPU`, is over-committed. Lock waiters can use this information to address the `BWW` problem in an over-committed scenario.

Figure 2 presents two scenarios in which the schedule context information is shared between a `vCPU` and the hypervisor. Figure 2 (a) shows how a `vCPU`, *i.e.*, entering an *e*CS, shares information with the hypervisor. During entry (❶), `vCPU`$_2$ first updates its corresponding state (`non_preemptable_ecs_count` or `preemptable_ecs_count`) (❷) and continues to execute its critical section. Meanwhile, the hypervisor, before scheduling out `vCPU`$_2$, checks `vCPU`$_2$'s *e*CS states (❸) and allows it to run for extra time if certain criteria are fulfilled (§3.2); otherwise, it schedules out `vCPU`$_2$ with other waiting tasks. When `vCPU`$_2$ exits the *e*CS, it decreases the *e*CS state count, denoting the end of critical section. Figure 2 (b) illustrates another scenario that addresses the `BWW` problem. in which the hypervisor updates the *e*CS states: `pcpu_overloaded` and `vcpu_preempted` while scheduling in and out `vCPU`$_2$, respectively, at each schedule boundary (❶). We devise a simple approach—virtualized scheduling-aware spinning (*e*SchdSpin)—that enables efficient scheduling aware waiting for both blocking and non-blocking locks (§4). That is, `vCPU`$_2$ reads both states (❷) and decides whether to keep spinning until the lock is acquired if the `pCPU` is not overloaded (❸), else it yields, which allows the other `vCPU` (in `VM`$_2$) or a hypervisor's task to progress forward by doing some useful task, thereby mitigating the double scheduling problems.

3.2 Eventual Fairness with Selective Scheduling

As mentioned before, the hypervisor relies on its scheduler to figure out whether a `vCPU` is executing an *e*CS. That is, when a `vCPU` with a marked *e*CS is about to be scheduled out, the hypervisor scheduler checks the value of *e*CS count variables (Figure 2). If any of these values are greater than zero, the hypervisor lets the vCPU run for an extra schedule. However, vCPU rescheduling introduces two problems: 1) How does the hypervisor handles a task with *e*CS, which the guest OS can preempt or schedule out? 2) How does it ensure the system fairness?

We handle an *e*CS preemptable task with preemptable_ecs_count counter APIs, which differentiate between a preemptable task and a non-preemptable task. We do so because the guest OS can schedule out a preemptable task. In this case, the hypervisor should avoid rescheduling that vCPU because 1) it will result in false rescheduling, and 2) it can hamper the VM performance. We address this issue inside the guest OS, *i.e.*, before scheduling out an *e*CS-marked task inside a guest OS, we save the value of preemptable_ecs_count to a task-specific structure and reset the counter to zero. Later, when the task is rescheduled again by the guest OS, we restore the preemptable_ecs_count with the saved value from the task-specific structure, thereby mitigating the false scheduling.

With vCPU rescheduling, we introduce unfairness at two levels: 1) An *e*CS marked vCPU will always ask for rescheduling on every schedule boundary.[2] 2) By rescheduling a vCPU, the hypervisor is unfair to other tasks in the system. We resolve the first issue by allowing the hypervisor to reschedule an *e*CS-marked vCPU only once during that schedule boundary as rescheduling extends the boundary. At the end of schedule boundary, the hypervisor schedules other tasks to avoid the starving other tasks or VMs and addresses indefinite rescheduling. In addition, the hypervisor also keeps track of this extra reschedule information and runs other vCPUs for longer duration and inherently balances the running time, an equivalent to vCPU penalization. Thus, our approach selectively reschedules and penalizes a vCPU rather than balancing the extra reschedule information across all cores, which will result in an unnecessary overhead of synchronizing all runtime information of rescheduling. We call our approach as the *local CPU penalization* approach, as we only penalize a vCPU that executed an *e*CS, thereby ensuring *eventual fairness* in the system. Moreover, our local vCPU scheduling is a form of selective-relaxed co-scheduling of vCPUs depending on what kind of tasks are being executed, while without maintaining any synchronization among vCPUs, unlike prior approaches [41, 45].

API	LHP	RP	RRP	ICP	LWP	BWW
activate_non_preemptable_vcs()	✓	✓	✓	✓	-	-
deactivate_non_preemptable_vcs()	✓	✓	✓	✓	-	-
activate_preemptable_vcs()	✓	✓	-	-	-	-
deactivate_preemptable_vcs()	✓	✓	-	-	-	-
is_vcpu_preempted()	-	-	-	-	✓	✓
is_pcpu_overcommitted()	-	-	-	-	-	✓

Table 2: Applicability of our six lightweight para-virtualized APIs that strive to address the symptoms of double scheduling.

Component	Lines of code
*e*CS annotation	60
*e*CS infrastructure	800
Scheduler extension	150
Total	1,010

Table 3: *e*CS requires small modifications to the existing Linux kernel, and the annotation effort is also minimal: 60 LoC changes to support the 10 million LoC Linux kernel that has around 12,000 of lock instances with 85,000 lock invocations.

4 Use Case

The double scheduling phenomenon introduces the semantic gap in three places: 1) from a vCPU to a physical CPU that results in LHP, RP, and ICP problems; 2) from a pCPU to a vCPU; and 3) from one vCPU to another in a VM, both suffer from LWP and BWW problems. Table 2 shows how to use our APIs to address these problems.

LHP, RP, RRP, and ICP problem. To circumvent these problems, we rely on the VM → hypervisor notification because a vCPU running any spinlocks, read-write locks, mutex, rwsem, or an interrupt context is already inside the critical section. Thus, we call activate_*() and deactivate_*() APIs for annotating critical sections. For example, the first two APIs are applicable to spinlocks, read-write locks, RCU, and interrupts, and the next two are for mutex and rwsem. (refer Table 2).

LWP and BWW problem. The LWP problem occurs in the case of FIFO-based locks such as MCS and Ticket locks [23]. However, unfair locks, such as qspinlock [6], mutex [29], and rwsem [37], do not suffer from this problem, and are currently used in Linux. The reason is that they allow other waiters to steal the lock, while suffering from the issue of starvation. On the other hand, all of these locks suffer from the BWW problem because the cost to wake up a sleeping in a virtualized environment varies from 4,000–10,000 cycles. as a wake-up call results in a VMexit, which adds an extra overhead to notify a vCPU to wake up a process. This problem is severe for blocking primitives because they are non-work conserving in nature [16], *i.e.*, the waiters schedule out themselves, even if a single task is present in the run queue of the guest OS. We partially mitigate this issue by allowing the waiters to spin rather than sleep if a single task is present in the run queue of the guest scheduler (SchdSpin). However, this approach is non-cooperative when multiple VMs are running. Thus, to avoid unnecessary spinning of waiters, we rely on our is_pcpu_overcommitted() API that notifies a waiter to only spin if the pCPU is not over-committed. We call this approach the virtualized scheduling-aware spinning approach (*e*SchdSpin).

[2] Such a VM can be either an I/O or an interrupt-intensive VM that spends most of its time in the kernel, or even a compromised VM.

5 Implementation

We realized the idea of *e*CS by implementing it on the Linux kernel version 4.13. Besides annotating various locks and interrupt contexts with *e*CS, we specifically modified the scheduler and the para-virtual interface of the KVM hypervisor. Our changes are portable enough to apply on the Xen hypervisor too. The whole modification consists of 1,010 lines of code (see Table 3).

Lightweight para-virtualized APIs. We share the information between the hypervisor and a VM with a shared memory between them, which is similar to the `kvm_steal_time` [4] implementation. For instance, each VM maintains a per-core *e*CS states, and the hypervisor maintains per-vCPU *e*CS states for each VM.

Scheduler extension. We extend a scheduler-to-task notification mechanism, `preempt_notifier` [18], for identifying an *e*CS-marked vCPU at the schedule boundary. Our extension allows the scheduler to know about the task scheduling requirement and decide scheduling strategy at the schedule boundary. For example, in our case, the extension reads the `non_preemptable_ecs_count` and `preemptable_ecs_count` to decide the scheduling strategy for the vCPU. Besides this, we rely on the notifier's in and out APIs to set the value of `vcpu_preempted` and `pcpu_overloaded` variables.

We implemented our vCPU rescheduling decision in the `schedule_tick` function [36]. The `schedule_tick` function performs two tasks: 1) It does the bookkeeping of the task runtime, which is used for ensuring the fairness in the system. 2) It also is responsible for setting the rescheduling flag (`TIF_NEED_RESCHED`) if there is more than one task on that run queue, which is used by the scheduler to schedule out the task if the reschedule flag is set. We implemented the rescheduling strategy by bypassing the setting up of the reschedule flag in case the `preempt_notifier` check function returned true, meanwhile updating the runtime statistics of the vCPU.

Annotating locks for *e*CS. We mark *e*CS by using the non-preemptable APIs for non-blocking primitives, preemptable ones for `mutex` and `rwsem`. Our annotation comprises only 60 LoC that covers around 12,000 lock instances with 85,000 lock API calls in the Linux kernel that has 10 million LoC for the kernel version 4.13.

6 Evaluation

We evaluate our approaches by answering the following questions:

- What is the overhead of an *e*CS annotation and the scheduler overhead to read the values? (§6.1)
- Does *e*CS helps in an over-committed case? (§6.2)
- How does *e*CS impact the scalability of a VM? (§6.3)
- How do our APIs address the BWW problem? (§6.4)
- Does our schedule penalization approach maintain the eventual fairness of the system? (§6.5)

Experimental setup. We extended VBench [13] for our evaluation. We chose four benchmarks: Apache web server [7], Metis [21], Psearchy from Mosbench, and Pbzip2 [9]. The Apache web server serves a 300 bytes static page for each request that is generated by WRK [10]. Both of them are running inside the VM to remove the network wire overhead and only stress the VM's kernel components. We choose Apache to stress the interrupt handler to emphasize the importance of *e*CS for an interrupt context. Metis is a map-reduce library for a single multi-core server that mostly stresses the memory allocator (spinlock) and the page-fault handler (`rwsem`) of the OS. Similar to Metis, Psearchy is an in-memory parallel search and indexer that stresses the writer side of the `rwsem` design. In addition, we also choose Pbzip2—a parallel compression and decompression program—because we wanted to use a minimally kernel-intensive application. Moreover, none of these workloads suffer from performance degradation from any known user space bottleneck in a non-virtualized environment. We use memory-based file system, `tmpfs`, to isolate the effect of I/O. We further pin the cores to circumvent vCPU migration at the hypervisor level to remove the jitter from our evaluation.

We evaluate our *e*CS approach against the following configurations: 1) PVM is a para-virtualized VM that includes unfair `qspinlock` implementation, which mitigates LWP and BWW issues, and it is the default configuration since Linux v4.5. 2) HVM is the one without paravirtualization support and also includes unfair `qspinlock` implementation. Both PVM and HVM are not *e*CS annotated. Note that we could not compare other prior works because they are not open sourced [3, 45] and are very specific to the Xen hypervisor [42]. We evaluate these configuration on an eight socket, 80-core machine with Intel E7-8870 processors. Another point is that the current version of KVM partially addresses the BWW problem that can occur from the user space [22].

6.1 Overhead of *e*CS

We evaluate the cost of our lightweight para-virtualized APIs on various blocking and non-blocking locks, and RCU. Table 4 enumerates the overhead of the sole API cost including the cost of executing a critical section with a simple microbenchmark that executes an empty critical section to quantify the impact of *e*CS API on these primitives in both lowest (1 core) and highest contention (80 core) scenarios. *1 core* denotes that a thread is trying to acquire a critical section, whereas *80 core* denotes that 80 threads are competing. We observe that *e*CS adds an overhead of almost 0.9–18.4 ns in low contention, whereas negligible overhead in high contention scenario, except RCU. For RCU, the empty critical section

	Time (ns)			
Critical sections	**1 core**		**80 core**	
	W/o *e*CS	W/ *e*CS	W/o *e*CS	W/ *e*CS
API cost	–	16.4	–	16.4
spinlock	31.2	44.8	4,782.3	4,772.9
rwlock (read)	32.0	38.8	2,418.2	2,519.4
rwlock (write)	27.4	45.8	4,363.3	4,784.5
mutex	33.5	34.4	49,116.4	48,125.7
rwsem (read)	35.6	36.6	2,588.8	2,737.0
rwsem (write)	33.3	38.1	7,055.7	7,150.1
RCU	9.8	19.7	9.8	19.8

Table 4: Cost of using our lightweight para-virtualized APIs with various synchronization primitives and mechanism. *1 core* and *80 core* denote the time (in ns) to execute an empty critical section with one and 80 threads, respectively. Although, our approach slightly adds an overhead on a single core count, there is no performance degradation for our evaluated workloads.

suffers from almost twice the overhead because both RCU's lock/unlock operations do a single memory update on the preempt_count variable for a preemptable kernel. Even though our APIs add an overhead in the low contended scenario, we do not observe any performance degradation for any of our evaluated workloads.

6.2 Performance in an Over-committed Scenario

We evaluate the performance of the aforementioned workloads in an over-committed scenario by running two VMs in which each vCPU from both VMs share a physical CPU. Figure 3 (i) shows the throughput of these workloads for PVM, HVM, and *e*CS; (ii) shows the number of unavoidable preemptions that we capture while running these workloads when a vCPU is about to be scheduled out for *e*CS; and (iii) represents the percentage of types of observed preemptions, namely, LHP for blocking (B-LHP) and non-blocking (NB-LHP) locks, RP, RRP, ICP problems that we observe for the *e*CS configuration, including both avoided and unavoided preemptions.

Apache. *e*CS outperforms both PVM and HVM by 1.2× and 1.6×, respectively (refer (t:a) in Figure 3). Moreover, our approach reduces the number of possible preemptions by 85.8–100% (refer (n:a)) because of our rescheduling approach. We cannot completely avoid all preemptions because of our schedule penalization approach, as some of the preemptions occur consecutively. Even though *e*CS adds overhead, especially to RCU, it still does not degrade the scalability for four reasons: 1) We address the BWW problem, which allows for more opportunities to acquire the lock on time; 2) both hypervisor → VM APIs allow cooperative co-scheduling of the VMs; 3) our extra schedule approach avoids 85.8–100% of captured preemptions with the help of our VM → hypervisor APIs; and 4) the APIs overhead partially mitigates the highly contended system at higher core count by acting as a back-off mechanism. Another interesting observation is that we observe almost every type of preemption (refer Figure 3 (p:a)) because of serving the static pages, which involves blocking locks for the socket connection and softirq and spinlocks use for the interrupts processing. In particular, the number of preemptions is dominated by LHP for non-blocking and blocking locks, followed by ICP and then RP. We believe that the ICP problem will further exacerbate with optimized interrupt delivery mechanisms [12, 43]. PVM is 1.36× faster than HVM at 80 cores because of the support of para-virtualized spinlock (qspinlock [20]) as well as the asynchronous page fault mechanism that decreases the contention [30].

The major bottleneck for this workload is the interrupt injection, which can be mitigated by proposed optimized methods [12, 43]. In addition, Figure 4 (b) presents the latency CDF for the Apache workload at 80 cores in both under- and over-compression case. We observe that *e*CS not only maintains almost equivalent latency as that of PVM in an under-committed case, but also decreases in the over-committed case by 10.3–17% and 9.5–27.9% against PVM and HVM, respectively.

Psearchy mostly stresses the writer side of rwsem as it performs 20,000 small and large mmap/munmap operations along with stressing the memory allocator for inode operations, which mostly idles the guest OS because of the non-work conserving blocking locks [16]. Figure 3 (t:b) shows the throughput, in which *e*CS outperforms both PVM and HVM by 2.3× and 1.7×, respectively. The reason is that we 1) partially mitigate the BWW problem with our *e*SchdSpin approach, and 2) decrease the number of preemptions by 95.7–100% with an extra schedule (refer (n:b)). In addition, our *e*SchdSpin approach decreases the idle time from 65.4% to 45.2%, as it allows waiters to spin than schedule out themselves, which severely degrades the scalability in a virtualized environment, as observed for both PVM and HVM. This workload is dominated by mostly blocking and non-blocking locks, as they account to almost 98% preemptions (refer (p:b)). We also observe that HVM outperforms PVM by 1.33× because the asynchronous page fault mechanism introduces more BWW issue as it schedules out a vCPU if the page is not available, which does not happen for HVM.

Metis is a mix of both page fault and mmap operations that stress both the reader and the writer of the rwsem. Hence, it also suffers from the BWW problem, as we observe in Figure 3 (t:c). *e*CS outperforms PVM and HVM by 1.3× at 80 cores because of the reduced BWW problem and decreased preemptions that account to 91.4–99.5% (Figure 3 (n:c)). Note that the reader preemptions are 20%, thereby illustrating that readers preemptions is possible for read-dominated workloads, which has not been observed by any prior works. We do not observe any difference in the throughput of HVM and PVM.

Pbzip2 is an efficient compression/decompression work-

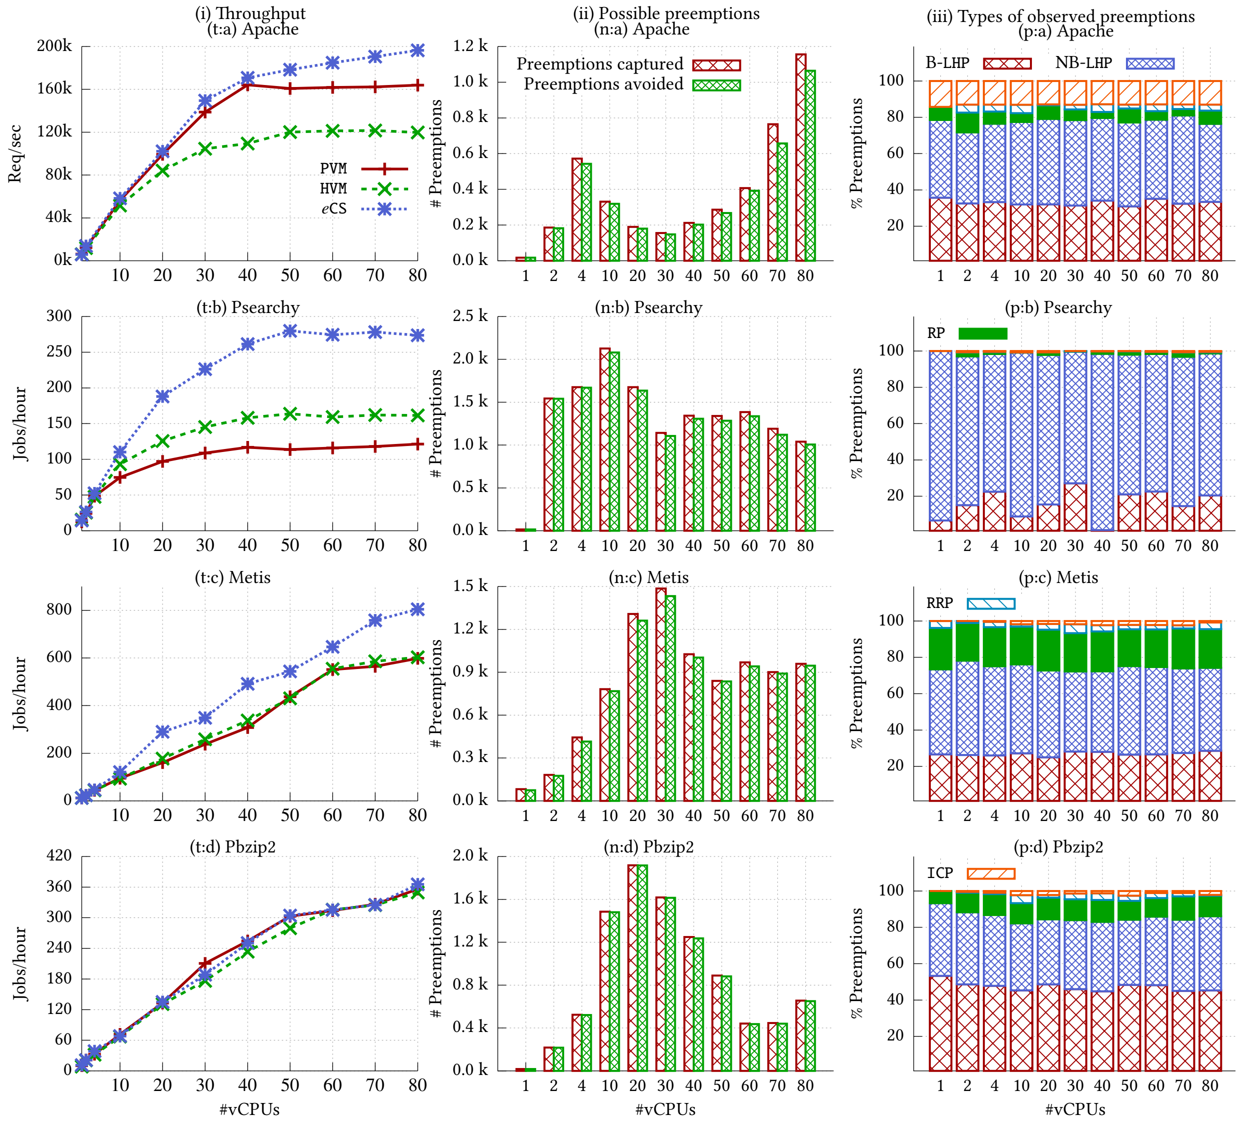

Figure 3: Analysis of real-world workloads in an over-committed scenario, *i.e.*, two instances of VM are executing the same workload. Column (i) represents the scalability of selected workloads in three settings: PVM, HVM, and with *e*CS annotations. Column (ii) represents the number of preemptions caught and prevented by the hypervisor with our APIs. Column (iii) represents the type of preemptions caught by the hypervisor (refer Table 4). By allowing an extra schedule, our approach reduces preemptions by 85–100% and improve scalability of applications by up to 2.5×, while observing almost all types of preemptions for each workload.

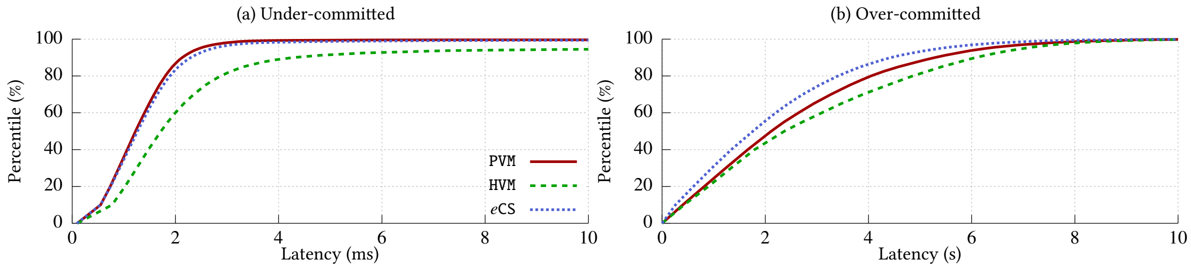

Figure 4: CDF of the latency of requests for the Apache web server workload in both under- and over-committed scenarios at 80 cores. It clearly shows the impact of *e*CS in the over-committed scenario, while having minimal impact in the under-committed case.

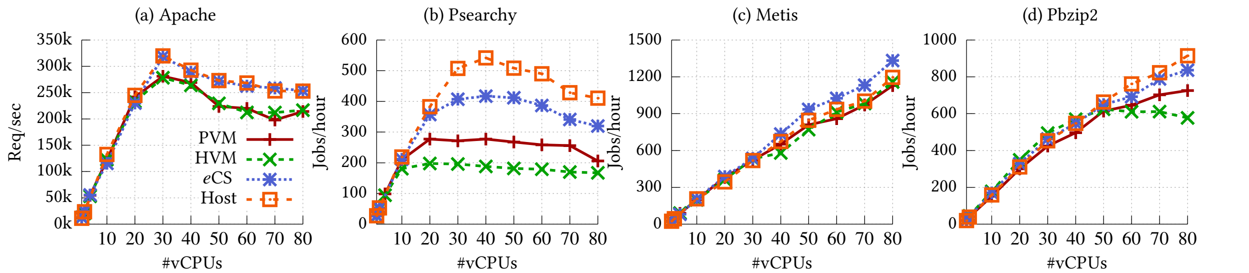

Figure 5: Performance of real-world workloads when running on the bare metal (Host), and inside a VM with three configurations: `PVM`, `HVM`, and with *e*CS annotations. In this scenario, only one VM is running. We use Host as the baseline for the comparison because we consider Host to have almost optimal performance.

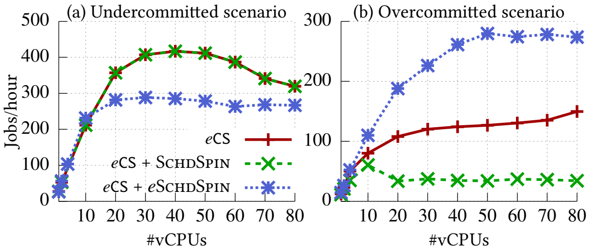

Figure 6: Impact of both `BWW` problem and *e*CS API (refer Hypersivor → VM in Table 1) on Psearchy in both under- and over-committed scenarios.

load that spends only around 5% of the time in the kernel space. Figure 3 (t:d) shows that the performance of *e*CS is similar to `PVM` and `HVM`, while decreasing the number of preemptions by 98.4–100% (refer (n:d)). We do not observe any performance gain in this scenario because 1) these preemptions may not be too critical to affect the application scalability, and 2) the overhead of our APIs, which do not provide any gains even after decreasing the preemptions. Similar to the other workloads, `LHP` dominates the preemption, followed by `RP`, `ICP`, and `RRP`.

In summary, our APIs not only reduce preemptions by 85–100%, but also improve the scalability of applications that use these synchronization primitives up to 2.5×, while no observable overhead on these applications. Moreover, we found that these preemptions occur for almost every type of primitives, specifically in the case of blocking synchronization primitives, read locks (Metis and Pbzip2), and interrupts (*e.g.*, TLB operations, packet processing etc.). In addition, most of the workloads still suffer from the `BWW` problem because of them being non-work conserving. We partially address this problem with the help of our *e*SchdSpin approach. One point to note is that we do not observe too many preemptions, as shown by prior works [42], because the current Linux kernel has dropped the FIFO-based Ticket `spinlock` and has replaced it with a highly optimized unfair queue-based lock [20] that mitigates the problem of `LHP` and `LWP`.

6.3 Performance in an Under-committed Case

We evaluate our *e*CS approach against `PVM` and `HVM` configurations in which a VM is running to show the impact of both APIs and *e*SchdSpin approach. We also include bare-metal configuration (Host) as a baseline (Figure 5). We observe that *e*CS addresses the `BWW` problem, and outperforms both `PVM` and `HVM` in the case of Apache (1.2× and 1.2×), Psearchy (1.6× and 1.9×), Metis (1.2× and 1.3×), and Psearchy (1.2× and 1.4×), while having almost similar latency for the Apache workload (Figure 4 (a)). Likewise, *e*CS performance is similar to that of bare-metal, except for the Psearchy workload.

For Apache, our APIs act as a back-off mechanism to improve its scalability, as the system is heavily contended. The throughput degrades after 30 cores because of the overhead of process scheduling, socket overhead, and inefficient kernel packet processing. Besides this, both Psearchy and Metis suffer from the `BWW` problem, which we improve with our *e*SchdSpin approach that results in better scalability as well as reduction in the idling of VMs. In particular, we decrease the idle time of Psearchy and Metis by 25% and 20%, respectively, by using our approach. One point to note is that blocking locks are based on the `TAS` lock, whose throughput severely degrades with increasing core count because of the increase cache-line contention, which we observe after 40 cores for Psearchy for all configurations. We also find that the Host is still 1.4× faster than *e*CS because *e*SchdSpin only partially mitigates the `BWW` problem, while introducing excessive cache-line contention, which we can circumvent with NUMA-aware locks [16]. For Pbzip2, we observe that *e*CS performs equivalent to the Host, while outperforming `PVM` and `HVM` after 60 cores, because Pbzip2 spends the least amount of time in the kernel space (5%), and starts to suffer from the `BWW` problem only after 60 cores, which our *e*SchdSpin easily tackles.

6.4 Addressing `BWW` Problem via *e*CS

We evaluate the impact of the `BWW` problem on Psearchy in both under- and over-committed scenarios. Figure 6 (a) shows that our scheduling-aware spinning approach (marked as *e*CS + SchdSpin) improves the throughput of Psearchy by 1.5× and 1.2× at 40 and 80 cores, respectively, in an under-committed scenario. SchdSpin approach allows a blocking waiter, both reader and writer, to actively spin for the lock if the number of tasks in the run queue is one, else the task schedules itself out. This approach is similar to the scheduling-aware parking/wake-up strategy [16], which we applied to the stock `mutex` and `rwsem`.

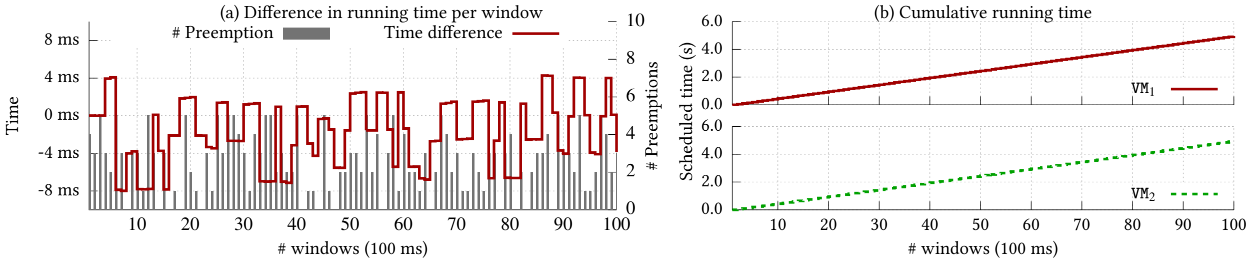

Figure 7: Fairness in *e*CS. Running time of a vCPU of two co-scheduled VMs (VM$_1$ and VM$_2$) with *e*CS annotations for a period of 10 seconds with 100 ms window granularity while executing a kernel intensive task (reading the contents of a file) that involves read side of rwsem. (a) shows the difference in running time of vCPU per window granularity as well as the number of preemptions occurring per window, while (b) illustrates the cumulative running time, and shows that the hypervisor maintains eventual fairness in the system, even if VM$_2$ is allowed extra schedules. Both VMs get 4.95 seconds to run.

As mentioned before, the reason for such an improvement is that the current design is not scheduling aware, as the waiter parks itself if it is unable to acquire the lock. With our approach, we try to mitigate this performance anomaly and allow the applications to scale further. Unfortunately, the scheduling-aware approach is inefficient in the case of the over-committed scenario, as shown in Figure 6 (b). The reason is that current waiters are guest OS agnostic, which leads to wasting CPU resources and resulting in more LHP and LWP problems, thereby degrading the scalability by almost 4.4× (marked *e*CS + SchdSpin in (b)) against a simple *e*CS configuration that still suffers from the BWW problem. We overcome this issue by using our `is_pcpu_overcommitted()` API that allows the SchdSpin approach to spin only when there is no active task on the pCPU's run queue; otherwise, the waiter is scheduled out when more than one task are in the run queue of the pCPU. By using our API (marked *e*CS + *e*SchdSpin), we outperform the baseline *e*CS approach by 1.8× and the *e*CS + SchdSpin approach by 8×.[3]

6.5 System Eventual Fairness

We now evaluate whether we are able to achieve eventual fairness while allowing *e*CS annotated VMs to obtain an extra schedule followed by local vCPU penalization. To evaluate the fairness, we run a simple micro-benchmark in two VMs (marked VM$_1$ and VM$_2$). VM$_1$ is a non-annotated VM, whereas VM$_2$ is an *e*CS annotated one. This micro-benchmark indefinitely reads the content of a file that stresses the read side of the rwsem and spends around 99% of the time in the kernel without scheduling out the task, thereby prohibiting the guest OS from doing any halt exits. Figure 7 (a) shows the time difference between two VM runtimes that we measure at every 100 ms window for each VM as well as the number of preemptions for VM$_2$ in that window. Figure 7 (b) shows the cumulative runtime of the VMs. We observe from Figure 7 (a) that even after allowing for extra schedules, the CFS scheduling policy balances out these extra schedules, which does not affect the runtime difference between VM$_1$ and VM$_2$. For example, at the end of one second window, marked 10, we observe that the number of extra schedules that the hypervisor granted VM$_2$ was 34 (34 milliseconds of extra time), but the runtime difference between VM$_1$ and VM$_2$ is 7.8 ms, which becomes -1.9 ms at the end of two seconds, while VM$_2$ received a total of 54 extra schedules (54 milliseconds). Hence, the extra schedule approach followed by our local vCPU penalization ensures that none of the tasks running on that particular physical CPU suffers from the fairness issue, also referred as eventual fairness. Moreover, Figure 7 (b) shows that both VMs get almost equivalent runtime in a lockstep fashion with both VMs getting almost 4.95 seconds at the end of 10 seconds.

7 Discussion

Our *e*CS approach addresses the problem of preemptions and BWW in both under- and over-committed scenarios by annotating all synchronization primitives and mechanisms in the kernel space. However, besides these primitives, kernel developers have to manually annotate a critical section if they want to avoid the preemptions while introducing their own primitives. One approach could be that the hypervisor can read the instruction pointer (IP) to figure out an *e*CS, but the guest OS must provide a guest OS symbol table to resolve the IP. In addition, the current design of *e*CS only targets the kernel space of a guest OS, and it is still agnostic of the user space critical sections such as pthread locks. Hence, we would like to extend our approach to the user space critical sections to further avoid the preemption problem, as we believe that *e*CS is a natural fit for multi-level scheduling. However, we need to communicate the scheduling hint down to the lowest layer effectively, which requires designing of the *e*CS composability extensions.

Our annotation approach does not open any security vulnerability because our approach is based on the paravirtualized VM, and it is similar to other approaches that share the information with the hypervisor [4, 19]. By using our virtualized scheduling-aware spinning ap-

[3] We have used *e*CS + *e*SchdSpin approach for our evaluation against PVM and HVM in §6.2 and §6.3.

proach (*e*SchdSpin), we partially mitigate the BWW problem. However, our Hypervisor → VM APIs expose scheduling information of the pCPU, but they only tell if a pCPU is overloaded or a vCPU is preempted. In addition, a VM cannot misuse this information as it will be later penalized by the hypervisor. There is also very slight possibility of priority inversion problem with our extra schedule approach. However, the window of that hypervisor-granted extra schedule is too small to incur priority inversion and performance, unlike co-scheduling approaches [41, 45] in which the scheduling window is in the order of several milliseconds.

8 Related work

The double scheduling phenomenon is a recurring problem in the domain of virtualization, which seriously impacts the performance of a VM. There have been comprehensive research efforts to mitigate this problem.

Synchronization primitives in VMs. Uhlig *et al.* [44] demonstrated the spinlock synchronization issue in a virtualized environment, which he addressed with synchronous hints to the hypervisor, and was later replaced by para-virtual hooks for the spinlock [8] for notifying the hypervisor to block the vCPU after it has exhausted its busy wait threshold. Meanwhile, other problems such as LWP [32], the BWW problem [5, 39], and RCU readers preemption problems were found. Gleaner [5] that addressed the BWW problem implemented a user space solution to handle tasks among a varying number of vCPUs, by manipulating tasks' processor affinity in the user space, which is difficult to maintain at runtime as it must accurately track each task launch and deletion. However, our *e*SchdSpin approach is user agnostic and mitigates the problem to certain extent for large core count.

Taebe *et al.* [42] addressed the LHP/LWP issue by exposing the time window from the hypervisor to the guest OS, which leverages this information that enables a waiter to either spin or join the waiting queue. However, their solution is not applicable to CFS [27] scheduler of Linux as it does not expose the scheduling window information. Their solution is orthogonal to our approach as we want the hypervisor to take a decision than the VM. Waiman Long [20] designed and implemented qspinlock that inherently overcomes the problem of LWP by exploiting the property of the TAS lock in the queue-based lock. It works by allowing the other waiters to steal the lock before joining the queue without disrupting the waiters' queue. However, qspinlock is still prone to LHP. Meanwhile, by annotating various locks as *e*CS, we confirm these problems, and further identify new sets of problems such as RP and ICP, and provide a simple solution to address the double scheduling phenomenon.

Partial handling of scheduling overhead in VMs. There have been several studies on virtualization overhead because of the software-hardware redirection [1, 39] and co-scheduling issues [17, 41, 45]. For example, VMware relies on relaxed co-scheduling [45] to mitigate double scheduling problem, in which vCPUs are scheduled in batches and the stragglers are synchronized within a predefined threshold. Besides this, other works have proposed balanced vCPU scheduling [41] or even IPI based demand scheduling [17]. However, these co-scheduling approaches suffer from CPU fragmentation. On the contrary, our approach neither introduces any CPU fragmentation nor it needs to synchronize the global scheduling information for all the vCPU of a VM because each vCPU is locally penalized by the hypervisor rather than synchronizing them among other vCPUs.

Song *et al.* [40] proposed the idea of dynamically adjusting vCPUs according to available CPU resources, while allowing guest OS to schedule its tasks. They used the approach of vCPU ballooning, which avoided the problem of double scheduling and was later extended by Cheng *et al.* [3] by designing a lightweight hotplug vCPU mechanism. Although their approach is effective in case of small VMs, it is complementary to our approach and may not scale effectively for large SMP VMs because of the overhead of migrating tasks from one vCPU to another as well as the frequent rescheduling of the targeted vCPUs. *e*CS, on the other hand, does not suffer from any explicit IPI and migration-specific tasks, as it only adds an overhead of a simple memory operations for a scheduling decision.

9 Conclusion

Double scheduling phenomenon is a well-known problem in the domain of virtualization that leads to several symptoms in the form of LHP, LWP, and BWW. We identify that it not only is limited to non-blocking locks, but also is applicable to blocking locks and reader side of locks. We present a single shot solution with our key insight: if a certain key component of a guest OS is allowed to proceed further, the guest OS will make forward progress. We identify these critical components as synchronization primitives and mechanism such as spinlocks, mutex, rwsem, RCU, and even interrupt context, which we call *enlightened critical sections* (*e*CS). We annotate *e*CS with our lightweight APIs that expose whether a VM is executing a critical section, which the hypervisor uses to provide an extra schedule at the scheduling boundary, thereby allowing the guest OS to progress forward. In addition, by leveraging the hypervisor scheduling context, a VM mitigates the effect of BWW problem with our simple virtualized spinning-aware spinning strategy. With *e*CS, we not only decrease the spurious preemptions by 85–100% but also improve the throughput of applications up to 1.6× and 2.5× in an under- and over-committed scenario, respectively.

Abstract

Unikernel specializes a minimalistic LibOS and a target application into a standalone single-purpose virtual machine (VM) running on a hypervisor, which is referred to as (virtual) *appliance*. Compared to traditional VMs, Unikernel appliances have smaller memory footprint and lower overhead while guaranteeing the same level of isolation. On the downside, Unikernel strips off the *process* abstraction from its monolithic appliance and thus sacrifices flexibility, efficiency, and applicability.

This paper examines whether there is a balance embracing the best of both Unikernel appliances (strong isolation) and processes (high flexibility/efficiency). We present KylinX, a dynamic library operating system for simplified and efficient cloud virtualization by providing the `pVM` (process-like VM) abstraction. A `pVM` takes the hypervisor as an OS and the Unikernel appliance as a process allowing both page-level and library-level dynamic mapping. At the page level, KylinX supports `pVM` fork plus a set of API for inter-`pVM` communication (IpC). At the library level, KylinX supports shared libraries to be linked to a Unikernel appliance at runtime. KylinX enforces mapping restrictions against potential threats. KylinX can fork a `pVM` in about 1.3 ms and link a library to a running `pVM` in a few ms, both comparable to process fork on Linux (about 1 ms). Latencies of KylinX IpCs are also comparable to that of UNIX IPCs.

1 Introduction

Commodity clouds (like EC2 [5]) provide a public platform where tenants rent virtual machines (VMs) to run their applications. These cloud-based VMs are usually dedicated to specific online applications such as big data analysis [24] and game servers [20], and are referred to as (virtual) appliances [56, 64]. The highly-specialized, single-purpose appliances need only a very small portion of traditional OS support to run their accommodated applications, while the current general-purpose OSs contain extensive libraries and features for multi-user, multi-application scenarios. The mismatch between the single-purpose usage of appliances and the general-purpose design of traditional OSs induces performance and security penalty, making appliance-based services cumbersome to deploy and schedule [62, 52], inefficient to run [56], and vulnerable to bugs of unnecessary libraries [27].

This problem has recently motivated the design of Unikernel [56], a library operating system (LibOS) architecture that is targeted for efficient and secure appliances in the clouds. Unikernel refactors a traditional OS into libraries, and seals the application binary and requisite libraries into a specialized appliance image which could run directly on a hypervisor such as Xen [30] and KVM [22]. Compared to traditional VMs, Unikernel appliances eliminate unused code, and achieve smaller memory footprint, shorter boot times and lower overhead while guaranteeing the same level of isolation [56]. The hypervisor's steady interface avoids hardware compatibility problems encountered by early LibOSs [39].

On the downside, Unikernel strips off the *process* abstraction from its statically-sealed monolithic appliances, and thus sacrifices flexibility, efficiency, and applicability. For example, Unikernel cannot support dynamic fork, a basis for commonly-used multi-process abstraction of conventional UNIX applications; and the compile-time determined immutability precludes runtime management such as online library update and address space randomization. This inability has largely reduced the applicability and performance of Unikernel.

In this paper, we examine whether there is a balance embracing the best of both Unikernel appliances (strong isolation) and processes (high flexibility/efficiency). We draw an analogy between appliances on a hypervisor and processes on a traditional OS and take one step forward from static Unikernels to present KylinX, a dynamic library operating system for simplified and efficient cloud virtualization by providing the `pVM` (process-like

VM) abstraction. We take the hypervisor as an OS and the appliance as a process allowing both page-level and library-level dynamic mapping for pVM.

At the page level, KylinX supports pVM fork plus a set of API for inter-pVM communication (IpC), which is compatible with conventional UNIX inter-process communication (IPC). The security of IpC is guaranteed by only allowing IpC between a *family* of mutually-trusted pVMs forked from the same root pVM.

At the library level, KylinX supports shared libraries to be dynamically linked to a Unikernel appliance, enabling pVMs to perform (i) online library update which replaces old libraries with new ones at runtime and (ii) recycling which reuses in-memory domains for fast booting. We analyze potential threats induced by dynamic mapping and enforce corresponding restrictions.

We have implemented a prototype of KylinX based on Xen [30] (a type-1 hypervisor) by modifying Mini-OS [14] (a Unikernel LibOS written in C) and Xen's toolstack. KylinX can fork a pVM in about 1.3 ms and link a library to a running pVM in a few ms, both comparable to process fork on Linux (about 1 ms). Latencies of KylinX IpCs are also comparable to that of UNIX IPCs. Evaluation on real-world applications (including a Redis server [13] and a web server [11]) shows that KylinX achieves higher applicability and performance than static Unikernels while retaining the isolation guarantees.

The rest of this paper is organized as follows. Section 2 introduces the background and design options. Section 3 presents the design of dynamically-customized KylinX LibOS with security restrictions. Section 4 reports the evaluation results of the KylinX prototype implementation. Section 5 introduces related work. And Section 6 concludes the paper and discusses future work.

2 Preliminaries

2.1 VMs, Containers & Picoprocesses

There are several conventional models in the literature of virtualization and isolation: processes, Jails, and VMs.

- OS processes. The process model is targeted for a conventional (partially-trusted) OS environment, and provides rich ABI (application binary interface) and interactivity that make it not suitable for truly adversarial tenants.
- FreeBSD Jails [47]. The jail model provides a lightweight mechanism to separate applications and their associated policies. It runs a process on a conventional OS, but restricts several of the syscall interfaces to reduce vulnerability.
- VMs. The VM model builds an isolation boundary matching hardware. It provides legacy compatibility for guests to run a complete OS, but it is costly due to duplicated and vestigial OS components.

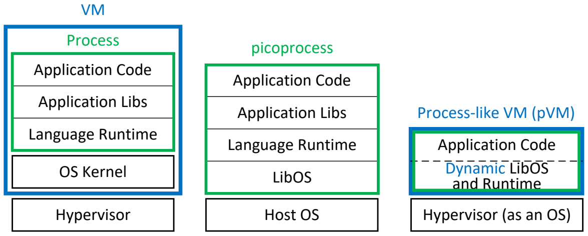

Figure 1: Alternative virtualization architectures.

VMs (Fig. 1(*left*)) have been widely used in multi-tenant clouds since it guarantees strong (type-1-hypervisor) isolation [55]. However, the current virtualization architecture of VMs is heavy with layers of hypervisor, VM, OS kernel, process, language runtime (such as glibc [16] and JVM [21]), libraries, and application, which are complex and could no longer satisfy the efficiency requirements of commercial clouds.

Containers (like LXC [9] and Docker [15]) leverage kernel features to package and isolate processes. They are recently in great demand [25, 7, 6] because they are lightweight compared to VMs. However, containers offer weaker isolation than VMs, and thus they often run in VMs to achieve proper security guarantees [58].

Picoprocesses [38] (Fig. 1 (*center*)) could be viewed as containers with stronger isolation but lighter-weight host obligations. They use a small interface between the host OSs and the guests to implement a LibOS realizing the host ABI and map high-level guest API onto the small interface. Picoprocesses are particularly suitable for client software delivery because client software needs to run on various host hardware and OS combinations [38]. They could also run on top of hypervisors [62, 32].

Recent studies [67, 32, 54] on picoprocesses relax the original static isolation model by allowing dynamics. For example, Graphene [67] supports picoprocess fork and multi-picoprocess API, and Bascule [32] allows OS-independent extensions to be attached to a picoprocess at runtime. Although these relaxations dilute the strict isolation model, they effectively extend the applicability of picoprocesses to a much broader range of applications.

2.2 Unikernel Appliances

Process-based virtualization and isolation techniques face challenges from the broad kernel syscall API that is used to interact with the host OS for, e.g., process/thread management, IPC, networking, etc. The number of Linux syscalls has reached almost 400 [3] and is continuously increasing, and the syscall API is much more difficult to secure than the ABI of VMs (which could leverage hardware memory isolation and CPU rings) [58].

Recently, researchers propose to reduce VMs, instead of augmenting processes, to achieve secure and efficient cloud virtualization [56, 19, 49]. Unikernel [56] is focused on single-application VM appliances [26] and adapts the Exokernel [39] style LibOS to VM guests to enjoy performance benefits while preserving the strong isolation guarantees of a type-1 hypervisor. It breaks the traditional general-purpose virtualization architecture (Fig. 1 (*left*)) and implements the OS features (e.g., device drivers and networking) as libraries. Compared to other hypervisor-based reduced VMs (like Tiny Core Linux [19] and OS^v [49]), Unikernel seals only the application and its requisite libraries into the image.

Since the hypervisor already provides a number of management features (such as isolation and scheduling) of traditional OSs, Unikernel adopts the *minimalism* philosophy [36], which minimizes the VMs by not only removing unnecessary libraries but also stripping off the duplicated management features from its LibOS. For example, Mirage [57] follows the multikernel model [31] and leverages the hypervisor for multicore scheduling, so that the single-threaded runtime could have fast sequential performance; MiniOS [14] relies on the hypervisor (instead of an in-LibOS linker) to load/link the appliance at boot time; and LightVM [58] achieves fast VM boot by redesigning Xen's control plane.

2.3 Motivation & Design Choices

Unikernel appliances and conventional UNIX processes both abstract the unit of isolation, privileges, and execution states, and provide management functionalities such as memory mapping, execution cooperation, and scheduling. To achieve low memory footprint and small trusted computing base (TCB), Unikernel strips off the process abstraction from its monolithic appliance and links a minimalistic LibOS against its target application, demonstrating the benefit of relying on the hypervisor to eliminate duplicated features. But on the downside, the lack of processes and compile-time determined monolithicity largely reduce Unikernel's flexibility, efficiency, and applicability.

As shown in Fig. 1 (*right*), KylinX provides the `pVM` abstraction by explicitly taking the hypervisor as an OS and the Unikernel appliance as a process. KylinX slightly relaxes Unikernel's compile-time monolithicity requirement to allow both page-level and library-level dynamic mapping, so that `pVMs` could embrace the best of both Unikernel appliances and UNIX processes. As shown in Table 1, KylinX could be viewed as an extension (providing the `pVM` abstraction) to Unikernel, similar to the extention of Graphene [67] (providing conventional multi-process compatibility) and Bascule [32] (providing runtime extensibility) to picoprocess.

	Static	**Dynamic**
Picoprocess	Embassies [43], Xax [38], etc.	Graphene [67], Bascule [32], etc
Unikernel	Mirage [57], MiniOS [14], etc.	**KylinX**

Table 1: Inspired by dynamic picoprocesses, KylinX explores new design space and extends the applicability of Unikernel.

We implement KylinX's dynamic mapping extension in the hypervisor instead of the guest LibOS for the following reasons. First, an extension outside the guest LibOS allows the hypervisor to enforce mapping restrictions (§3.2.3 and §3.3.4) and thus improves security. Second, the hypervisor is more flexible to realize dynamic management for, e.g., restoring live states during `pVM`'s online library update (§3.3.2). And third, it is natural for KylinX to follow Unikernel's minimalism philosophy (§2.2) of leveraging the hypervisor to eliminate duplicated guest LibOS features.

Backward compatibility is another tradeoff. The original Mirage Unikernel [56] takes an extreme position where existing applications and libraries have to be completely rewritten in OCaml [10] for type safety, which requires a great deal of engineering effort and may introduce new vulnerabilities and bugs. In contrast, KylinX aims to support source code (mainly `C`) compatibility, so that a large variety of legacy applications could run on KylinX with minimum effort for adaptation.

Threat model. KylinX assumes a traditional threat model [56, 49], the same context as Unikernel [56] where VMs/`pVMs` run on the hypervisor and are expected to provide network-facing services in a public multi-tenant cloud. We assume the adversary can run untrusted code in the VMs/`pVMs`, and applications running in the VMs/`pVMs` are under potential threats both from other tenants in the same cloud and from malicious hosts connected via Internet. KylinX treats both the hypervisor (with its toolstacks) and the control domain (dom0) as part of the TCB, and leverages the hypervisor for isolation against attacks from other tenants. The use of secure protocols like SSL and SSH helps KylinX `pVMs` trust external entities.

Recent advance in hardware like Intel Software Guard eXtensions (SGX) [12] demonstrates the feasibility of shielded execution in *enclaves* to protect VMs/`pVMs` from the privileged hypervisor and dom0 [33, 28, 45], which will be studied in our future work. We also assume hardware devices are not compromised, although in rare cases hardware threats have been identified [34].

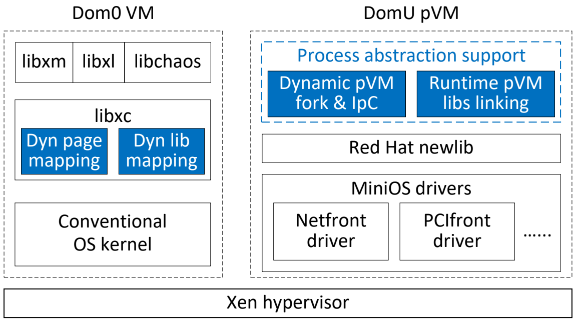

Figure 2: KylinX components. Blue parts are newly designed. DomU pVM is essentially a Unikernel appliance.

3 KylinX Design

3.1 Overview

KylinX extends Unikernel to realize desirable features that are previously applicable only to processes. Instead of designing a new LibOS from scratch, we base KylinX on MiniOS [27], a C-style Unikernel LibOS for user VM domains (domU) running on the Xen hypervisor. MiniOS uses its front-end drivers to access hardware, which connect to the corresponding back-end drivers in the privileged dom0 or a dedicated driver domain. MiniOS has a single address space without kernel and user space separation, as well as a simple scheduler without preemption. MiniOS is tiny but fits the bill allowing a neat and efficient LibOS design on Xen. For example, Erlang on Xen [1], LuaJIT [2], ClickOS [59] and LightVM [58] leverage MiniOS to provide Erlang, Lua, Click and fast boot environments, respectively.

As shown in Fig. 2, the MiniOS-based KylinX design consists of (i) the (restricted) dynamic page/library mapping extensions of Xen's toolstack in Dom0, and (ii) the process abstraction support (including dynamic pVM fork/IpC and runtime pVM library linking) in DomU.

3.2 Dynamic Page Mapping

KylinX supports process-style appliance fork and communication by leveraging Xen's shared memory and grant tables to perform cross-domain page mapping.

3.2.1 pVM Fork

The fork API is the basis for realizing traditional multiprocess abstractions for pVMs. KylinX treats each user domain (pVM) as a process, and when the application invokes fork() a new pVM will be generated.

We leverage the memory sharing mechanism of Xen to implement the fork operation, which creates a *child* pVM by (i) duplicating the xc_dom_image structure and (ii) invoking Xen's unpause() API to fork the calling parent pVM and return its domain ID to the parent. As shown in Fig. 3, when fork() is invoked in the parent pVM, we use inline assemblies to get the current states of CPU registers and pass them to the child. The control domain (dom0) is responsible for forking and starting the child pVM. We modify *libxc* to keep the xc_dom_image structure in memory when the parent pVM was created, so that when fork() is invoked the structure could be directly mapped to the virtual address space of the child pVM and then the parent could share sections with the child using grant tables. Writable data is shared in a copy-on-write (CoW) manner.

return do_fork();
```

Figure 3: pVM fork. After *fork* is invoked, KylinX creates a child pVM by sharing the parent (caller) pVM's pages.

After the child pVM is started via unpause(), it (i) accepts the shared pages from its parent, (ii) restores the CPU registers and jumps to the next instruction after fork, and (iii) begins to run as a child. After fork() is completed, KylinX asynchronously initializes an event channel and shares dedicated pages between the parent and child pVMs to enable their IpC, as introduced in the next subsection.

3.2.2 Inter-pVM Communication (IpC)

KylinX provides a multi-process (multi-pVM) application with the view that all of its processes (pVMs) are collaboratively running on the OS (hypervisor). Currently KylinX follows the strict isolation model [67] where only mutually-trusted pVMs can communicate with each other, which will be discussed in more details in §3.2.3.

The two communicating pVMs use an event channel and shared pages to realize inter-pVM communication. If two mutually-trusted pVMs have not yet initialized an event channel when they communicate for the first time because they have no parent-child relationship via fork() (§3.2.1), then KylinX will (i) verify their mutual trustworthiness (§3.2.3), (ii) initialize an event channel, and (iii) share dedicated pages between them.

Type	API	Description
Pipe	pipe	Create a pipe and return the fds.
	write	Write *value* to a pipe.
	read	Read *value* from a pipe.
Signal	kill	Send signal to a domain.
	exit	Child sends SIGCHLD to parent.
	wait	Parent waits for child's signal.
Message Queue	ftok	Return the key for a given *path*.
	msgget	Create a message queue for *key*.
	msgsnd	Write *msg* to message queue.
	msgrcv	Read *msg* from message queue.
Shared Memory	shmget	Create & share a memory region.
	shmat	Attach shared memory (of *shmid*).
	shmdt	Detach shared memory.

Table 2: Inter-pVM communication API.

The event channel is used to notify events, and the shared pages are used to realize the communication. KylinX has already realized the following four types of inter-pVM communication APIs (listed in Table. 2).

(1) pipe(fd) creates a pipe and returns two file descriptors (fd[0] and fd[1]), one for write and the other for read.

(2) kill(domid, SIG) sends a signal (SIG) to another pVM (domid) by writing SIG to the shared page and notifying the target pVM (domid) to read the signal from that page; exit and wait are implemented using kill.

(3) ftok(path, projid) translates the path and projid to an IpC key, which will be used by msgget(key, msgflg) to create a message queue with the flag (msgflg) and return the queue ID (msgid); msgsend(msgid, msg, len) and msgrcv(msgid, msg, len) write/read the queue (msgid) to/from the msgbuf structure (msg) with length len.

(4) shmget(key, size, shmflg) creates and shares a memory region with the key (key), memory size (size) and flag (shmflg), and returns the shared memory region ID (shmid), which could be attached and detached by shmat(shmid, shmaddr, shmflg) and shmdt(shmaddr).

3.2.3 Dynamic Page Mapping Restrictions

When performing dynamic pVM fork, the parent pVM shares its pages with an empty child pVM, the procedure of which introduces no new threats.

When performing IpC, KylinX guarantees the security by the abstraction of a *family* of mutually-trusted pVMs, which are forked from the same root pVM. For example, if a pVM *A* forks a pVM *B*, which further forks another pVM *C*, then the three pVMs *A*, *B*, and *C* belong to the same family. For simplicity, currently KylinX follows the all-all-nothing isolation model: only the pVMs belonging to the same family are considered to be trusted and are allowed to communicate with each other. KylinX rejects communication requests between untrusted pVMs.

3.3 Dynamic Library Mapping

3.3.1 pVM Library Linking

Inherited from MiniOS, KylinX has a single flat virtual memory address space where application binary and libraries, system libraries (for bootstrap, memory allocation, etc.), and data structures co-locate to run. KylinX adds a *dynamic segment* into the original memory layout of MiniOS, so as to accommodate dynamic libraries after they are loaded.

As depicted in Fig. 2, we implement the dynamic library mapping mechanism in the Xen control library (*libxc*), which is used by the upper-layer toolstacks such as *xm/xl/chaos*. A pVM is actually a para-virtualized domU, which (i) creates a domain, (ii) parses the kernel image file, (iii) initializes the boot memory, (iv) builds the image in the memory, and (v) boots up the image for domU. In the above 4th step, we add a function (xc_dom_map_dyn()) to map the shared libraries into the *dynamic segment*, by extending the static linking procedure of *libxc* as follows.

- First, KylinX reads the addresses, offsets, file sizes and memory sizes of the shared libraries from the program header table of the appliance image.
- Second, it verifies whether the restrictions (§3.3.4) are satisfied. If not, the procedure terminates.
- Third, for each dynamic library, KylinX retrieves the information of its dynamic sections including the dynamic string table, symbol table, etc.
- Fourth, KylinX maps all the requisite libraries throughout the dependency tree into the dynamic segment of the pVM, which will *lazily* relocate an unresolved symbol to the proper virtual address when it is actually accessed.
- Finally, it jumps to the pVM's entry point.

KylinX will not load/link the shared libraries until they are actually used, which is similar to lazy binding [17] for conventional processes. Therefore, the boot times of KylinX pVMs are lower than that of previous Unikernel VMs. Further, compared to previous Unikernels which support only static libraries, another advantage of KylinX using shared libraries is that it effectively reduces the memory footprint in high-density deployment (e..g., 8K VMs per machine in LightVM [58] and 80K containers per machine in Flurries [71]), which is the single biggest factor [58] limiting both scalability and performance.

Next, we will discuss two simple applications of dynamic library mapping of KylinX pVMs.

3.3.2 Online pVM Library Update

It is important to keep the system/application libraries up to date to fix bugs and vulnerabilities. Static Unikernel [56] has to recompile and reboot the entire appliance image to apply updates for each of its libraries, which may result in significant deployment burdens when the appliance has many third-party libraries.

Online library update is more attractive than rolling reboots mainly in *keeping connections* to the clients. First, when the server has many long-lived connections, rebooting will result in high reconnection overhead. Second, it is uncertain whether a third-party client will re-establish the connections or not, which imposes complicated design logic for reconnection after rebooting. Third, frequent rebooting and reconnection may severely degrade the performance of critical applications such as high-frequency trading.

Dynamic mapping makes it possible for KylinX to realize online library update. However, libraries may have their own states for, e.g., compression or cryptography, therefore simply replacing stateless functions cannot satisfy KylinX's requirement.

Like most library update mechanisms (including DYMOS [51], Ksplice [29], Ginseng [61], PoLUS [37], Katana [63], Kitsune [41], etc), KylinX requests the new and old libraries to be binary-compatible: it is allowed to add new functions and variables to the library, but it is not allowed to change the interface of functions, remove functions/variables, or change fields of structures. For library states, we expect all the states are stored as variables (or dynamically-allocated structures) that would be saved and restored during update.

KylinX provides the `update(domid, new_lib, old_lib)` API to dynamically replace `old_lib` with `new_lib` for a domU `pVM` (ID = `domid`), with necessary update of library states. We also provide an *update* command "`update domid, new_lib, old_lib`" for parsing parameters and calling the `update()` API.

The difficulty of dynamic `pVM` update lies in manipulating symbol tables in a sealed VM appliance. We leverage dom0 to address this problem. When the `update` API is called, dom0 will (i) map the new library into dom0's virtual address space; (ii) share the loaded library with domU; (iii) verify whether the old library is quiescent by asking domU to check the call stack of each kernel thread of domU; (iv) wait until the old library is not in use and pause the execution; (v) modify the entries of affected symbols to the proper addresses; and finally (vi) release the old library. In the above 5th step, there are two kinds of symbols (*functions* and *variables*) which will be resolved as discussed below.

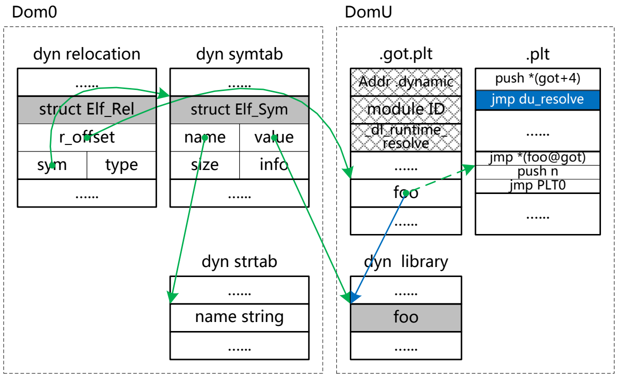

Figure 4: KylinX dynamic symbol resolution for functions. The green lines represent pointers for normal lazy binding of processes. The blue line represents the result of KylinX's resolution, pointing to the real function instead of the .plt table entry (dashed green line).

Functions. The dynamic resolution procedure for functions is illustrated in Fig. 4. We keep the relocation table, symbol table and string table in dom0 as they are not in the loadable segments. We load the global offset table of functions (.got.plt) and the procedure linkage table (.plt) in dom0 and share them with domU. In order to resolve symbols across different domains, we modify the 2nd line of assembly in the 1st entry of the .plt table (as shown in the blue region in Fig. 4) to point to KylinX's symbol resolve function (`du_resolve`). After the new library (`new_lib`) is loaded, the entry of each function of `old_lib` in the .got.plt table (e.g., `foo` in Fig. 4) is modified to point to the corresponding entry in the .plt table, i.e., the 2nd assembly (`push n`) shown by the dashed green line in Fig. 4. When a function (`foo`) of the library is called for the first time after `new_lib` is loaded, `du_resolve` will be called with two parameters (`n` and `*(got+4)`), where `n` is the offset of the symbol (`foo`) in the .got.plt table, and `*(got+4)` is the ID of the current module. `du_resolve` then asks dom0 to call its counterpart `d0_resolve`, which finds `foo` in `new_lib` and updates the corresponding entry (located by `n`) in the .got.plt table of the current module (ID = `module_ID`) to the proper address of `foo` (the blue line in Fig. 4).

Variables. Dynamic resolution for variables is slightly complex. Currently we simply assume that `new_lib` expects all its variables to be set to their live states in `old_lib` instead of their initial values. Without this restriction, the compiler will need extensions to allow developers to specify their intention for each variable.

(1) Global variables. If a global variable (g) of the library is accessed in the main program, then g is stored in the data segment (.bss) of the program and there is

an entry in the global offset table (.got) of the library pointing to g, so after new_lib is loaded KylinX will resolve g's entry in the .got table of new_lib to the proper address of g. Otherwise, g is stored in the data segment of the library and so KylinX is responsible for copying the global variable g from old_lib to new_lib.

(2) Static variables. Since static variables are stored in the data segment of the library and cannot be accessed from outside, after new_lib is loaded KylinX will simply copy them one by one from old_lib to new_lib.

(3) Pointers. If a library pointer (p) points to a dynamically-allocated structure, then KylinX preserves the structure and set p in new_lib to it. If p points to a global variable stored in the data segment of the program, then p will be copied from old_lib to new_lib. If p points to a static variable (or a global variable stored in the library), then p will point to the new address.

3.3.3 pVM Recycling

The standard boot (§3.3.1) of KylinX pVMs and Unikernel VMs [58] is relatively slow. As evaluated in §4.1, it takes 100+ ms to boot up a pVM or a Unikernel VM, most time of which is spent in creating the empty domain. Therefore, we design a pVM recycling mechanism for KylinX pVMs which leverages dynamic library mapping to bypass domain creation.

The basic idea of recycling is to reuse an in-memory empty domain to dynamically map the application (as a shared library) to that domain. Specifically, an empty recyclable domain is checkpointed and waits for running an application before calling the app_entry function of a *placeholder* dynamic library. The application is compiled into a shared library instead of a bootable image, using app_entry as its entry. To accelerate the booting of a pVM for the application, KylinX restores the checkpointed domain, and links the application library by replacing the placeholder library following the online update procedure (§3.3.2).

3.3.4 Dynamic Library Mapping Restrictions

KylinX should isolate any new vulnerabilities compared to the statically and monolithically sealed Unikernel when performing dynamic library mapping. The main threat is that the adversary may load a malicious library into the pVM's address space, replace a library with a compromised one that has the same name and symbols, or modify the entries in the symbol table of a shared library to the fake symbols/functions.

To address these threats, KylinX enforces restrictions on the identities of libraries as well as the loaders of the libraries. KylinX supports developers to specify the restrictions on the signature, version, and loader of the dynamic library, which are stored in the header of the pVM image and will be verified before linking a library.

Signature and version. The library developer first generates the library's SHA1 digest that will be encrypted by RSA (Rivest-Shamir-Adleman). The result is saved in a *signature* section of the dynamic library. If the appliance requires signature verification of the library, the signature section will be read and verified by KylinX using the public key. Version restrictions are requested and verified similarly.

Loader. The developer may request different levels of restrictions on the loader of the libraries: (i) only allowing the pVM itself to be the loader; (ii) also allowing other pVMs of the same application; or (iii) even allowing pVMs of other applications. With the first two restrictions a malicious library in one compromised application would not affect others. Another case for loader check is to load the application binary as a library and link it against a pVM for fast recycling (§3.3.3), where KylinX restricts the loader to be an empty pVM.

With these restrictions, KylinX introduces no new threats compared to the statically-sealed Unikernel. For example, runtime library update (§3.3.2) of a pVM with restrictions on the signature (to be the trusted developer), version (to be the specific version number), and loader (to be the pVM itself) will have the same level of security guarantees as recompiling and rebooting.

4 Evaluation

We have implemented a prototype of KylinX on top of Ubuntu 16.04 and Xen. Following the default settings of MiniOS [14], we respectively use RedHat Newlib and lwIP as the libc/libm libraries and TCP/IP stack. Our testbed has two machines each of which has an Intel 6-core Xeon E5-2640 CPU, 128 GB RAM, and one 1GbE NIC.

We have ported a few applications to KylinX, among which we will use a multi-process Redis server [13] as well as a multi-thread web server [11] to evaluate the application performance of KylinX in §4.6. Due to the limitation of MiniOS and RedHat Newlib, currently two kinds of adaptations are necessary for porting applications to KylinX. First, KylinX can support only select but not the more efficient epoll. Second, inter-process communications (IPC) are limited to the API listed in Table 2.

4.1 Standard Boot

We evaluate the time of the standard boot procedure (§3.3.1) of KylinX pVMs, and compare it with that of MiniOS VMs and Docker containers, all running a Redis

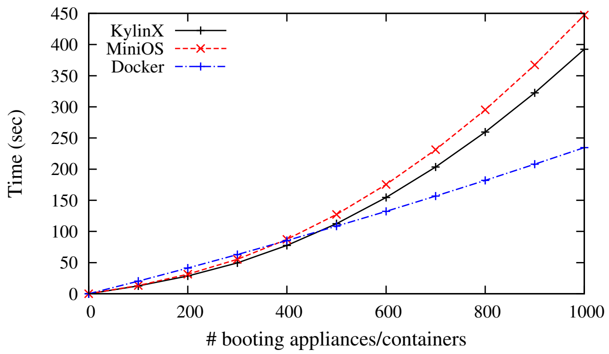

Figure 5: Total time of standard booting (reduced Redis).

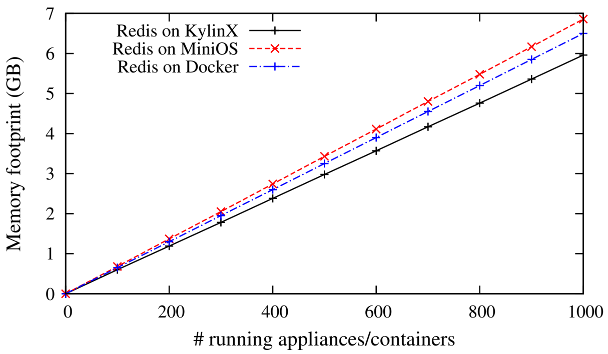

Figure 6: Memory usage (reduced Redis).

server. Redis is an in-memory key-value store that supports fast key-value storage/queries. Each key-value pair consists of a fixed-length key and a variable-length value. It uses a single-threaded process to serve user requests, and realizes (periodic) serialization by forking a new backup process.

We disable XenStore logging to eliminate the interference of periodic log file flushes. The C library (*libc*) of RedHat Newlib is static for use in embedded systems and difficult to be converted into a shared library. For simplicity, we compile *libc* into a static library and *libm* (the math library of Newlib) into a shared library that will be linked to the KylinX `pVM` at runtime. Since MiniOS cannot support `fork`, we (temporarily) remove the corresponding code in this experiment.

It takes about 124 ms to boot up a single KylinX `pVM` which could be roughly divided into two stages, namely, creating the domain/image in memory (steps 1 $\sim$ 4 in §3.3.1), and booting the image (step 5). Dynamic mapping is performed in the first stage. Most of the time (about 121 ms) is spent in the first stage, which invokes hypercalls to interact with the hypervisor. The second stage takes about 3 ms to start the `pVM`. In contrast, MiniOS takes about 133 ms to boot up a VM, and Docker takes about 210 ms to start a container. KylinX takes less time than MiniOS mainly because its shared libraries are not read/linked during the booting.

We then evaluate the total times of sequentially booting up a large number (up to 1K) of `pVMs` on one machine. We also evaluate the total boot times of MiniOS VMs and Docker containers for comparison.

The result is depicted in Fig. 5. First, KylinX is slightly faster than MiniOS owing to its lazy loading/linking. Second, the boot times of both MiniOS and KylinX increase superlinearly as the number of VMs/`pVMs` increases while the boot time of Docker containers increases only linearly, mainly because XenStore is highly inefficient when serving a large number of VMs/`pVMs` [58].

4.2 Fork & Recycling

Compared to containers, KylinX's standard booting cannot scale well for a large number of `pVMs` due to the inefficient XenStore. Most recently, LightVM [58] completely redesigns Xen's control plane by implementing chaos/libchaos, `noxs` (no XenStore), and split toolstack, together with a number of other optimizations, so as to achieve ms-level booting times for a large number of VMs. We adopt LightVM's `noxs` for eliminating XenStore's affect and test the `pVM` fork mechanism running *unmodified* Redis emulating conventional process fork. LightVM's `noxs` enables the boot times of KylinX `pVMs` to increase linearly even for a large number of `pVMs`. The fork of a single `pVM` takes about 1.3 ms (not shown here due to lack of space), several times faster than LightVM's original boot procedure (about 4.5 ms). KylinX `pVM` fork is slightly slower than a process fork (about 1 ms) on Ubuntu, because several operations including page sharing and parameter passing are time-consuming. Note that the initialization for the event channel and shared pages of parent/child `pVMs` is asynchronously performed and thus does not count for the latency of fork.

4.3 Memory Footprint

We measure the memory footprint of KylinX, MiniOS and Docker (Running Redis) for different numbers of `pVMs`/VMs/containers on one machine. The result (depicted in Fig. 6) proves that KylinX `pVMs` have smaller memory footprint compared to statically-sealed MiniOS and Docker containers. This is because KylinX allows the libraries (except *libc*) to be shared by all appliances of the same application (§3.3), and thus the shared libraries need to be loaded at most once. The memory footprint advantage facilitates ballooning [42] which could be used to dynamically share physical memory between VM appliances, and enables KylinX to achieve comparable memory efficiency with page-level deduplication [40] while introducing much less complexity.

	pipe	msg_que	kill	exit/wait	sh_m
KylinX[1]	55	43	41	43	39
KylinX[2]	240	256	236	247	232
Ubuntu	54	97	68	95	53

Table 3: IpC vs. IPC in latency (μs). KylinX[1]: a pair of lineal pVMs which already have an event channel and shared pages. KylinX[2]: a pair of non-lineal pVMs.

4.4 Inter-pVM Communication

We evaluate the performance of inter-pVM communication (IpC) by forking a parent pVM and measuring the parent/child communication latencies. We refer to a pair of parent/child pVMs as *lineal* pVMs. As introduced in §3.2.1, two lineal pVMs already have an event channel and shared pages and thus they could communicate with each other directly. In contrast, non-lineal pVM pairs have to initialize the event channel and shared pages before their first communication.

The result is listed in Table 3, and we compare it with that of the corresponding IPCs on Ubuntu. KylinX IpC latencies between two lineal pVMs are comparable to the corresponding IPC latencies on Ubuntu, owing to the high-performance event channel and shared memory mechanism of Xen. Note that the latency of pipe includes not only creating a pipe but also writing and reading a value through the pipe. The first-time communication latencies between non-lineal pVMs are several times higher due to the initialization cost.

4.5 Runtime Library Update

We evaluate runtime library update of KylinX by dynamically replacing the default *libm* (of RedHat Newlib 1.16) with a newer version (of RedHat Newlib 1.18). *libm* is a math library used by MiniOS/KylinX and contains a collection of 110 basic math functions.

To test KylinX's update procedure for global variables, we also add 111 pseudo global variables as well as one read_global function (reading out all the global variables) to both the old and the new *libm* libraries. The main function first sets the global variables to random values and then periodically verifies these variables by calling the read_global function.

Consequently, there are totally 111 functions as well as 111 variables that need to be updated in our test. The update procedure could be roughly divided into 4 stages and we measure the time of each stage's execution.

First, KylinX loads new_lib into the memory of dom0 and shares it with domU. Second, KylinX modifies the relevant entries of the functions in the .got.plt table to point to the corresponding entries in the .plt table. Third, KylinX calls du_resolve for each of the functions which asks dom0 to resolve the given function and returns its address in new_lib, and then updates the corresponding entries to the returned addresses. Finally, KylinX resolves the corresponding entries of the global variables in the .got table of new_lib to the proper addresses. We modify the third stage in our evaluation to update all the 111 functions in *libm* at once, instead of lazily linking a function when it is actually being called (§3.3.2), so as to present an overview of the entire runtime update cost of *libm*.

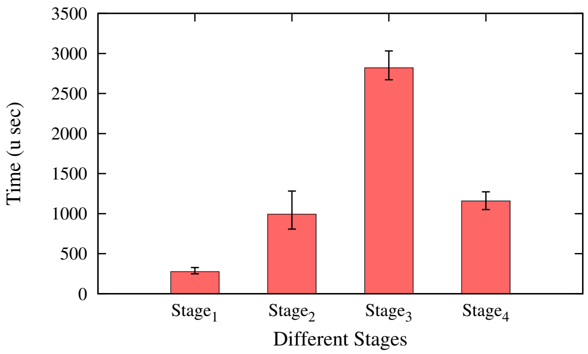

Figure 7: Runtime library update.

The result is depicted in Fig. 7, where the total overhead for updating all the functions and variables is about 5 milliseconds. The overhead of the third stage (resolving functions) is higher than others including the fourth stage (resolving variables), which is caused by several time-consuming operations in the third stage including resolving symbols, cross-domain invoking d0_resolve, returning real function addresses and updating corresponding entries.

4.6 Applications

Besides the process-like flexibility and efficiency of pVM scheduling and management, KylinX also provides high performance for its accommodated applications comparable to that of their counterparts on Ubuntu, as evaluated in this subsection.

4.6.1 Redis Server Application

We evaluate the performance of Redis server in a KylinX pVM, and compare it with that in MiniOS/Ubuntu. Again, since MiniOS cannot support fork(), we temporarily remove the code for serialization. The Redis server uses select instead of epoll to realize asynchronous I/O, because epoll is not yet supported by the lwIP stack [4] used by MiniOS and KylinX.

We use the Redis benchmark [13] to evaluate the performance, which uses a configurable number of busy loops asynchronously writing KVs. We run different

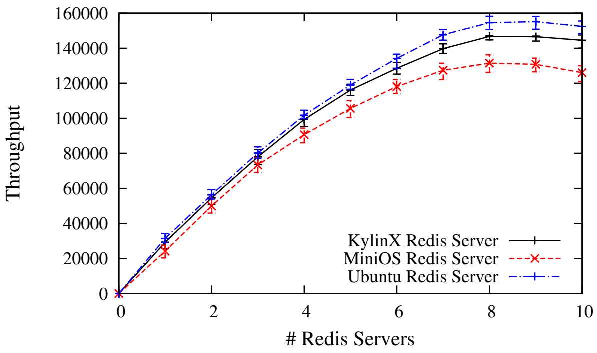

Figure 8: Redis server application.

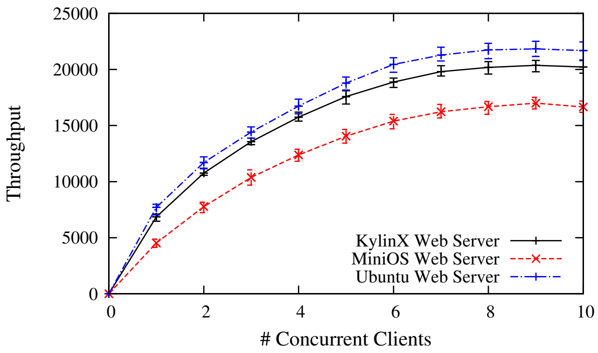

Figure 9: Web server application.

numbers of pVMs/VMs/processes (each for 1 server) servicing write requests from clients. We measure the write throughput as a function of the number of servers (Fig. 8). The three kinds of Redis servers have similar write throughput (due to the limitation of `select`), increasing almost linearly with the numbers of concurrent servers (scaling being linear up to 8 instances before the lwIP stack becomes the bottleneck).

4.6.2 Web Server Application

We evaluate the JOS web server [11] in KylinX, which adopts multithreading for multiple connections. After the main thread accepts an incoming connection, the web server creates a worker thread to parse the header, reads the file, and sends the contents back to the client. We use the Weighttp benchmark that supports a small fraction of the HTTP protocol (but enough for our web server) to measure the web server performance. Similar to the evaluation of Redis server, we test the web server by running multiple Weighttp [8] clients on one machine, each continuously sending `GET` requests to the web server.

We evaluate the throughput as a function of the number of concurrent clients, and compare it with the web servers running on MiniOS and Ubuntu, respectively. The result is depicted in Fig. 9, where the KylinX web server achieves higher throughput than the MiniOS web server since it provides higher sequential performance. Both KylinX and MiniOS web servers are slower than the Ubuntu web server, because the asynchronous `select` is inefficiently scheduled with the netfront driver of MiniOS [27].

5 Related Work

KylinX is related to static Unikernel appliances [56, 27], reduced VMs [19, 48, 49], containers [66, 9, 15], and picoprocess [38, 62, 32, 54, 67, 33].

5.1 Unikernel & Reduced VMs

KylinX is an extension of Unikernel [56] and is implemented on top of MiniOS [27]. Unikernel OSs include Mirage [56], Jitsu [55], Unikraft [18], etc. For example, Jitsu [55] leverages Mirage [56] to design a power-efficient and responsive platform for hosting cloud services in the edge networks. LightVM [58] leverages Unikernel on Xen to achieve fast booting.

MiniOS [27] designs and implements a C-style Unikernel LibOS that runs as a para-virtualized guest OS within a Xen domain. MiniOS has better backward compatibility than Mirage and supports single-process applications written in C. However, the original MiniOS statically seals an appliance and suffers from similar problems with other static Unikernels.

The difference between KylinX and static Unikernels (like Mirage [56], MiniOS [27], and EbbRT [65]) lies in the pVM abstraction which explicitly takes the hypervisor as an OS and supports process-style operations like pVM fork/IpC and dynamic library mapping. Mapping restrictions (§3.3.4) make KylinX introduce as little vulnerability as possible and have no larger TCB than Mirage/MiniOS [56, 55]. KylinX supports source code (C) compatibility instead of using a type-safe language to rewrite the entire software stack [56].

Recent research [19, 49, 48] tries to improve the hypervisor-based type-1 VMs to achieve smaller memory footprint, shorter boot times, and higher execution performance. Tiny Core Linux [19] trims an existing Linux distribution down as much as possible to reduce the overhead of the guest. OS^v [49] implements a new guest OS for running a single application on a VM, resolving libc function calls to its kernel that adopts optimization techniques such as the spinlock-free mutex [70] and the net-channel networking stack [46]. RumpKernel [48] reduces the VMs by implementing a optimized guest OS. Different from KylinX, these general-purpose LibOS designs consist of unnecessary features for a target application leading to larger attack surface. They cannot support the multi-process abstraction. Besides, KylinX's pVM fork is much faster than replication-based VM_fork in SnowFlock [50].

5.2 Containers

Containers use OS-level virtualization [66] and leverage kernel features to package and isolate processes, instead of relying on the hypervisors. In return they do not need to trap syscalls or emulate hardware, and could run as normal OS processes. For example, Linux Containers (LXC) [9] and Docker [15] create containers by using a number of Linux kernel features (such as *namespaces* and *cgroups*) to package resource and run container-based processes.

Containers require to use the same host OS API [49], and thus expose hundreds of system calls and enlarging the attack surface of the host. Therefore, although LXC and Docker containers are usually more efficient than traditional VMs, they provide less security guarantees since attackers may compromise processes running inside containers.

5.3 Picoprocess

A picoprocess is essentially a container which implements a LibOS between the host OS and the guest, mapping high-level guest API onto a small interface. The original picoprocess designs (Xax [38] and Embassies [43]) only permit a tiny syscall API, which can be small enough to be convincingly (even verifiably) isolated. Howell et al. show how to support a small subset of single-process applications on top of a minimal picoprocess interface [44], by providing a POSIX emulation layer and binding existing programs.

Recent studies relax the static and rigid picoprocess isolation model. For example, Drawbridge [62] is a Windows translation of the Xax [38] picoprocess, and creates a picoprocess LibOS which supports rich desktop applications. Graphene [67] broadens the LibOS paradigm by supporting multi-process API in a family (sandbox) of picoprocesses (using message passing). Bascule [32] allows OS-independent extensions to be attached safely and efficiently at runtime. Tardigrade [54] uses picoprocesses to easily construct fault-tolerant services. The success of these relaxations on picoprocess inspires our dynamic KylinX extension to Unikernel.

Containers and picoprocesses often have a large TCB since the LibOSs contain unused features. In contrast, KylinX and other Unikernels leverage the hypervisor's virtual hardware abstraction to simplify their implementation, and follow the *minimalism* philosophy [36] to link an application only against requisite libraries to improve not only efficiency but also security.

Dune [34] leverages Intel VT-x [69] to provide a process (rather than a machine) abstraction to isolate processes and access privileged hardware features. IX [35] incorporates virtual devices into the Dune process model and achieves high throughput and low latency for networked systems. lwCs [53] provides independent units of protection, privilege, and execution state within a process.

Compared to these techniques, KylinX runs directly on Xen (a type-1 hypervisor), which naturally provides strong isolation and enables KylinX to focus on the flexibility and efficiency issues.

6 Conclusion

The tension between strong isolation and rich features has been long lived in the literature of cloud virtualization. This paper exploits the new design space and proposes the pVM abstraction by adding two new features (dynamic page and library mapping) to the highly-specialized static Unikernel. The simplified virtualization architecture (KylinX) takes the hypervisor as an OS and safely supports flexible process-style operations such as pVM fork and inter-pVM communication, runtime update, and fast recycling.

In the future, we will improve security through modularization [27], disaggregation [60], and SGX enclaves [33, 28, 45, 68]. We will improve the performance of KylinX by adopting more efficient runtime like MUSL [23], and adapt KylinX to the MultiLibOS model [65] which allows spanning pVMs onto multiple machines. Currently, the pVM recycling mechanism is still tentative and conditional: it can only checkpoint an empty domain; the recycled pVM cannot communicate with other pVMs using event channels or shared memory; the application can only be in the form of a self-contained shared library that does not need to load/link other shared libraries; and there are still no safeguards inspecting potential security threats between the new and old pVMs after recycling. We will address these shortcomings in our future work.

Virtualizing Energy Storage Management Using RAIBA

Tzi-cker Chiueh[1] Mao-Cheng Huang Kai-Cheung Juang Shih-Hao Liang Welkin Ling

Industrial Technology Research Institute

Abstract

Because of the intermittent nature of renewable energy-based electricity generation, a key building block for a sustainable renewable energy-based electricity infrastructure is cost-effective energy storage management, which is largely determined by the cost of electric batteries. Despite substantial technological advances in recent years, batteries used in consumer devices and electric vehicles are still too expensive to be feasible for large-scale deployment. One promising way to reduce the battery cost of an energy storage system is to leverage retired batteries from electric vehicles. However, because the charging/discharging characteristics of retired batteries tend to vary widely from one another, putting these heterogeneous batteries into the same module or energy storage system pose significant safety risks and efficiency challenges. This paper presents the design, implementation and evaluation of a *reconfigurable* battery array system called *RAIBA* that is designed to address the heterogeneity issue in retired battery-based energy storage systems by allowing the inter-battery connectivity to be reconfigurable at run time. In addition, *RAIBA* also enables virtualization of the electrical energy resources in a battery array in the same way as how computing, storage and network resources are virtualized. Empirical measurements on a fully operational *RAIBA* prototype demonstrate that it can effectively increase the discharge service time by more than 80% under a set of real-world electric load traces.

1 Introduction

In light of the global warming and resulting climate change effects triggered by carbon-based fossil energy sources, more and more counties are charging ahead to build an energy infrastructure in which renewable energy plays a major role. Because most important renewable energy sources, such as sun, wind and tidal wave, generate electricity in a way dictated by weather conditions, this intermittent nature renders them unfit as a base load electric energy source, unless they are supplemented by an energy storage system that could bridge the time gaps between energy production and energy consumption. Therefore, for renewable energy to become a significant element of the future clean energy infrastructure, cost-effective energy storage management is a key factor. Most grid-scale energy storage systems today are pumped hydroelectric energy storage, which stores energy in the form of gravitational potential energy of water, which is pumped by off-peak low-cost electricity from a lower-elevation reservoir to one with a higher elevation. However, as electric vehicles become more and more prevalent, the electric batteries they use will increasingly become an important part of the energy storage element of the renewable energy infrastructure.

Despite substantial technological advances in recent years, batteries used in consumer devices and electric vehicles are still too expensive to be feasible for large-scale deployment. In 2017, the LCOE (levelized cost of electricity) of Lithium-based battery [18] is about $0.4 USD per kWh discharge, but US DOE's LCOE target [8] for a cost-effective renewable energy storage is $0.1 USD per kWh discharge. A promising way to facilitate the reduction of the battery cost of an energy storage system is to leverage retired batteries from electric vehicles, as has already been done by several electric or hybrid vehicle manufacturers, such as Tesla, Nissan, Toyota, and BMW. The reason that batteries retired from electric vehicles are still usable as energy storage is because the residual capacity of retired batteries is generally between 70% to 80% of their original full capacity. However, the charging/discharging characteristics of these retired batteries may deviate substantially from those when they were in mint condition.

Conventional battery energy storage systems assume that the charging/discharging characteristics of constituent batteries are homogeneous, as it greatly reduces

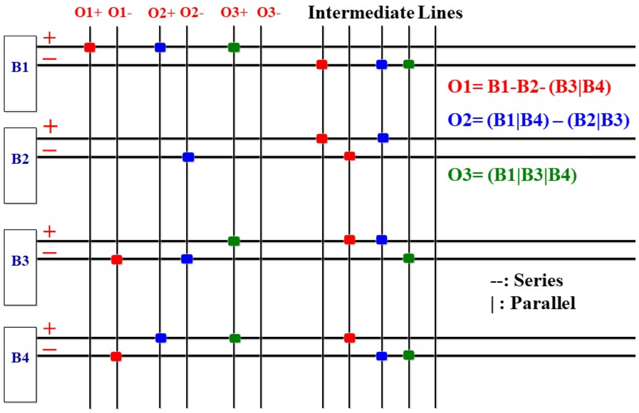

Figure 1: *The most general form of the proposed* RAIBA *architecture, in which each battery could be attached or detached from the interconnect, and any battery could be connected to any other battery in series or in parallel. Intersecting signal lines are connected when they are joined by a dot.*

energy utilization inefficiency. For example, consider a set of batteries that are connected in series, and the capacity of one of them is significantly smaller than the others. In this case, the effective charging/discharging capacity of the entire battery series is dictated by the weakest battery, and the additional capacity of all the other stronger batteries is essentially left wasted. Because retired batteries come from a wide variety of sources, their charging/discharging characteristics are bound to vary widely from one another, and putting these heterogeneous batteries into the same module or energy storage system pose safety risks and utilization efficiency challenges.

In this work, we propose a *Reconfigurable Array of Inexpensive Battery Architecture* (*RAIBA*) [12, 7, 6] to address the heterogeneity issue inherent in energy storage systems that are built from retired batteries. Tesla pioneered the idea of applying commodity batteries used in 3C consumer devices, i.e., 18650 lithium batteries, to building large-scale battery arrays used in electric vehicles. For example, the number of 18650 batteries used in Tesla Model S's battery array is more than 7,000. These battery arrays are provisioned with a certain amount of redundancy to cope with potential battery failures, but when a battery fails, the entire module containing it is impacted because the inter-battery connectivity is fixed. To more effectively minimize the impacts of battery failures and degradations, we propose that a battery array be *reconfigurable* so as to work around failed or degraded batteries at run time.

The most general form of *RAIBA* is shown in Figure 1, which, via software control, controls whether each battery is attached to or detached from the array's interconnect, and how the batteries are connected to one another at run time. The three outputs, O1, O2 and O3, shown in red, blue and green in the figure, represent the outputs of this 4-battery array at three different points in time. The first output (O1) is driven by a series connection among Battery 1 (B1), Battery 2 (B2), and a parallel connection between Battery 3 (B3) and Battery 4 (B4), whereas the second output (O2) corresponds to a series connection between a parallel connection between Battery 1 (B1) and Battery 4 (B4), and another parallel connection between Battery 2 (B2) and Battery 3 (B3). The third output (O3), to which Battery 2 (B2) does not contribute, is simply a parallel connection among B1, B3 and B4. The dynamic reconfigurability afforded by *RAIBA* allows the inter-battery connectivity to be tailored to a given electrical load so as to make the best of available battery resources and minimize unnecessary energy loss, as illustrated by the following three use cases:

- For a series-connected battery array, when the capacity of the weakest battery is exhausted during a discharge operation, *RAIBA* could temporarily put it aside to prevent it from blocking the entire array, and then continues the discharge operation by making the best of the additional capacities of other stronger batteries.
- For a parallel-connected battery array, when the capacity of the weakest battery becomes significantly smaller than that of the others during a discharge operation, *RAIBA* could temporarily put it aside to prevent unwanted inter-battery capacity balancing, which consumes energy, and then continues the discharge operation by making the best of the additional capacities of other stronger batteries.
- Given an electric load request, *RAIBA* makes it possible to use a proper subset of batteries to provide an aggregate voltage and current level which *barely* exceeds those of the request, with their differences and thus the associated down-conversion losses being reduced to the minimum .

The reconfigurability of *RAIBA* opens up myriad battery resource management flexibilities that are not previously possible, and in particular enables virtualization of a physical battery pool in a way similar to how computing and networking resources are virtualized. Given an electric load request $< V, I >$, *RAIBA* dynamically configures a *virtual battery* best fit to satisfy the request by first selecting a proper subset of qualified batteries, and then connecting them in the most appropriate way, so that the virtual battery's aggregate voltage level exceeds V, its aggregate current exceeds I, and the incurred energy loss due to conversion and balancing is minimized.

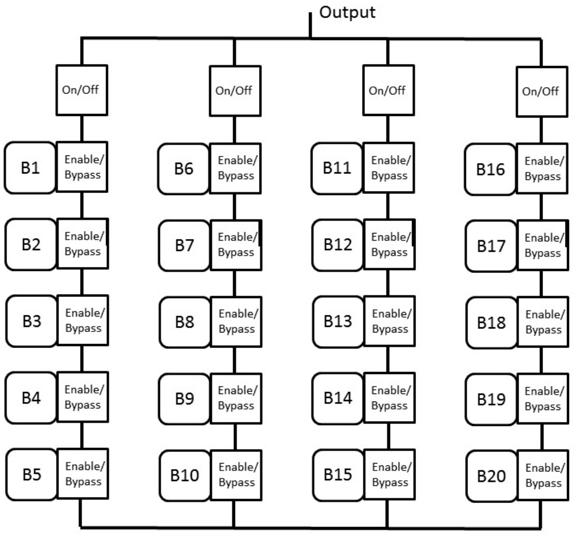

Figure 2: *The system architecture of* RAIBA-1 *consists of N columns connected in parallel, each of which contains M batteries connected in series, with each battery's connectivity to the interconnect via an* enable/bypass *switch.*

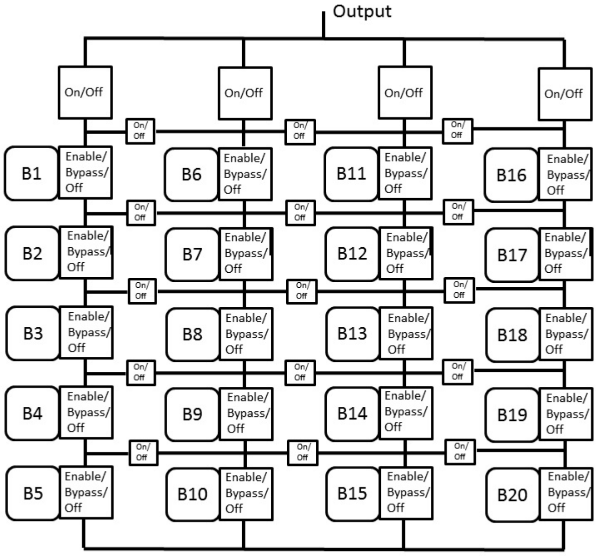

Figure 3: *The system architecture of* RAIBA-2 *is a refinement of* RAIBA-1, *with each* enable/bypass *switch replaced with an* enable/bypass/off *switch, and horizontal inter-column connectivity controlled by* on/off *switches.*

2 RAIBA Levels

The inter-battery interconnect of a *RAIBA* system shown in Figure 1 is deceivingly similar to that of a programmable logic array (PLA) digital logic circuit [14], with a series connection corresponding to an AND operation and a parallel connection corresponding to an OR operation. But the analogy quickly breaks down because of the following two technical challenges:

- The inter-battery interconnect is an energy delivery network that is tasked with carrying much larger electric energy than typical digital logic circuits, and thus require advanced power electronics circuit design techniques to support complex connectivity patterns while guaranteeing operational safety.
- To render inter-battery connectivity reconfiguration completely seamless to an electric load served by a *RAIBA* system, *RAIBA* requires *on-line reconfigurability*, which means the entire system remains functional across each reconfiguration operation and the electric energy pattern delivered to the load before a reconfiguration operation is very close to that after the reconfiguration operation.

Taking into account the significant added circuit complexities involved in supporting dynamic reconfiguration of inter-battery connectivity, we design three RAIBA levels that offer increasing reconfiguration flexibility but also impose growing circuit design challenges.

A *RAIBA-1* array, as shown in Figure 2, consists of *N* columns connected in parallel, each of which contains *M* batteries connected in series. At any point in time, each battery is either part of or insulated from a certain column through an *enable/bypass* switch. When the switch is *enable*, the battery participates in the series connectivity of the column; when the switch is *bypass*, the battery takes itself off the series connectivity of the column. Moreover, above all batteries in each column is an *on/off* switch that allows a column to participate in or sit out of the overall inter-column parallel connection. Each battery in a RAIBA-1 system could only be connected in series with other batteries in the same column.

A *RAIBA-2* array, as shown in Figure 3, is basically a *RAIBA-1* array augmented with row-wise inter-column connectivity controllable by *on/off* switches. In addition, each battery is equipped with a *enable/bypass/off* switch that allows a battery to be part of or insulated from its column, or to disconnect the batteries above it in the same column from those below it. That is, when a battery's switch to the battery array's interconnect is off, the battery breaks off the series connectivity of the column to which it belongs. The switchable inter-column interconnects run horizontally and provide additional connectivity flexibility of allowing a battery in the *i*-th column to be connected in series with another battery in the *j*-th column, or be connected in parallel with another battery in the *j*-th column without bypassing all other batteries in the *i*-th and *j*-th column. For example, if the horizontal on/off switches above and below B4 and B9 are turned on, B4 and B9 are effectively connected in parallel; if B3 is off and the on/off switch above B4 and B9 is turned on, B4 and B8 are effectively connected in series.

While *RAIBA-1* and *RAIBA-2* are designed to support a single electric load at a time, *RAIBA-3*, as shown in Figure 1, is able to support multiple electric loads simultaneously. In addition, a *RAIBA-3* array allows any battery to be connected in series or in parallel with any other battery in the array. This generality provides much more room for battery resource optimization, but requires each battery to be equipped with approximately as many *on/off* switches as the sum of the numbers of the output lines and intermediate lines, a significant increase hardware implementation complexity.

Although increasing RAIBA levels offer more dynamic reconfigurability, whether the additional hardware complexity associated with higher RAIBA levels is worth the potential gains due to the additional flexibility they provide is an open question. For the rest of this paper, we will only focus on the *RAIBA-1* architecture.

3 Hardware Support

The key building block of the *RAIBA-1* architecture is the *enable/bypass* switch, which either enables a battery to participate in its column, i.e., connecting it in series with the other batteries, or bypasses a battery from its column, i.e., insulating it from the other batteries. While conceptually straightforward, two operational requirements render its design technically challenging:

- The transition between the enable mode and the bypass mode should be as short as possible so as to minimize the energy consumed by each transition.
- The electric current flowing through a *enable/bypass* switch should remain constant during each transition between the enable mode and the bypass mode, so as to minimize the disruption to the electric loads being served.

We have designed and implemented an analog ASIC for the enable/bypass switch, whose architecture and circuit layout are shown in Figure 4. Rather than with an individual battery, this ASIC is designed to work with a battery module, which in turn consists of multiple batteries, in this example, 5 batteries connected in series. An enable/bypass switch includes two on/off switches, S1 and S2, a *battery monitor*, which keeps track of the temperature (Tsen), voltage (Vsen) and current (Isen) of each of batteries in the module, and a *Mux controller*, which controls how S1 and S2 are turned on and off. When S1 is on and S2 is off, the enable/bypass switch bypasses the battery module and the voltage drop across the enable/bypass switch is zero. When S1 is off and S2 is on, the enable/bypass switch enables the battery module and so the voltage drop across the enable/bypass switch is the voltage difference between the two ends of the battery module. When S1 and S2 are both off, the enable/bypass switch cuts off the entire column to which it is connected. When S1 and S2 are both on, the effective circuit becomes a short circuit, and I2 may grow to a dangerously large level. Therefore, this mode of operation is strictly prohibited.

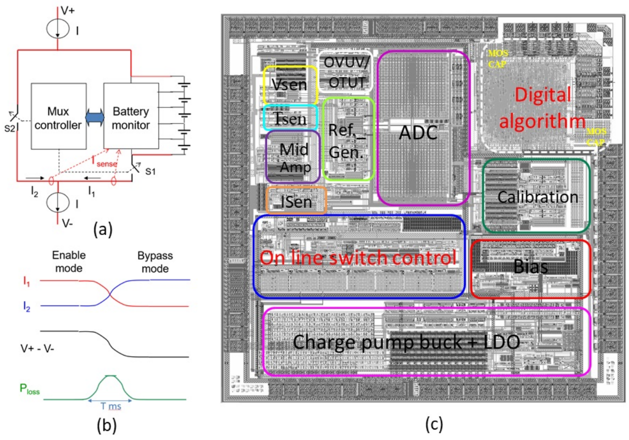

Figure 4: *The (a) circuit architecture and (b) physical layout of the ASIC implementing the* enable/bypass *switch required by the* RAIBA-1 *architecture. (b) shows its ideal transient electric circuit behavior during a transition between the enable and the bypass mode.*

When an enable/bypass switch goes from the enable (bypass) mode to the bypass (enable) mode, the current running through S1, I1, is decreasing (increasing), but the current running through S2, I2, is increasing (decreasing). During a transition between the enable mode and the bypass mode, the *Mux controller* constantly measures I1 and I2, and applies a feedback control mechanism to dynamically tuning the degree to which S1 and S2 are on so that the sum of I1 and I2 remains constant throughput the transition.

To decrease the power consumption incurred by each transition (P_{loss}), the amount of time during which neither S1 nor S2 is off should be minimized, because P_{loss} is equal to the product of the voltage drop and the sum of I1 and I2 during this period, as shown in the lower left of Figure 4. Minimizing the length of the transition period conflicts with the goal of keeping the sum of I1 and I2 constant during the transition period, because, intuitively, it is easier to slowly tune S1 and S2 to keep the total current constant than to try to do so quickly.

When a battery module is enabled by an enable/bypass switch, it may seem that S1 could incur additional energy consumption due to its on-resistance, which is typically very small. However, even for a non-*RAIBA* system, each battery module is typically paired with an on/off switch in order to protect the module from being damaged by unexpected charging currents. This protection on/off switch is no different from S1.

4 Configuration Control Algorithm

Because of its dynamic configurability, *RAIBA* is able to apply a different configuration to each electric load request. Given an electric load $< V, I >$, *RAIBA*'s configuration control algorithm computes a configuration that best serves this load using the following optimization criteria:

- The configuration's delivered current and voltage level exceed I and V, respectively.
- The difference between the configuration's delivered power and $V * I$ is minimized.
- The residual capacities of the batteries in the array are as equalized as possible.

Because every configuration change itself incurs energy loss, *RAIBA* keeps on using its current configuration to satisfy a new electric load request until either the current configuration cannot satisfy the load's $< I, V >$ requirement or the batteries in the current configuration is seriously imbalanced.

The design of *RAIBA*'s configuration control algorithm aims to maximize the energy output of each charge/discharge cycle and the total number of charge/discharge cycles. To squeeze out every bit of the energy accumulated in a charge cycle, it is essential that the left-over battery capacity at the end of a charge cycle be reduced to the minimum. The most likely scenario of squandered battery capacity occurs when one of the batteries in a series-connected battery chain exhausts its capacity and the remaining capacities of the other batteries in the chain are forced to be laid to waste. To avoid this, one should balance the residual capacities of a *RAIBA* array as much as possible. The key to maximizing a battery array's total number of charge cycles is to use each battery in it as gently as possible. Towards this end, when serving an electric load, it is desirable to involve as many batteries and thus draw as little electric current from each battery as possible.

Even though an *enable/bypass* switch in a *RAIBA* system is associated with a battery module, to simplify the exposition below we will assume that each battery modules consists of a single battery. The configuration control algorithm (CCA) used in the current *RAIBA* prototype is shown in Figure 5. Designed with in mind the above optimization objectives, CCA first identifies all possible configurations in an NxM battery array that meet the requirements of the given electric load request, and then picks the one that best balances the residual capacities of all the batteries in the array. Instead of trying out all possible battery combinations, CCA takes a greedy approach by processing each column independently, and within each column, considering only battery combinations that consist of top K batteries in the column's battery list sorted according to their residual capacity and whose aggregate voltage level lies between V and $\alpha * V$. A column is disqualified if the aggregate voltage level of all M batteries in it is below V. The α parameter bounds the search scope and prevents CCA from examining "over-provisioned" configurations. If no satisfactory configuration could be identified for a given α value, CCA increases α and repeats the algorithmic process in Figure 5 again.

```
Input: $< I, V >$ of an electric load request, and the
      residual capacity and voltage level of each
      battery in an NxM array;
for (each of the N columns) {
    Sort the batteries in the column according to
    their residual capacity into a list;

    Traverse the list in the sorted order, find all
    possible battery combinations whose
    accumulated voltage level is between $V$ and $V * \alpha$,
    and place the resulting combinations into a set;

    Disqualify the column if its set is empty;
}

Form a candidate configuration by picking one
battery combination from each qualified column's
set, and put all candidate configurations into a
list, CCL;

for (each candidate configuration in CCL) {
    Simulate the candidate configuration for one
    time step according to a battery model derived
    from dynamic measurements;

    Compute the candidate configuration's
    eventual output voltage level, $V_{out}$, and
    switching cost, $Cost_{switch}$;

    Derive the residual capacity of all
    participating batteries one time step later,
    and compute the standard deviation of the
    residual capacities of all batteries, $STD_c$;

    Disqualify the candidate configuration if
    the current going through any participating
    column is negative or its total power output
    is less than $V * I$;
}

Select the qualified candidate configuration that
minimizes $\beta * \frac{V_{out} - V}{V_{out}}$ + $\gamma * STD_c$ + $\delta * Cost_{switch}$;
```

Figure 5: RAIBA*'s configuration control algorithm, which aims to balance the aggregate voltage levels of participating columns and the residual capacities of all the batteries*

When the aggregate voltage level of one column of a candidate configuration is significantly lower than those of the other columns, other columns may charge the weaker column to bring its voltage level up to par with others, in which case the electric current going through the weaker column is *negative*, or opposite in direction to the electric current requirement (I) of the electric load request. Because the overhead incurred by such inter-column charging represents an unnecessary energy loss, CCA disqualifies all candidate configurations that lead to inter-column charging from consideration.

To maximize the life time of an array's batteries, CCA spreads an electric load over as many columns as possible by considering only those configurations that include all the qualified columns. That is, if L columns in an N-column array are qualified, CCA considers only configurations that consists of all L columns, but not those consisting of a proper subset of these L columns. It is conceivable that configurations using fewer than L columns could lead to lower STD_c or V_{out} or both, but including them into consideration would significantly enlarge the search space.

CCA takes into account the following three factors when selecting the best among the candidate configurations. First, to reduce the amount of wasted battery capacity at the end of a charge cycle, CCA strives to balance the residual capacity of an array's batteries, STD_c, by minimizing the standard deviation of their residual capacity after a time period. Second, to reduce the energy loss due to the inverter, which down-converts a candidate configuration's eventual output voltage (V_{out}) to V, CCA also minimizes the difference between V_{out} and V. Finally, because each switching of an *enable/bypass* switch also incurs an energy loss, it is desirable to pick a configuration that is as close to the current configuration as possible. For this, CCA computes the switching energy cost of each candidate configuration, $Cost_{switch}$. Because these factors may conflict with one another, CCA uses three empirically determined parameters, β, γ and δ, to adjust their relative importance or weight.

Given a candidate configuration that comprises L columns, each of which consists of a variable number of batteries, to execute the above algorithm, CCA needs to compute the eventual output voltage V_{out}, the current going through each of the columns, and the residual capacity of each participating battery after a time period. Because of the non-linear discharging characteristics of modern batteries, CCA resorts to a simulation approach to deriving the equivalent electrical circuit behavior of each participating battery. Instead of pre-calibrating each battery in advance, CCA adopts a *trace-based* strategy to build up a simulation model for each battery by periodically measuring the instantaneous *discharge current*, *voltage level* and *used capacity* when it is discharged, generating a sampled version of its discharge characteristic curves (DCC) [17, 19], which describes how a battery's voltage level evolves with its used (not residual) capacity at a discharge current, and then applying linear interpolation to approximating those points on the DCCs that do not have measured values. For example, Figure 6 shows the measured DCCs for a 400-cycle Panasonic NCR 18650B battery for four different discharge currents, 0.31A, 1.55A, 3.1A, and 4.65A, with measurements taken in the temperature range between 25 and 35 degrees Celsius. Note that there is a distinct linear and thus easier to predict range for the DCC corresponding to a particular discharge current. The smaller the discharge current, the larger the corresponding DCC's linear range. Also, suppose the cut-off voltage level is 3V, then the total usable capacity of this battery is around 2Ah when it is discharged at 4.65A, but is about 2.95Ah when it is discharged at 0.31A. This example illustrates that discharging batteries as gently as possible not only lengthens their total lifetime, but also increases their per-charge usable capacity.

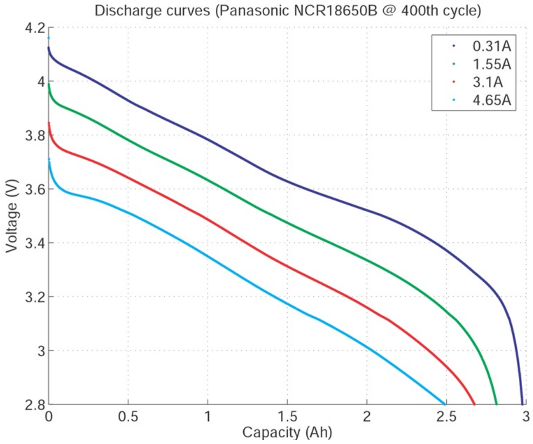

Figure 6: *The discharge characteristic curves for a Panasonic NCR 18650B battery that has been charged 400 times for four different discharge currents, 0.31A, 1.55A, 3.1A, and 4.65A. Measurements were taken in the temperature range between 25 and 35 degrees Celsius.*

CCA models a battery as a voltage source connected in series with an internal resistance. For an L-column candidate configuration, CCA assumes the initial current going through each column and thus each battery in the array is $\frac{I}{L}$. To compute the internal resistance of a battery with a used capacity X and a discharge current of $\frac{I}{L}$, CCA first identifies the two DCC measurements (<discharge current, voltage level, used capacity>) that are closest to $< \frac{I}{L},, X >$, say $< I_a, V_a, UC_a >$ and $< I_b, V_b, UC_b >$, and then approximates its internal resistance as $\frac{\triangle V}{\triangle I} = \frac{V_b - V_a}{I_a - I_b}$. For example, to calculate the internal resistance of the Panasonic battery whose DCC is shown in Figure 6 when

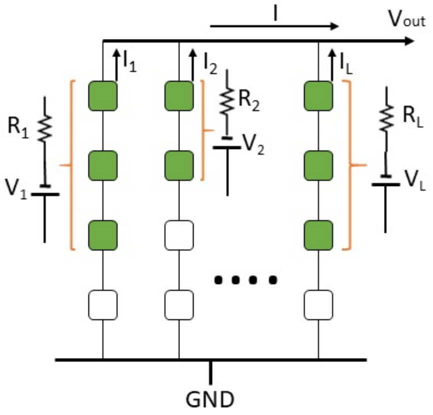

Figure 7: *The equivalent circuit of an L-column candidate configuration, which selects the first 3 batteries of the first column, the first 2 batteries of the second column,... and the first 3 batteries of the L-th column. Each column's effective resistance is the sum of the internal resistances of the participating batteries in that column.*

its used battery is 2Ah and discharge current is 3.6A, we identify the closest measurements $< 3.0V, 4.65A, 2Ah >$ and $< 3.18V, 3.1A, 2Ah >$, and then compute its internal resistance as $\frac{3.18-3.0}{4.65-3.1} = 0.12$ Ohm.

With the internal resistance of every participating battery, CCA computes the aggregate voltage level (V_i)and aggregate internal resistance R_i for each column in the candidate configuration, represents the L-column candidate configuration as an equivalent circuit as shown in Figure 7, and then solves the corresponding linear system of equations as follows, to derive V_{out} and the actual current going through each column, I_i:

$$\begin{aligned} V_1 - I_1 * R_1 &= V_{out} \\ V_2 - I_2 * R_2 &= V_{out} \\ V_3 - I_3 * R_3 &= V_{out} \\ &\ldots\ldots\ldots \\ V_L - I_L * R_L &= V_{out} \\ I_1 + I_2 + I_3 + \ldots I_L &= I \end{aligned}$$

If V_{out} is larger than some V_j, then the corresponding current I_j must be negative, the corresponding (j-th) column is disqualified, and the associated candidate configuration is considered unusable. Once the current going through each column of a candidate configuration is known, CCA computes, for each participating battery, the amount of charge that will be discharged within a fixed time period by multiplying the discharge current with the period's length, subtracts the multiplication result from the battery's residual capacity, and finally derives the standard deviation of the residual capacities of all batteries in the configuration, STD_c.

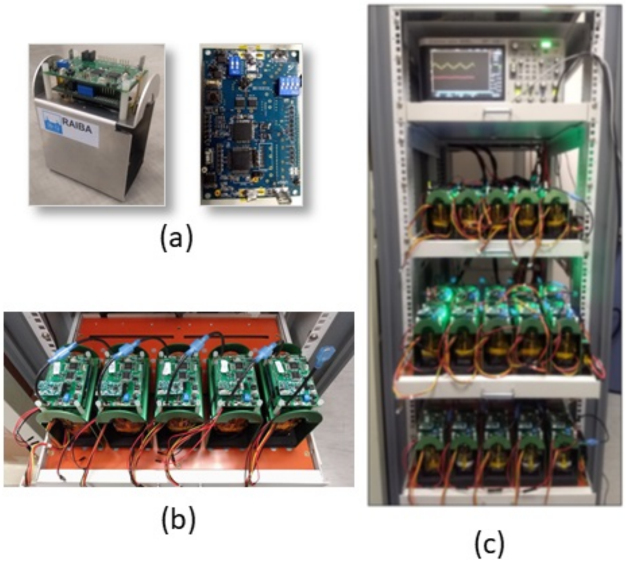

Figure 8: *The hardware implementation of the first* RAIBA *prototype, whose building block is a 4S2P battery module protected by an* ensemble/bypass *switch, shown in (a). Five such battery modules are connected in series to form a column, shown in (b), and the entire prototype contains five such columns connected in parallel and other measurement/control/protection circuits, and is housed in a rack, as shown in (c).*

A nice benefit of the *trace-based* approach to battery modeling is the model derived from measurements taken on a battery is tailored to and ages with the battery, and is thus more likely to better approximate the battery's ground truth than a pre-calibrated model.

5 Prototype Implementation

The first *RAIBA* prototype is a 5x5 array of battery modules, each of which in turn consists of 2 parallel-connected columns with each column comprising 4 Panasonic INR18650GA 3.4Ah batteries connected in series. Therefore, the entire prototype is composed of two hundred 18650 batteries and contains an energy capacity of 2.5KWh. As shown in Figure 8(a), associated with each battery module is an *enable/bypass* switch board and a cooling subsystem that provides thermal load management for the 4S2P (2 parallel-connected columns each having 4 series-connected batteries) batteries in the module. Five of these battery modules are connected in series to form a column, as shown in Figure 8(b), and five of these columns are connected in parallel and placed in a rack to form the complete battery array, as shown in Figure 8(c).

In addition to the battery array, the *RAIBA* prototype also contains a *RAIBA controller*, which is a Linux-based

Raspberry Pi 3 board that runs the Configuration Control algorithm based on electric load requests and battery status measurements, a *battery status measurement and communication module*, which uses a Linear Technology LTC6804-1 battery monitor to constantly measure the voltage, current, and temperature of each battery in the array, and an ATmega328P MCU to report these measurements in real time through the UART protocol to the RAIBA controller, and a *surge protector* that offers a safeguard mechanism to limit unexpected transient surge currents during battery array reconfiguration. The charger circuit and the DC/AC inverter for discharging are connected to the *surge protector* to charge and discharge the *RAIBA* prototype, respectively.

6 Performance Evaluation

6.1 Efficiency of Enable/Bypass Switch

Unlike digital logic switch or computer network switch, signals flowing on *RAIBA*'s enable/bypass switches represent energies to be delivered to and consumed by electric loads. Because these signals' magnitude is much larger and their transmission behavior is driven by instantaneous voltage level differences and thus largely analog, whether it is feasible to successfully implement an electrically safe enable/bypass switch that keeps the traversed electric current constant during the transitions between the enable mode and the bypass mode, raised serious doubts in the beginning of the *RAIBA* project. We have two IC implementations for the enable/bypass switch IC. The electric circuit behaviors of the version used in the current *RAIBA* prototype during the transitions of the enable and the bypass mode are shown in Figure 9. Red represents the current traversing the entire enable/bypass switch, White and Blue represent the currents traversing the two constituent switches S1 and S2 (shown in Figure 4(a)), respectively, and Green represent the voltage across the enable/bypass switch.

When the voltage drop across an enable/bypass switch is 16V and the running current is 15A, the total switch time is 50 μsec for this switch to go from the bypass to enable mode, and is 30 μsec for an enable/bypass switch to go from the enable to the bypass mode. The resulting power loss (P_{loss}) is 3mJ for the transition from the bypass to enable mode, and is 1.8mJ for the transition from the enable to bypass mode. Although there are still some glitches in the traversed current during the transitions, as indicated by the dips and bumps in the red curves in Figure 9 (a) and (b), these glitches are relatively small in magnitude and thus seamless to the electric loads.

The above results conclusively demonstrates that an implementation of an electrically safe enable/bypass switch IC which keeps the current traversing it constant during transitions not only is feasible, but also could be made highly efficient in terms of switch time and switching-induced energy loss.

6.2 Gains from Dynamic Reconfigurability

Intuitively, the more heterogeneous the batteries in a *RAIBA* array and the more fluctuated the electric load facing a *RAIBA* array, the higher performance gain *RAIBA*'s dynamic reconfigurability is expected to provide. To empirically assess the gain from *RAIBA*'s dynamic reconfigurability, we tested the first *RAIBA* prototype under a set of electric load traces until it cannot be discharged any further, and measure the total discharge service time, the percentage of wasted battery capacity at the end of the discharge cycle, and the number of enable/bypass mode transitions.

To reduce the amount of time required for each experiment run, we limited the capacity of each battery module to under 4Ah, but still used the entire 5x5 array. Because *RAIBA* is designed to minimize unnecessary energy waste when the constituent batteries in an array ex-

Electric Load	Discharge Service Time (hr)	Wasted Capacity (Ah)	Standard Deviation (Ah)	Transition Count
Simple	4.59 / 8.42 (83.4%)	35.5698 / 2.3747 (-93.3%)	0.8372 / 0.0428 (-94.9%)	0 / 3059
eBus	3.77 / 6.89 (82.9%)	35.5325 / 2.4114 (-93.2%)	0.8372 / 0.0695 (-91.7%)	0 / 1385
Data center	4.16 / 7.66 (84.0%)	35.5472 / 2.0324 (-94.3%)	0.8372 / 0.0931 (-88.9%)	0 / 2083
NYC	2.98 / 5.77 (93.4%)	35.4782 / 2.1170 (-94.3%)	0.8372 / 0.1040 (-87.6%)	0 / 2493
TaiPower	2.93 / 6.09 (108.1%)	35.4609 / 2.4612 (-93.1%)	0.8372 / 0.2510 (-70.0%)	0 / 545

Table 1: *Comparison between the* Fixed *configuration (left) and the* Reconfigurable *configuration (right) in terms of the total discharge service time, the total wasted capacity at the end, the standard deviation in battery capacity at the end, and the number of mode transitions, under five electric load traces. Numbers inside the parenthesis represent the percentage difference between the* Reconfigurable *configuration and the* Fixed *configuration.*

hibit diverse discharging characteristics or have different initial capacities, we focused below on a test case in which the initial capacities of the battery modules in the array vary from 1.49Ah to 3.99Ahm, as shown in Figure 10, where the standard deviation of the individual battery capacity across the array is 0.8377Ah. The total battery capacity of the entire array is 72.4544Ah, and the maximum power is 1790.3365W. To evaluate how the *RAIBA* prototype performs under different electric load patterns, we used the following five electric load traces that represent a wide variety of use cases:

- *Simple*: A constant load at the level of 120W.
- *eBus*: A simplified version of an electric load trace captured from an electric bus that consists of periods each of which includes a 5-sec accelerate phase of 200W, a 50-sec cruise phase of 150W, and a 10-sec decelerate phase of 100W.
- *Data center*: An electric load trace that was collected on 2016/08/02 from a 700+-server cloud computing data center within Industrial Technology Research Institute, and then scaled down in the power magnitude by a factor of 0.02.
- *NYC*: A scaled down version of the electric load trace for New York City on 2016/04/01 by a factor of $3 * 10^{-8}$.
- *Taipower*: A scaled down version of the electric load trace for the Northern part of Taiwan on 2016/03/29 by a factor of 10^{-7}.

We exercised each of the five electric load traces against the *RAIBA* prototype twice, once when we enabled the array's reconfigurability capability (*Reconfigurable* configuration), and the other time when we enabled it completely (*Fixed* configuration). At the beginning of each run, we charged each battery in the array according to the specification in Figure 10, and then discharged the array using a programmable electric load generator that drew power over time according to a given electric load trace. Each experiment run terminates when the *RAIBA* prototype can no longer continue servicing the corresponding electric load trace.

Table 1 shows the detailed comparisons between the *Fixed* and *Reconfigurable* configuration under the five electric load traces. For each and every of the five electric load traces, the *Reconfigurable* configuration outperforms the *Fixed* configuration in terms of the total discharge service time by between 82.9% and 108.1%. That is, for the same initial array condition and electric load trace, the *Reconfigurable* configuration lasts almost twice as long as the *Fixed* configuration. This gain mainly comes from the reduction in the imbalance of the batteries' residual capacity, as shown in the Standard Deviation column, which that indicates the *Reconfigurable* configuration reduces the standard deviation in residual battery capacity at the end of an experiment run by between 70% to 94.9% when compared with that of the *Fixed* configuration, which is roughly the same as the initial standard deviation because each battery contributes equally during the discharging process. Figure 11 shows visually how an array's batteries' residual capacities evolve over time under an *eBus* trace when dynamic reconfigurability is turned on and off. As expected, the residual capacities of an array's batteries converge over time towards a common value when *RAIBA*'s dynamic reconfigurability is enabled, but progress largely independently of one another when dynamic reconfigurability is disabled.

Hardware-based inter-battery capacity balancing, which transfers charge from larger-capacity batteries to lower-capacity batteries, and inevitably incurs energy loss. In contrast, *RAIBA* balances the residual capacities of an array's batteries by drafting different subsets of batteries to work at different time, and thus is more general because it could balance the residual capacities of those batteries that are not electrically connected, and more energy-efficient because it does not involve any movement of electric charges between batteries.

When the residual capacities of an array's batteries are more balanced, it is less likely that the array is forced to

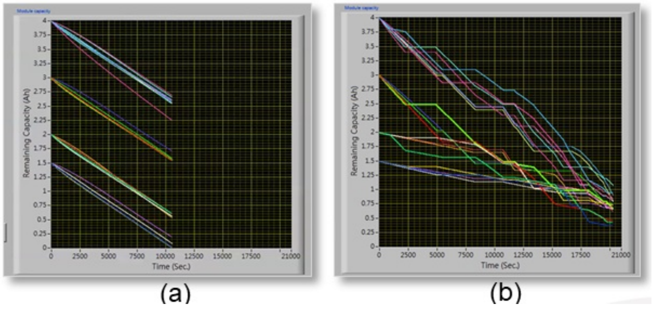

Figure 11: *The residual capacities of a* RAIBA *array's batteries evolve over time under an* eBus *trace when dynamic reconfigurability is turned (a) off and (b) on.*

terminate earlier on because of the capacity exhaustion of some batteries, and the amount of residual capacity lying unused and wasted at the end of each experiment run is expected to be smaller. The Wasted Capacity column of Table 1 shows that the wasted capacity at the end of an experiment run for the *Reconfigurable* configuration is less than 10% of that of the *Fixed* configuration for each of the five electric load traces. This demonstrates the *Reconfigurable* configuration's capability to eliminate energy waste due to fragmentation via more effective inter-battery capacity balancing.

That there is not much correlation between the Transition Count column and the Discharge Service Time column of Table 1 suggests that a higher number of mode transitions does not necessarily result in a higher gain in the total discharge service time. The gain also has a lot to do with the degree of mismatch between the demand patterns of an electric load trace and the energy profile that the *Fixed* configuration could offer.

The price of dynamic reconfigurability is the additional energy consumption due to transitions between the enable and the bypass mode. However, the associated energy consumption is rather miniscule. For example, even if a discharge cycle requires 3000 mode transitions, as in the case of the *Simple* trace in Table 1, the total energy consumption is about $3000 * 3mJ = 9J$, which is about 0.001% of the total energy capacity of the 5x5 battery array used in the test.

7 Related Work

Song Ci et al. [4] provides a detailed survey of the reconfigurable battery techniques, including various reconfigurable battery array designs proposed in the literature, their management and fault tolerance properties, and the design considerations of the associated battery management mechanisms. Baronti et al. [3] and Miyatake et al. [20] explored the effective capacity of a battery array with different inter-battery connectivity configurations. Baronti et al. [2] explored the design space for the bypass/enable switch module. Kim and Shin [15] first proposed a dynamically reconfigurable architecture for large-scale battery arrays used in electric vehicles in order to tolerate battery cell failures. Jin and Shin [13] followed up on [15] with the development of battery pack sizing and reconfiguration algorithms. Kim et al. [16] built the first small-scale (6x3) reconfigurable battery array called self-X, which aimed to tolerate battery failures, balance the capacities among batteries and optimize energy conversion efficiency. He et al. [9] took into account battery conditions, particularly state of health, to dynamically reconfigure a battery array to maximize its total capacity. He et al. [10] improved the performance of charging operations by leveraging various battery state information to best exploit dynamic reconfigurability. He et al. [11] used dynamic reconfigurability to allow weaker cells to rest longer so as to balance inter-battery capacity and increase the battery array's effective capacity.

Badam et al. [1] proposed a software-defined battery system that includes batteries of different charging/discharging characteristics and provides an API for the control software to use the most appropriate batteries to service given electric loads. While dynamic reconfigurability was originally proposed for large-scale battery arrays, Visairo and Kumar [21] and Ci et al. [5] explored the effectiveness of applying dynamic reconfigurability to portable and mobile devices.

RAIBA differs from the research efforts described in the following ways. First, RAIBA features a real implementation of a switching IC that is able to enable and bypass a battery of a battery array while keeping the traversing current constant and the array continuing operating. This real-time dynamic reconfigurability makes it possible to apply RAIBA to applications beyond stand-by energy storage systems, such as electric vehicles. Second, RAIBA supports a dynamic battery array reconfiguration algorithm that takes into account the capacity/state of each battery and the target electric load, and produces in real time a battery array configuration that meets the energy needs of the target load while minimizing unnecessary energy waste due to inter-battery balancing and power conversion. Third, RAIBA adopts a trace-based battery model that removes the need for batteries with homogeneous quality, and is able to accommodate batteries that age over times.

8 Conclusion

This work proposes a *RAIBA* approach to using retired batteries to build cost-effective energy storage systems that make up for the intermittent nature of renewable energy generation systems. The key idea in *RAIBA* is to use dynamic reconfigurability to make the best of heterogeneity in retired batteries, so as to enable continued operations even in the presence of individual battery failures, maximize the energy output of each charge/discharge cycle, and minimize energy loss due to conversion, analog inter-battery capacity balancing and resource fragmentation. The paper describes the design, implementation and evaluation of a fully operational *RAIBA* -1 prototype. More specifically, this paper makes the following contributions to the energy storage management area:

- A taxonomic framework for analyzing varying degrees of flexibility of dynamically reconfiguring the inter-battery connectivity of large-scale battery arrays at run time,
- The first successful and efficient implementation of an *enable/bypass* switch IC that keeps the traversed current constant during transitions between the bypass and enable mode, and
- The completion of a fully operational software-defined virtualized battery array prototype, and an empirical demonstration of the efficacy of its dynamic reconfigurability in increasing the effective discharge service time by more than 80% for a variety of electric load traces.

Abstract

Container-based virtualization has become the de-facto standard for deploying applications in data centers. However, deployed containers frequently include a wide-range of tools (e.g., debuggers) that are not required for applications in the common use-case, but they are included for rare occasions such as in-production debugging. As a consequence, containers are significantly larger than necessary for the common case, thus increasing the build and deployment time.

CNTR[1] provides the *performance* benefits of lightweight containers and the *functionality* of large containers by splitting the traditional container image into two parts: the "fat" image — containing the tools, and the "slim" image — containing the main application. At run-time, CNTR allows the user to efficiently deploy the "slim" image and then expand it with additional tools, when and if necessary, by dynamically attaching the "fat" image.

To achieve this, CNTR transparently combines the two container images using a new nested namespace, without any modification to the application, the container manager, or the operating system. We have implemented CNTR in Rust, using FUSE, and incorporated a range of optimizations. CNTR supports the full Linux filesystem API, and it is compatible with all container implementations (i.e., Docker, rkt, LXC, systemd-nspawn). Through extensive evaluation, we show that CNTR incurs reasonable performance overhead while reducing, on average, by 66.6% the image size of the Top-50 images available on Docker Hub.

1 Introduction

Containers offer an appealing, lightweight alternative to VM-based virtualization (e.g., KVM, VMware, Xen) that relies on process-based virtualization. Linux, for instance, provides the `cgroups` and `namespaces` mechanisms that enable strong performance and security isolation between containers [24]. Lightweight virtualization is fundamental to achieve high efficiency in virtualized datacenters and enables important use-cases, namely just-in-time deployment of applications. Moreover, containers significantly reduce operational costs through higher consolidation density and power minimization, especially in multi-tenant environments. Because of all these advantages, it is no surprise that containers have seen wide-spread adoption by industry, in many cases replacing altogether traditional virtualization solutions [17].

Despite being lightweight, deployed containers often include a wide-range of tools such as shells, editors, coreutils, and package managers. These additional tools are usually not required for the application's core function — the common operational use-case — but they are included for management, manual inspection, profiling, and debugging purposes [64]. In practice, this significantly *increases container size* and, in turn, translates into slower container deployment and inefficient datacenter resource usage (network bandwidth, CPU, RAM and disk). Furthermore, larger images degrade container deployment time [52, 44]. For instance, previous work reported that downloading container images account for 92% of the deployment time [52]. Moreover, a larger code base directly affects the reliability of applications in datacenters [50].

Given the impact of using large containers, users are discouraged from including additional tools that would otherwise simplify the process of debugging, deploying, and managing containers. To mitigate this problem, Docker has recently adopted smaller run-times but, unfortunately, these efforts come at the expense of compatibility problems and have limited benefits [13].

To quantify the practical impact of additional tools on the container image size, we employed Docker Slim [11] on the 50 most popular container images available on the Docker Hub repository [10]. Docker Slim uses a combination of static and dynamic analyses to generate smaller-sized container images, in which, only files needed by the core application are included in the final image. The results of this experiment (see Figure 5) are

[1] Read it as "center".

encouraging: we observed that by excluding unnecessary files from typical containers it is possible to reduce the container size, on average, by 66.6%. Similarly, others have found that a only small subset (6.4%) of the container images is read in the common case [53].

CNTR addresses this problem[2] by building lightweight containers that still remain fully functional, even in uncommon use-cases (e.g., debugging and profiling). CNTR enables users to deploy the application and its dependencies, while the additional tools required for other use-cases are supported by expanding the container "on-demand", during runtime (Figure 1 (a)). More specifically, CNTR splits the traditional container image into two parts: the "fat" image containing the rarely used tools and the "slim" image containing the core application and its dependencies.

During runtime, CNTR allows the user of a container to efficiently deploy the "slim" image and then expand it with additional tools, when and if necessary, by dynamically attaching the "fat" image. As an alternative to using a "fat" image, CNTR allows tools from the *host* to run inside the container. The design of CNTR simultaneously preserves the performance benefits of lightweight containers and provides support for additional functionality required by different application workflows.

The key idea behind our approach is to create a new *nested namespace* inside the application container (i.e., "slim container"), which provides access to the resources in the "fat" container, or the host, through a FUSE filesystem interface. CNTR uses the FUSE system to combine the filesystems of two images without any modification to the application, the container implementation, or the operating system. CNTR selectively redirects the filesystem requests between the mount namespace of the container (i.e., what applications within the container observe and access) and the "fat" container image or the host, based on the filesystem request path. Importantly, CNTR supports the full Linux filesystem API and all container implementations (i.e., Docker, rkt, LXC, systemd-nspawn).

We evaluated CNTR across three key dimensions: (1) *functional completeness* – CNTR passes 90 out of 94 (95.74%) `xfstests` filesystem regression tests [14] supporting applications such as SQLite, Postgres, and Apache; (2) *performance* – CNTR incurs reasonable overheads for the `Phoronix` filesystem benchmark suite [18], and the proposed optimizations significantly improve the overall performance; and lastly, (3) *effectiveness* – CNTR's approach on average results in a 66.6% reduction of image size for the Top-50 images available on Docker hub [10]. We have made publicly available the CNTR implementation along with the experimental setup [6].

2 Background and Motivation

2.1 Container-Based Virtualization

Containers consist of a lightweight, process-level form of virtualization that is widely used and has become a cornerstone technology for datacenters and cloud computing providers. In fact, all major cloud computing providers (e.g., Amazon [2], Google [16] and Microsoft [4]) offer Containers as a Service (CaaS).

Container-based virtualization often relies on three key components: (1) the OS mechanism that enforces the process-level isolation (e.g., the Linux `cgroups` [41] and `namespaces` [40] mechanisms), (2) the application packaging system and runtime (e.g., Docker [9], Rkt [38]), and (3) the orchestration manager that deploys, distributes and manages containers across machines (e.g., Docker Swarm [12], Kubernetes [22]). Together, these components enable users to quickly deploy services across machines, with strong performance and security isolation guarantees, and with low-overheads.

Unlike VM-based virtualization, containers do not include a guest kernel and thus have often smaller memory footprint than traditional VMs. Containers have important advantages over VMs for both users and data centers:

1. **Faster deployment.** Containers are transferred and deployed faster from the registry [44].
2. **Lower resource usage.** Containers consume fewer resources and incur less performance overhead [62].
3. **Lower build times.** Containers with fewer binaries and data can be rebuilt faster [64].

Unfortunately, containers in practice are still unnecessarily large because users are forced to decide which auxiliary tools (e.g. debugging, profiling, etc.) should be included in containers at *packaging-time*. In essence, users are currently forced to strike a balance between lightweight containers and functional containers, and end up with containers that are neither as light nor as functional as desirable.

2.2 Traditional Approaches to Minimize Containers

The container-size problem has been a significant source of concern to users and developers. Unfortunately, existing solutions are neither practical nor efficient.

An approach that has gained traction, and has been adopted by Docker, consists of packing containers using smaller base distributions when building the container runtime. For instance, most of Docker's containers are now based on the Alpine Linux distribution [13], resulting in smaller containers than traditional distributions. Alpine Linux uses the `musl` library, instead of `libc`, and bundles `busybox` , instead of `coreutils` — these differences enable a smaller container runtime but at the expense of compatibility problems caused by runtime differences. Further, the set of tools included is still restricted and fundamentally does not help users when less common auxiliary tools are required (e.g., custom debugging tools).

[2] Note that Docker Slim [11] does not solve the problem; it simply identifies the files not required by the application, and excludes them from the container, but it does not allow users to access those files at run-time.

The second approach to reduce the size of containers relies on union filesystems (e.g., UnionFS [60]). Docker, for instance, enables users to create their containers on top of commonly-used base images. Because such base images are expected to be shared across different containers (and already deployed in the machines), deploying the container only requires sending the diff between the base image and the final image. However, in practice, users still end up with multiple base images due to the use of different base image distributions across different containers.

Another approach that has been proposed relies on the use of *unikernels* [57, 58], a single-address-space image constructed from a *library OS* [61, 49, 65]. By removing layers of abstraction (e.g., processes) from the OS, the unikernel approach can be leveraged to build very small virtual machines—this technique has been considered as containerization because of its low overhead, even though it relies on VM-based virtualization. However, unikernels require additional auxiliary tools to be statically linked into the application image; thus, it leads to the same problem.

2.3 Background: Container Internals

The container abstraction is implemented by a userspace container run-time, such as Docker [9], rkt [38] or LXC [37]. The kernel is only required to implement a set of per-process isolation mechanisms, which are inherited by child processes. This mechanism is in turn leveraged by container run-times to implement the actual container abstraction. For instance, applications in different containers are isolated and have all their resources bundled through their own filesystem tree. Crucially, the kernel allows the partitioning of system resources, for a given process, with very low performance overhead thus enabling efficient process-based virtualization.

The Linux operating system achieves isolation through an abstraction called namespaces. Namespaces are modular and are applied to individual processes inherited by child processes. There are seven namespaces to limit the scope what a process can access (e.g., filesystem mountpoints, network interfaces, or process IDs[40]).

During the container startup, by default, namespaces of the host are unshared. Hence, processes inside the container only see files from their filesystem image (see Figure 1 (a)) or additional volumes, that have been statically added during setup. New mounts on the host are not propagated to the container since by default, the container runtime will mount all mount points as private.

2.4 Use-cases of CNTR

We envision three major use cases for CNTR that cover three different debugging/management scenarios:

Container to container debugging in production. CNTR enables the isolation of debugging and administration tools in *debugging containers* and allows application containers to use debugging containers on-demand. Consequently, application containers become leaner, and the isolation of debugging/administration tools from applications allows users to have a more consistent debugging experience. Rather than relying on disparate tools in different containers, CNTR allows using a single debugging container to serve many application containers.

Host to container debugging. CNTR allows developers to use the debugging environments (e.g., IDEs) in their host machines to debug containers that do not have these environments installed. These IDEs can sometimes take several gigabytes of disk space and might be not even compatible with the distribution of the container image is based on. Another benefit of using CNTR in this context is that development environments and settings can be also efficiently shared across different containers.

Container to host administration and debugging. Container-oriented Linux distributions such as CoreOS [8] or RancherOS [30] do not provide a package manager and users need to extend these systems by installing containers even for basic system services. CNTR allows a user of a privileged container to access the root filesystem of the host operating system. Consequently, administrators can keep tools installed in a debug container while keeping the host operating system's filesystem lean.

3 Design

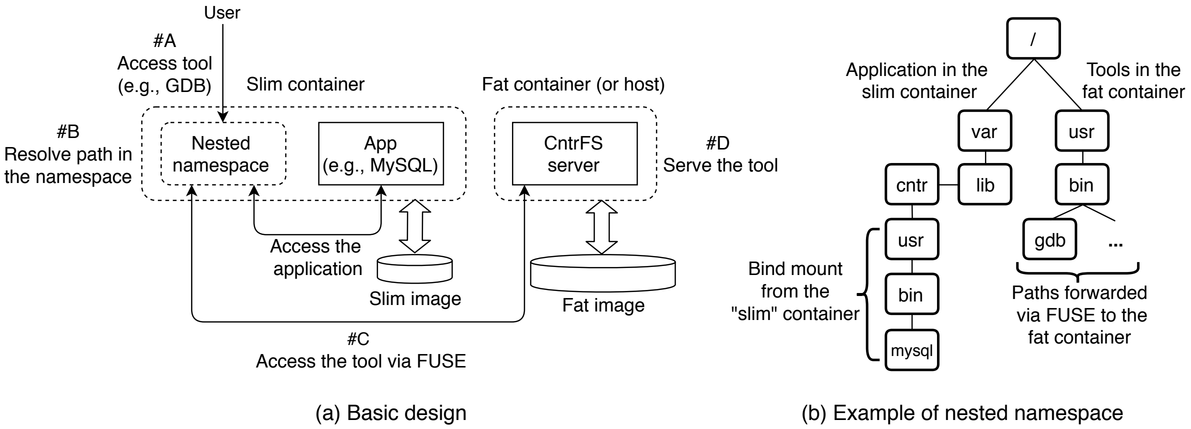
In this section, we present the detailed design of CNTR.

3.1 System Overview

Design goals. CNTR has the following design goals:

- *Generality:* CNTR should support a wide-range of workflows for seamless management and problem diagnosis (e.g., debugging, tracing, profiling).
- *Transparency:* CNTR should support these workflows without modifying the application, the container manager, or the operating system. Further, we want to be compatible with all container implementations.
- *Efficiency:* Lastly, CNTR should incur low performance overheads with the split-container approach.

Basic design. CNTR is composed of two main components (see Figure 1 (a)): a nested namespace, and the CNTRFS filesystem. In particular, CNTR combines slim and fat containers by creating a new *nested namespace* to merge the namespaces of two containers (see Figure 1 (b)). The nested namespace allows CNTR to selectively break the isolation between the two containers by transparently redirecting the requests based on the accessed path. CNTR achieves this redirection using the CNTRFS filesystem. CNTRFS is mounted as the root filesystem (`/`), and the application filesystem is remounted to another path (`/var/lib/cntr`) in the nested namespace. CNTRFS implements a filesystem in userspace (FUSE), where the CNTRFS server handles the requests for auxiliary tools installed on the fat container (or on the host).



(a) Basic design

(b) Example of nested namespace

Figure 1: Overview of CNTR

At a high-level, CNTR connects with the CNTRFS server via the generic FUSE kernel driver. The kernel driver simply acts as a proxy between processes accessing CNTRFS, through Linux VFS, and the CNTRFS server running in userspace. The CNTRFS server can be in a different mount namespace than the nested namespace, therefore, CNTR establishes a proxy between two mount namespaces through a request/response protocol. This allows a process that has all its files stored in the fat container (or the host) to run within the mount namespace of the slim container.

Cntr workflow. CNTR is easy to use. The user simply needs to specify the name of the "slim" container and, in case the tools are in another container, the name of the "fat" container. CNTR exposes a shell to the user that has access to the resources of the application container as well as the resources forwarded from the fat container.

Figure 1 (a) explains the workflow of CNTR when a user requests to access a tool from the slim container (#A): CNTR transparently resolves the requested path for the tool in the nested namespace (#B). Figure 1 (b) shows an example of CNTR's nested namespace, where the requested tool (e.g., gdb) is residing in the fat container. After resolving the path, CNTR redirects the request via FUSE to the fat container (#C). Lastly, CNTRFS serves the requested tool via the FUSE interface (#D). Behind the scenes, CNTR executes the following steps:

1. *Resolve container name to process ID and get container context.* CNTR resolves the name of the underlying container process IDs and then queries the kernel to get the complete execution context of the container (container namespaces, environment variables, capabilities, ...).
2. *Launch the* CNTRFS *server.* CNTR launches the CNTRFS server. CNTR launches the server either directly on the host or inside the specified "fat" container containing the tools image, depending on the settings that the user specified.
3. *Initialize the tools namespace.* Subsequently, CNTR attaches itself to the application container by setting up a nested mount namespace within the namespace of the application container. CNTR then assigns a forked process to the new namespace. Inside the new namespace, the CNTR process proceeds to mount CNTRFS, providing access to files that are normally out of the scope of the application container.
4. *Initiate an interactive shell.* Based on the configuration files within the debug container or on the host, CNTR executes an interactive shell, within the nested namespace, that the user can interact with. CNTR forwards its input/output to the user terminal (on the host). From the shell, or through the tools it launches, the user can then access the application filesystem under `/var/lib/cntr` and the tools filesystem in `/`. Importantly, tools have the same view on system resources as the application (e.g., `/proc`, `ptrace`). Furthermore, to enable the use of graphical applications, CNTR forwards Unix sockets from the host/debug container.

3.2 Design Details

This section explains the design details of CNTR.

3.2.1 Step #1: Resolve Container Name and Obtain Container Context

Because the kernel has no concept of a container name or ID, CNTR starts by resolving the container name, as defined by the used container manager, to the process IDs running inside the container. CNTR leverages wrappers based on the container management command line tools to achieve this translation and currently, it supports Docker, LXC, rkt, and systemd-nspawn.

After identifying the process IDs of the container, CNTR gathers OS-level information about the container namespace. CNTR reads this information by inspecting the `/proc` filesystem of the main process within the container.

This information enables CNTR to create processes inside the container in a *transparent* and *portable* way.

In particular, CNTR gathers information about the container namespaces, cgroups (resource usage limits), mandatory access control (e.g., AppArmor [26] and SELinux [19] options), user ID mapping, group ID mapping, capabilities (fine-grained control over super-user permissions), and process environment options. Additionally, CNTR could also read the seccomp options, but this would require non-standard kernel compile-time options and generally has limited value because seccomp options have significant overlap with the capability options. CNTR reads the environment variables because they are heavily used in containers for configuration and service discovery [36].

Before attaching to the container, in addition, to gather the information about the container context, the CNTR process opens the FUSE control socket (`/dev/fuse`). This file descriptor is required to mount the CNTRFS filesystem, after attaching to the container.

3.2.2 Step #2: Launch the CNTRFS Server

The CNTRFS is executed either directly on the host or inside the "fat" container, depending on the option specified by the user (i.e., the location of the tools). In the host case the CNTRFS server simply runs like a normal host process.

In case the user wants to use tools from the "fat" container, the CNTRFS process forks and attaches itself to the "fat" container. Attaching to the "fat" container is implemented by calling the `setns()` system call, thereby assigning the child process to the container namespace that was collected in the previous step.

After initialization, the CNTRFS server waits for a signal from the nested namespace (Step #3) before it starts reading and serving the FUSE requests (reading before an unmounted FUSE filesystem would otherwise return an error). The FUSE requests then will be read from the `/dev/fuse` file descriptor and redirected to the filesystem of the server namespace (i.e., host or fat container).

3.2.3 Step #3: Initialize the Tools Namespace

CNTR initializes the tool namespace by first attaching to the container specified by the user—the CNTR process forks and the child process assigns itself to the cgroup, by appropriately setting the `/sys/` option, and namespace of the container, using the `setns()` system call.

After attaching itself to the container, CNTR creates a new nested namespace, and marks all mountpoints as private so that further mount events (regarding the nested namespace) are not propagated back to the container namespace. Subsequently, CNTR creates a new filesystem hierarchy for the nested namespace, mounting the CNTRFS in a temporary mountpoint (`TMP/`).

Within the nested namespace, the child process mounts CNTRFS, at `TMP/`, and signals the parent process (running outside of the container) to start serving requests. Signalling between the parent and child CNTR processes is implemented through a shared Unix socket.

Within the nested namespace, the child process remounts all pre-existing mountpoints, from the application container, by moving them from `/` to `TMP/var/lib/cntr`. Note that the application container is not affected by this since all mountpoints are marked as private.

In addition, CNTR also mounts special container-specific files from the application over files from the tools or host (using bind mount [42]). The special files include the pseudo filesystems `procfs` (`/proc`), ensuring the tools can access the container application, and devtmpfs (`/dev`), containing block and character devices that have been made visible to our container. Furthermore, we bind mount a set of configuration files from the application container into the temporary directory (e.g., `/etc/passwd`, and `/etc/hostname`).

Once the new filesystem hierarchy has been created in the temporary directory, CNTR atomically executes a `chroot` turning the temporary directory (`TMP/`) into the new root directory (`/`).

To conclude the container attachment and preserve the container isolation guarantees, CNTR updates the remaining properties of the nested namespace: (1) CNTR drops the capabilities by applying the AppArmor/SELinux profile and (2) CNTR applies all the environment variables that were read from the container process; with the exception of `PATH` – the `PATH` is instead inherited from the debug container since it is often required by the tools.

3.2.4 Step #4: Start Interactive Shell

Lastly, CNTR launches an interactive shell within the nested namespace, enabling users to execute the tools. CNTR forwards the shell I/O using a pseudo-TTY, and supports graphical interface using Unix sockets forwarding.

Shell I/O. Interactive shells perform I/O through standard file descriptors (i.e., stdin, stdout, and stderr file descriptors) that generally refer to terminal devices. For isolation and security reasons, CNTR prevents leaking the terminal file descriptors of the host to a container by leveraging pseudo-TTYs – the pseudo-TTY acts as a proxy between the interactive shell and the user terminal device.

Unix socket forwarding. CNTR forwards connections to Unix sockets, e.g., the X11 server socket and the D-Bus daemon running on the host. Unix sockets are also visible as files in our FUSE. However, since our FUSE has inode numbers that are different from the underlying filesystem, the kernel does not associate them with open sockets in the system. Therefore, we implemented a socket proxy that runs an efficient event loop based on epoll. It uses the splice syscall to move data between clients in the application container and servers listening on Unix sockets in the debug container/host.

3.3 Optimizations

We experienced performance slowdown in CNTRFS when we measured the performance using the Phoronix benchmark suite [18] (§5.2). Therefore, we incorporated the following performance optimizations in CNTR.

Caching: Read and writeback caches. The major performance improvement gain was by allowing the FUSE kernel module to cache data returned from the read requests as well as setting up a writeback buffer for the writes. CNTR avoids automatic cache invalidation when a file is opened by setting the `FOPEN_KEEP_CACHE` flag. Without this flag the cache cannot be effectively shared across different processes. To allow the FUSE kernel module to batch smaller write requests, we also enable the writeback cache by specifying the `FUSE_WRITEBACK_CACHE` flag at the mount setup time. This optimization sacrifices write consistency for performance by delaying the sync operation. However, we show that it still performs correctly according to the POSIX semantics in our regression experiments (see § 5.1).

Multithreading. Since the I/O operations can block, we optimized the CNTRFS implementation to use multiple threads. In particular, CNTR spawns independent threads to read from the CNTRFS file descriptor independently to avoid contentions while processing the I/O requests.

Batching. In addition to caching, we also batch operations to reduce the number of context switches. In particular, we apply the batching optimization in three places: (a) pending inode lookups, (b) forget requests, and (c) concurrent read requests.

Firstly, we allow concurrent inode lookups by applying `FUSE_PARALLEL_DIROPS` option on mount. Secondly, the operating system sends `forget` requests, when inodes can be freed up by CNTRFS. The kernel can batch a forget intent for multiple inodes into a single request. In CNTR we have also implemented this request type. Lastly, we set `FUSE_ASYNC_READ` to allow the kernel to batch multiple concurrent read requests at once to improve the responsiveness of read operations.

Splicing: Read and write. Previous work suggested the use of splice reads and writes to improve the performance of FUSE [66]. The idea behind splice operation is to avoid copying data from and to userspace. CNTR uses splice for read operations. Therefore, the FUSE userspace process moves data from the source file descriptor into a kernel pipe buffer and then to the destination file descriptor with the help of the `splice` syscall. Since splice does not actually copy the data but instead remaps references in the kernel, it reduces the overhead.

We also implemented a splice write optimization. In particular, we use a pipe as a temporary storage, where the data is part of the request, and the data is not read from a file descriptor. However, FUSE does not allow to read the request header into userspace without reading the attached data. Therefore, CNTR has to move the whole request to a kernel pipe first in order to be able to read the request header separately. After parsing the header it can move the remaining data to its designated file descriptor using the splice operation. However, this introduces an additional context switch, and slowdowns all FUSE operations since it is not possible to know in advance if the next request will be a write request. Therefore, we decided not to enable this optimization by default.

4 Implementation

To ensure portability and maintainability, we decided not to rely on container-specific APIs, since they change quite often. Instead, we built our system to be as generic as possible by leveraging more stable operating system interfaces. Our system implementation supports all major container types: Docker, LXC, systemd-nspawn and rkt. CNTR's implementation resolves container names to process ids. Process ids are handled in an implementation-specific way. On average, we changed only 70 LoCs for each container implementation to add such container-specific support for CNTR.

At a high-level, our system implementation consists of the following four components:

- *Container engine* (1549 LoC) analyzes the container that a user wants to attach to. The container engine also creates a nested mount namespace, where it starts the interactive shell.
- CNTRFS (1481 LoC) to serve the files from the fat container. We implemented CNTRFS based on Rust-FUSE [33]. We extended Rust-FUSE to be able to mount across mount namespaces and without a dedicated FUSE mount executable.
- A *pseudo TTY* (221 LoC) to connect the shell input/output with the user terminal.
- A *socket proxy* (400 LoC) to forward the Unix socket connection between the fat (or the host) and slim containers for supporting X11 applications.

All core system components of CNTR were implemented in Rust (total 3651 LoC). To simplify deployment, we do not depend on any non-Rust libraries. In this way, we can compile CNTR as a ∼1.2MB single self-contained static executable by linking against musl-libc [23]. This design is imperative to ensure that CNTR can run on container-optimized Linux distributions, such as CoreOS [8] or RancherOS [30], that do not have a package manager to install additional libraries.

Since CNTR makes heavy use of low-level filesystem system calls, we have also extended the Rust ecosystem with additional 46 system calls to support the complete Linux filesystem API. In particular, we extended the nix Rust library [34], a library wrapper around the Linux/`POSIX` API. The changes are available in our fork [29].

5 Evaluation

In this section, we present the experimental evaluation of CNTR. Our evaluation answers the following questions.

1. Is the implementation complete and correct? (§5.1)
2. What are the performance overheads and how effective are the proposed optimizations? (§5.2)
3. How effective is the approach to reducing container image sizes? (§5.3)

5.1 Completeness and Correctness

We first evaluate the completeness and correctness claim of the CNTR implementation. The primary goal is to evaluate whether CNTR implements the same features (completeness) as required by the underlying filesystem, and it follows the same POSIX semantics (correctness).

Benchmark: xfstests regression test suite. For this experiment, we used the xfstests [14] filesystem regression test suite. The xfstests suite was originally designed for the XFS filesystem, but it is now widely used for testing all of Linux's major filesystems. It is regularly used for quality assurance before applying changes to the filesystem code in the Linux kernel. xfstests contains tests suites to ensure correct behavior of all filesystem related system calls and their edge cases. It also includes crash scenarios and stress tests to verify if the filesystem correctly behaves under load. Further, it contains many tests for bugs reported in the past.

Methodology. We extended xfstests to support mounting CNTRFS. For running tests, we mounted CNTRFS on top of tmpfs, an in-memory filesystem. We run all tests in the generic group once.

Experimental results. xfstests consists of 94 unit tests that can be grouped into the following major categories: *auto*, *quick*, *aio*, *prealloc*, *ioctl*, and *dangerous*.

Overall, CNTR passed 90 out of 94 (95.74%) unit tests in xfstests. Four tests failed due minor implementation details that we currently do not support. Specifically, these four unit tests were automatically skipped by xfstests because they expected our filesystem to be backed by a block device or expected some missing features in the underlying tmpfs filesystem, e.g. copy-on-write ioctl. We next explain the reasons for the failed four test cases:

1. **Test #375** failed since SETGID bits were not cleared in chmod when the owner is not in the owning group of the access control list. This would require manual parsing and interpreting ACLs in CNTR. In our implementation, we delegate POSIX ACLs to the underlying filesystem by using setfsuid/setfsguid on inode creation.
2. **Test #228** failed since we do not enforce the per-process file size limits (RLIMIT_FSIZE). As replay file operations and RLIMIT_FSIZE of the caller is not set or enforced in CNTRFS, this has no effect.
3. **Test #391** failed since we currently do not support the direct I/O flag in open calls. The support for direct I/O and mmap in FUSE is mutually exclusive. We chose mmap here, since we need it to execute processes. In practice, this is not a problem because not all docker drivers support this feature, including the popular filesystems such as overlayfs and zfs.
4. **Test #426** failed since our inodes are not exportable. In Linux, a process can get inode references from filesystems by the name_to_handle_at system call. However, our inodes are not persisted and are dynamically requested and destroyed by the operating system. If the operating system no longer uses them, they become invalid. Many container implementations block this system call as it has security implications.

To summarize, the aforementioned failed test cases are specific to our current state of the implementation, and they should not affect most real-world applications. As such, these features are not required according to the POSIX standard, but, they are Linux-specific implementation details.

5.2 Performance Overheads and Optimizations

We next report the performance overheads for CNTR's split-containers approach (§5.2.1), detailed experimental results (§5.2.2), and effectiveness of the proposed optimizations (§5.2.3).

Experimental testbed. To evaluate a realistic environment for container deployments [3], we evaluated the performance benchmarks using m4.xlarge virtual machine instances on Amazon EC2. The machine type has two cores of Intel Xeon E5-2686 CPU (4 hardware threads) assigned and 16GB RAM. The Linux kernel version was 4.14.13. For storage, we used a 100GB EBS volume of type GP2 formatted with ext4 filesystem mounted with default options. GP2 is an SSD-backed storage and attached via a dedicated network to the VM.

Benchmark: Phoronix suite. For the performance measurement, we used the disk benchmarks [39] from the Phoronix suite [18]. Phoronix is a meta benchmark that has a wide range of common filesystem benchmarks, applications, and realistic workloads. We compiled the benchmarks with GCC 6.4 and CNTR with Rust 1.23.0.

Methodology. For the performance comparison, we ran the benchmark suite once on the native filesystem (the baseline measurement) and compared the performance when we access the same filesystem through CNTRFS. The Phoronix benchmark suite runs each benchmark at least three times and automatically adds additional trials if the variance is too high. To compute the relative overheads with respect to the baseline, we computed the ratio between the native filesystem access and CNTRFS (*native/cntr*) for benchmarks where higher values are better (e.g. throughput), and the inverse ratio

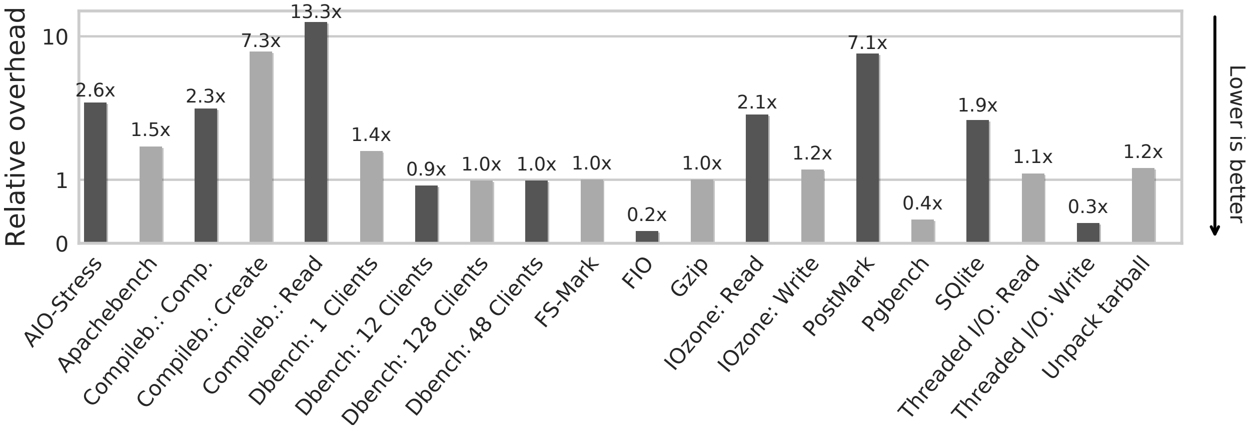


Figure 2: Relative performance overheads of CNTR for the `Phoronix` suite. The absolute values for each benchmark is available online on the openbenchmark platform [31].

(*cntr*/*native*), where lower values are better (e.g. time required to complete the benchmark).

5.2.1 Performance Overheads

We first present the summarized results for the entire benchmark suite. Thereafter, we present a detailed analysis of each benchmark individually (§5.2.2).

Summary of the results. Figure 2 shows the relative performance overheads for all benchmarks in the `Phoronix` test suite. We have made the absolute numbers available for each benchmark on the openbenchmark platform [31].

Our experiment shows that 13 out of 20 (65%) benchmarks incur moderate overheads below 1.5× compared to the native case. In particular, three benchmarks showed significantly higher overheads, including `compilebench-create` (7.3×) and `compilebench-read` (13.3×) and the `postmark` benchmark (7.1×). Lastly, we also had three benchmarks, where CNTRFS was faster than the native baseline execution: `FIO` (0.2×), `PostgreSQL Bench` (0.4×) and the write workload of `Threaded I/O` (0.3×).

To summarize, the results show the strengths and weaknesses of CNTRFS for different applications and under different workloads. At a high-level, we found that the performance of inode lookups and the double buffering in the page cache are the main performance bottlenecks in our design (much like they are for FUSE). Overall, the performance overhead of CNTR is reasonable. Importantly, note that while reporting performance numbers, we resort to the worst-case scenario for CNTR, where the "slim" application container aggressively uses the "fat" container to run an I/O-intensive benchmark suite. However, we must emphasize the primary goal of CNTR: to support auxiliary tools in uncommon operational use-cases, such as debugging or manual inspection, which are not dominated by high I/O-intensive workloads.

5.2.2 Detailed Experimental Results

We next detail the results for each benchmark.

AIO-Stress. `AIO-Stress` submits 2GB of asynchronous write requests. In theory, CNTRFS supports asynchronous requests, but only when the filesystem operates in the direct I/O mode. However, the direct I/O mode in CNTRFS restricts the `mmap` system call, which is required by executables. Therefore, all requests are, in fact, processed synchronously resulting in 2.6× slowdown.

Apache Web server. The `Apache Web server` benchmark issues 100K `http` requests for test files (average size of 3KB), where we noticed a slowdown of up to 1.5×. However, the bottleneck was not due to serving the actual content, but due to writing of the webserver access log, which triggers small writes (< 100 bytes) for each request. These small requests trigger lookups in CNTRFS of the extended attributes `security.capabilities`, since the kernel currently neither caches such attributes nor it provides an option for caching them.

Compilebench. `Compilebench` simulates different stages in the compilation process of the Linux kernel. There are three variants of the benchmark: (a) the `compile` stage compiles a kernel module, (b) the `read tree` stage reads a source tree recursively, and lastly, (c) the `initial creation` stage simulates a tarball unpack. In our experiments, `Compilebench` has the highest overhead of all benchmarks with the `read tree` stage being the slowest (13.4×). This is due to the fact that inode lookups in CNTRFS are slower compared to the native filesystem: for every lookup, we need one `open()` system call to get a file handle to the inode, followed by a `stat()` system call to check if we already have lookup-ed this inode in a different path due hardlinks. Usually, after the first lookup, this information can be cached in the kernel, but in this benchmark for every run, a different source tree with many files are read. The slowdown of

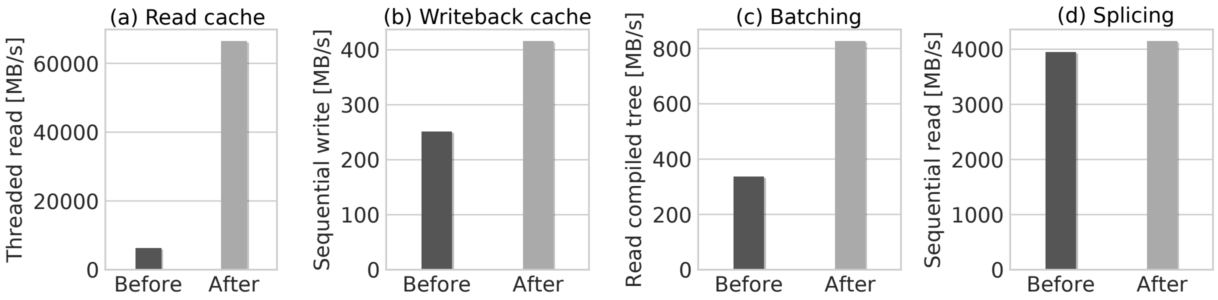

Figure 3: Effectiveness of optimizations

(a) `Threaded I/O` bench - Read (b) `IOZone` - Sequential write with 4GB (record size 4KB)
(c) `Compilebench` - Read (d) `IOZone` - Sequential read 4GB (record size 4KB)

lookups for the other two variants, namely the `compile stage` (2.3×) and `initial create` (7.3×) is lower, since they are shadowed by write operations.

Dbench. `Dbench` simulates a file server workload, and it also simulates clients reading files and directories with increasing concurrency. In this benchmark, we noticed that with increasing number of clients, CNTRFS is able to cache directories and file contents in the kernel. Therefore, CNTRFS does not incur performance overhead over the native baseline.

FS-Mark. `FS-Mark` sequentially creates 1000 1MB files. Since the write requests are reasonably large (16 KB per `write` call) and the workload is mostly disk bound. Therefore, there is no difference between CNTRFS and `ext4`.

FIO benchmark. The `FIO` benchmark profiles a fileserver and measures the read/write bandwidth, where it issues 80% random reads and 20% random writes for 4GB data with an average blocksize of 140KB. For this benchmark, CNTRFS outperforms the native filesystem by a factor of 4× since the writeback cache leads to fewer and larger writes to the disk compared to the underlying filesystem.

Gzip benchmark. The `Gzip` benchmark reads a 2GB file containing only zeros and writes the compressed version of it back to the disk. Even though the file is highly compressible, `gzip` compresses the file slower than the data access in CNTRFS or `ext4`. Therefore, there was no significant performance difference between CNTR and the native version.

IOZone benchmark. `IOZone` performs sequential writes followed by sequential reads of a blocksize of 4KB. For the write requests, as in the `apache` benchmark, CNTR incurs low overhead (1.2×) due to extended attribute lookup overheads. Whereas, for the sequential read request, both filesystems (underlying native filesystem and CNTRFS) can mostly serve the request from the page cache. For smaller read sizes (4GB) the read throughput is comparable for both CNTRFS and `ext4` filesystems because the data fits in the page cache. However, a larger workload (8GB) no longer fits into the page cache of CNTRFS and degrades the throughput significantly.

Postmark mailserver benchmark. `Postmark` simulates a mail server that randomly reads, appends, creates or deletes small files. In this benchmark, we observed higher overhead (7.1×) for CNTR. In this case, inode lookups in CNTRFS dominated over the actual I/O because the files were deleted even before they were sync-ed to the disk.

PGBench – PostgreSQL Database Server. `PGBench` is based on the `PostgreSQL` database server. It simulates both read and writes under normal database load. Like `FIO`, CNTRFS was faster in this benchmark also, since `PGBench` flushes the writeback buffer less often.

SQLite benchmark. The `SQlite` benchmark measures the time needed to insert 1000 rows in a SQL table. We observed a reasonable overhead (1.9×) for CNTR, since each insertion is followed by a filesystem `sync`, which means that we cannot make efficient use of our disk cache.

Threaded I/O benchmark. The `Threaded I/O` benchmark separately measures the throughput of multiple concurrent readers and writers to a 64MB file. We observed good performance for reads (1.1×) and even better performance for writes (0.3×). This is due to the fact that the reads can be mostly served from the page cache, and for the writes, our writeback buffer in the kernel holds the data longer than the underlying filesystem.

Linux Tarball workload. The `Linux tarball` workload unpacks the kernel source code tree from a compressed tarball. This workload is similar to the `create` stage of the `compilebench` benchmark. However, since the source is read from a single tarball instead of copying an already unpacked directory, there are fewer lookups performed in CNTRFS. Therefore, we incur relatively lower overhead (1.2×) even though many small files are created in the unpacking process.

5.2.3 Effectiveness of Optimizations

We next evaluate the effectiveness of the proposed optimizations in CNTR (as described in §3.3).

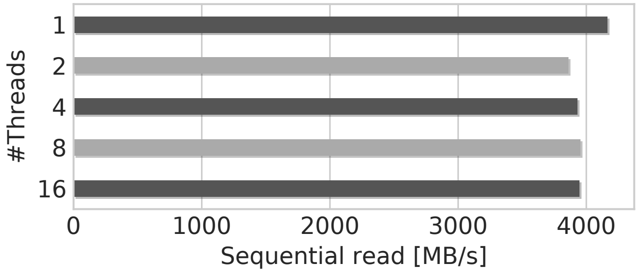

Figure 4: Multithreading optimization with IOZone: Sequential read 500MB/4KB record size with increasing number of CNTRFS threads.

Read cache. The goal of this optimization is to allow the kernel to cache pages across multiple processes. Figure 3 (a) shows the effectiveness of the proposed optimization for `FOPEN_KEEP_CACHE`: we observed 10× higher throughput with `FOPEN_KEEP_CACHE` for concurrent reads with 4 threads for the `Threaded I/O` benchmark.

Writeback cache. The writeback optimization was designed to reduce the amount of write requests by maintaining a kernel-based write cache. Figure 3 (b) shows the effectiveness of the optimization: CNTR can achieve 65% more write throughput with the writeback cache enabled compared to the native I/O performance for sequential writes for the `IOZone` benchmark.

Multithreading. We made CNTRFS multi-threaded to improve responsiveness when the filesystem operations block. While threads improve the responsiveness, their presence hurts throughput as measured in Figure 4 (up to 8% for sequential read in `IOZone`). However, we still require multithreading to cope with blocking filesystem operations.

Batching. To improve the directory and inode lookups, we batched requests to kernel by specifying the `PARALLEL_DIROPS` flag. We observed a speedup of 2.5× in the `compilebench` read benchmark with this optimization (Figure 3 (c)).

Splice read. Instead of copying memory into userspace, we move the file content with the `splice()` syscall in the kernel to achieve zero-copy I/O. Unfortunately, we did not notice any significant performance improvement with the splice read optimization. For instance, the sequential read throughput in `IOZone` improved slightly by just 5% as shown in Figure 3 (d).

5.3 Effectiveness of CNTR

To evaluate the effectiveness of CNTR's approach to reducing the image sizes, we used a tool called Docker Slim [11].

Docker Slim applies static and dynamic analyses to build a smaller-sized container image that only contains the files that are actually required by the application. Under the hood, Docker Slim records all files that have been accessed during a container run in an efficient way using the `fanotify` kernel module.

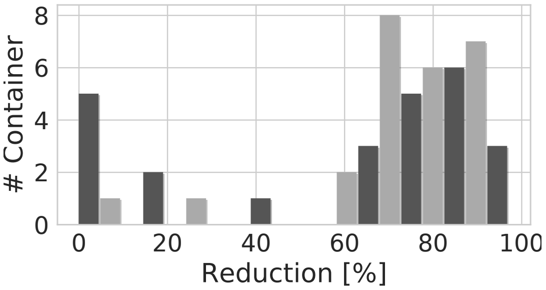

Figure 5: Reduction of container size after applying docker-slim on Top-50 Docker Hub images.

For our analysis, we extended Docker Slim to support container links, which are extensively used for service discovery and it is available as a fork [28].

Dataset: Docker Hub container images. For our analysis, we chose the Top-50 popular official container images hosted on Docker Hub [10]. These images are maintained by Docker and contain commonly used applications such as web servers, databases and web applications. For each image, Docker provides different variants of Linux distributions as the base image. We used the variant set to be `default` as specified by the developer.

Note that Docker Hub also hosts container images that are not meant to be used directly for deploying applications, but they are meant to be used as base images to build applications (such as language SDKs or Linux distributions). Since CNTR targets concrete containerized applications, we did not include such base images in our evaluation.

Methodology. For our analysis, we instrumented the Docker container with Docker Slim and manually ran the application so it would load all the required files. Thereafter, we build new smaller containers using Docker Slim. These new smaller images are equivalent to containers that developers could have created when having access to CNTR. We envision the developers will be using a combination of CNTR and tools such as Docker Slim to create smaller container images. Lastly, we tested to validate that the smaller containers still provide the same functionality.

Experimental results. On average, we could reduce the size by 66.6% for the Top-50 Docker images. Figure 5 depicts the histogram plot showcasing percentage of container size that could be removed in this process. For over 75% of all containers, the reduction in size was between 60% and 97%. Beside the applications, these containers are packaged with common used command line auxiliary tools, such as coreutils, shells, and package managers. For only 6 out of 50 (12%) containers, the reduction was below 10%. We inspected these 6 images and found out they contain only single executables written in Go and a few configuration files.

6 Related Work

In this section, we survey the related work in the space of lightweight virtualization.

Lambda functions. Since the introduction of AWS Lambda [1], all major cloud computing providers offer serverless computing, including Google Cloud Functions [15], Microsoft Azure Functions [5], IBM OpenWhisk [20]. Moreover, there exists a research implementation called Open Lambda [55]. In particular, serverless computing offers a small language runtime rather than the full-blown container image. Unfortunately, lambdas offer limited or no support for interactive debugging or profiling purposes [63] because the clients have no access to the lambda's container or container-management system. In contrast, the goal of the CNTR is to aim for lightweight containers, in the same spirit of lambda functions, but to also provide an on-demand mechanism for auxiliary tools for debugging, profiling, etc. As a future work, we plan to support auxiliary tools for lambda functions [43] using CNTR.

Microkernels. The microkernel architecture [54, 46, 56] shares a lot of commonalities with the CNTR architecture, where the applications/services are horizontally partitioned and the communication happens via the inter-process communication (IPC) mechanism. In CNTR, the application container obtains additional service by communicating with the "fat" container via IPC using CNTRFS.

Containers. Recently, there has been a lot of interest in reducing the size of containers, but still allowing access to the rich set of auxiliary tools. For instance, Toolbox [35] in CoreOS [7] allows to bind the mount of the host filesystem in a container to administrate or debug the host system with installing the tools inside the container. In contrast to Toolbox, CNTR allows bidirectional access with the debug container. Likewise, `nsenter` [27] allows entering into existing container namespaces, and spawning a process into a new set of namespaces. However, `nsenter` only covers namespaces, and it does not provide the rich set of filesystem APIs as provided by CNTR. Lastly, Slacker [53] proposed an opportunistic model to pull images from registries to reduce the startup times. In particular, Slacker can skip downloading files that are never requested by the filesystem. Interestingly, one could also use Slacker to add auxiliary tools such as gdb to the container in an "on-demand" fashion. However, Slacker could support additional auxiliary tools to a container, but these tools would be only downloaded to the container host, if the container is started by the user. Furthermore, Slacker also has a longer build time and greater storage requirements in the registry. In contrast, CNTR offers a generic lightweight model for the additional auxiliary tools.

Virtual machines. Virtual machines [25, 47, 51] provide stronger isolation compared to containers by running applications and the OS as a single unit. On the downside, full-fledged VMs are not scalable and resource-efficient [62]. To strike a balance between the advantages of containers and virtual machines, Intel Clear Containers (or Kata Containers) [21] and SCONE [45] offer stronger security properties for containers by leveraging Intel VT and Intel SGX, respectively. Likewise, LightVM [59] uses unikernel and optimized Xen to offer lightweight VMs. In a similar vein, CNTR allows creating lightweight containers, which are extensively used in the data center environment.

Unikernels and Library OSes. Unikernels [57, 58] leverage library OSes [61, 49, 65, 48] to selectively include only those OS components required to make an application work in a single address space. Unikernels use a fraction of the resources required compared to full, multipurpose operating systems. However, Unikernels also face a similar challenge as containers — If Unikernels need additional auxiliary tools, they must be statically linked in the final image as part of the library OS. Moreover, unikernel approach is orthogonal since it targets the kernel overhead, whereas CNTR targets the tools overhead.

7 Conclusion

We presented CNTR, a system for building and deploying lightweight OS containers. CNTR partitions existing containers into two parts: "slim" (application) and "fat" (additional tools). CNTR efficiently enables the application container to dynamically expand with additional tools in an on-demand fashion at runtime. Further, CNTR enables a set of new development workflows with containers:

- When testing the configuration changes, instead of rebuilding containers from scratch, the developers can use their favorite editor to edit files in place and reload the service.
- Debugging tools no longer have to be manually installed in the application container, but can be placed in separate debug images for debugging or profiling in production.

To the best of our knowledge, CNTR is the first generic and complete system that allows attaching to container and inheriting all its sandbox properties. We have used CNTR to debug existing container engines [32]. In our evaluation, we have extensively tested the completeness, performance, and effectiveness properties of CNTR. We plan to further extend our evaluation to include the nested container design.

Software availability. We have made CNTR along with the complete experimental setup publicly available [6].

Abstract

Increasingly sophisticated Rowhammer exploits allow an attacker that can execute code on a vulnerable system to escalate privileges and compromise browsers, clouds, and mobile systems. In all these attacks, the common assumption is that attackers first need to obtain code execution on the victim machine to be able to exploit Rowhammer either by having (unprivileged) code execution on the victim machine or by luring the victim to a website that employs a malicious JavaScript application. In this paper, we revisit this assumption and show that an attacker can trigger and exploit Rowhammer bit flips directly from a remote machine by *only* sending network packets. This is made possible by increasingly fast, RDMA-enabled networks, which are in wide use in clouds and data centers. To demonstrate the new threat, we show how a malicious client can exploit Rowhammer bit flips to gain code execution on a remote key-value server application. To counter this threat, we propose protecting unmodified applications with a new buffer allocator that is capable of fine-grained memory isolation in the DRAM address space. Using two real-world applications, we show that this defense is practical, self-contained, and can efficiently stop remote Rowhammer attacks by surgically isolating memory buffers that are exposed to untrusted network input.

1 Introduction

A string of recent papers demonstrated that the Rowhammer hardware vulnerability poses a growing threat to system security. From a potential security hole in 2014 [36], it grew into an attack vector to mount end-to-end exploits in browsers [15, 29, 52], cloud environments [47, 51, 60], and smartphones [24, 59]. Recent work even generated Rowhammer-like bit flips on flash storage [17, 38]. Even so, however advanced the attacks have become and however worrying for the research community, these attacks never progressed beyond local privilege escalations or sandbox escapes. The attacker needs the ability to run code on the victim machine in order to flip bits in sensitive data. Hence, Rowhammer posed little threat from attackers without code execution on the victim machines. In this paper, we show that this is no longer true and attackers can flip bits by only sending network packets to a victim machine connected to RDMA-enabled networks commonly used in clouds and data centers [1, 20, 45, 62].

Rowhammer exploits today Rowhammer allows attackers to flip a bit in one physical memory location by aggressively reading (or writing) other locations (i.e., *hammering*). As bit flips occur at the physical level, they are beyond the control of the operating system and may well cross security domains. A Rowhammer attack requires the ability to hammer memory sufficiently fast to trigger bit flips in the victim. Doing so is not always trivial as several levels of caches in the memory hierarchy often absorb most of the memory requests. To address this hurdle, attackers resort to accessing cache eviction buffers [12] or using direct memory access (DMA) [59] for hammering. But even with these techniques in place, triggering a bit flip still requires hundreds of thousands of memory accesses to specific DRAM locations within tens of milliseconds. As a result, the current assumption is that Rowhammer may only serve local privilege escalation, but not to launch attacks from over the network.

Remote Rowhammer attacks In this paper, we revisit this assumption. While it is true that millions of DRAM accesses per second is harder to accomplish from across the network than from code executing locally, today's networks are becoming very fast. Modern NICs are able to transfer large amounts of network traffic to remote memory. In our experimental setup, we observed bit flips when accessing memory 560,000 times in 64 ms, which translates to 9 million accesses per second. Even regular 10 Gbps Ethernet cards can easily send 9 million packets per second to a remote host that end up being stored on the host's memory. Might this be enough for an attacker to effect a Rowhammer attack from across the network? In the remainder of this paper, we demonstrate that this is the case and attackers can use these bit flips induced by network traffic to compromise a *remote server* application. To our knowledge, this is the first reported case of a Rowhammer attack over the network. Specifically, we managed to flip bits remotely using a commodity 10 Gbps network. We rely on the commonly-deployed RDMA technology in clouds and data centers for reading from remote DMA buffers quickly to cause Rowhammer corruptions outside these untrusted buffers. These corruptions allow us to compromise a remote memcached server without relying on any software bug.

Mitigating remote Rowhammer attacks It is unclear whether existing hardware mitigations can protect against these dangerous network attacks. For instance, while clouds and data centers may (and sometimes do) use ECC memory to guard against bit flips, researchers have, from the first paper on Rowhammer [36], warned that ECC may not be sufficient to protect against such attacks. Targeted Row Refresh, specifically designed to address Rowhammer is also shown not to be always effective [41, 59]. Unfortunately, existing software defenses are also unprepared to deal with network attacks: ANVIL [12] relies on performance counters that are not available for DMA, CATT [16] only protects the kernel from user-space attacks and VUsion [47] only protects the memory deduplication subsystem.

We make the observation that compared to local attackers, remote attackers can only target memory that is allocated for DMA buffers. Hence, instead of protecting the entire memory, we only need to make sure that these buffers cannot cause bit flips in the rest of the system. Specifically, we show that we can isolate the buffers for fast network communication using a new memory allocation strategy that places CATT-like guard zones around them. These guard zones absorb any attacker-generated bit flips, protecting the rest of the system. Properly implementing this allocation strategy is not trivial: the guard zones need to be placed in the DRAM address space to effectively absorb the bit flips. Unfortunately, the physical address space is *not* consecutively mapped to the DRAM address-space, unlike what is assumed in existing defenses [12, 16]. Memory controllers use complex functions to translate a physical address into a DRAM address. We therefore present a new allocator, called ALIS (ALlocations ISolated), which uses a novel approach to translate between physical address-space and DRAM address-space and safely allocates the DMA buffers and their guard zones. Since we need to protect only a limited number of DMA buffers, doing so is inexpensive as we show using microbenchmarks and two real-world applications.

Contributions We make the following contributions:

- We describe Throwhammer, the first Rowhammer profiling tool that scans a host over the network for bit flips. We evaluate Throwhammer using different configurations (i.e., different link speeds and DIMMs). We then show how an attacker can use these bit flips to exploit a remote memcached server.

- We design and implement ALIS, a new allocator for safe allocation of network buffers. We show that ALIS correctly finds guard rows at the DRAM address space level, provided an address mapping that satisfies certain prerequisites. Furthermore, we show that ALIS is compatible with existing software. We further evaluate ALIS using microbenchmarks and real-world applications to show that it incurs negligible performance and memory overhead.

- We release Throwhammer and ALIS as open-source software in the URL that follows.

  `https://vusec.net/projects/throwhammer`

  Concerned parties can use Throwhammer to check for remote bit flips and ALIS for protecting their applications against remote Rowhammer attacks.

2 Background

With software becoming increasingly more difficult due to a variety of defenses deployed in practice [11, 25, 30, 39, 55, 57], security researchers have started exploring new directions for exploitation. For example, CPU caches can be abused to leak information [19, 26, 37, 42, 48, 61] or wide-spread reliability issues in hardware [18, 36] can be abused to compromise software [29, 52, 59]. These attacks require code execution on the victim machine. In this paper, we show for the first time that this requirement is not strictly necessary, and it is possible to trigger reliability issues in DRAM by merely sending network packets. We provide necessary background on DRAM and its unreliabilities and high-speed networks that expose them remotely.

2.1 Unreliable DRAM

DRAM Organization The basic unit of storage in DRAM is cell made out of a capacitor used to hold the value of a single bit of information. Since capacitors leak charge over time, the memory controller should frequently (typically every 64 ms) recharge them in order to maintain the stored values, a process known as *refreshing*. DRAM cells are ganged together to form what is known as a *row* (typically 1024 cells or *columns* wide).

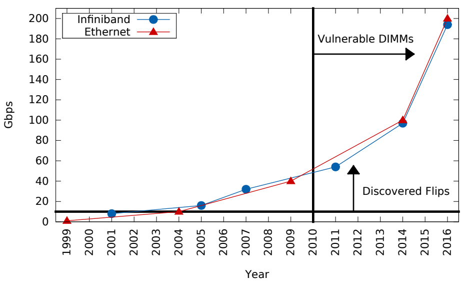

Figure 1: Trends in network performance and Rowhammer.

Whenever a row is accessed the contents of that particular row are put on a special buffer, called *row buffer*, and the row is said to be activated. Once access is finished, the activated row is written (i.e., recharged) with the contents of the row buffer. Multiple rows along with a row buffer are stacked together to form a *bank*. There are multiple banks on a DRAM integrated circuit (IC). Multiple DRAM ICs are laid out to for a DRAM *rank*. The DRAM chips are accessed in parallel when reading a memory word. For example, with a DIMM that has 8 bit wide ICs, eight ICs are accessed in parallel to form a 64 bit memory word.

DRAM addressing Addressing a memory word within a DRAM rank is done by the system memory controller using three addresses: bank, row and column. Further parallelism can be added by having two ranks on a single memory module (DIMM), adding multiple DIMMs on the same memory bus (also known as *channel*), and providing multiple independent memory channels. Hence, to address a specific word of memory, the memory controller uses a <channel, DIMM, rank, bank, row, column> hextuple. This hextuple, which we call a *DRAM address* is constructed from the physical memory address bits using formulas which are either documented [10] or have been (partially) reverse engineered [49]. An important take-away here is that contiguous physical address space is not necessarily contiguous in the DRAM address space where Rowhammer bit flips happen. This information is important when developing our defense discussed in §6.

Rowhammer As DRAM chips become denser, the charge used for each capacitor to denote the two bit states is reduced. A reduced charge level increases the possibility of errors. Kim et al. [36] show that intentionally activating a row many times in a short duration (i.e., Rowhammering) can cause the charge in the capacitors to leak in close-by rows. If this happens fast enough, before the memory controller can refresh the adjacent rows, this charge leakage passes a certain threshold and as a result bits in these adjacent, or *victim*, rows will flip. To exploit these flips, the attackers need to first find bit flips in interesting offsets within a memory page and then force the system to store sensitive information on that memory page. For instance, the first known exploit by Seaborn [52] finds a memory page with a bit flip that can affect page table entries. It then frees that memory page and sprays the system with page table pages. The hope is that the page that is now freed is used by a page table page and the bit flip causes the page table entry to point to another page table page, effectively giving the attacker control over all of physical memory. Similarly, Rowhammer.js [29], Drammer [59] and Xiao et al. [60] target page table pages but focus on browser, mobile and cloud environments respectively. Other attacks target cryptographic keys [51] or JavaScript objects [15, 24].

2.2 Fast Networks

Figure 1 shows the evolution of network performance over time. Since 2010, the trend follows an exponential increase in the amount of available network bandwidth. This is putting a lot of pressure on other components of the system, namely the CPU and the memory subsystem, and has forced systems engineers to rethink their software stack in order to make use of all this bandwidth [22, 23, 33, 34, 43, 44].

Figure 1 also shows that DIMMs with the Rowhammer vulnerability have been produced since 2010 and their production continues to date [40, 59]. As we will show in §4, we observed bit flips with capacities available in 10 Gbps or faster networks, suggesting that already back in 2010, Rowhammer was exploitable over the network.

While faster than 10 Gbps networks are very common in data centers on bare metal [45, 53, 62], even today's clouds offer high-speed networking. Amazon EC2 provides VMs with 20 Gbps connectivity [2] and Microsoft Azure provides VMs with 56 Gbps [1]. As we will soon show 10 Gbps networks already make remote bit flips a dangerous threat to regular users today.

Remote DMA To achieve high-performance networking, some systems entirely remove the interruptions and expensive privilege switching from the fast path and deliver network packets directly to the applications [13, 31, 50]. Such approaches often resort to polling in order to guarantee high-performance, wasting CPU cycles that are becoming more precious as Moore's law stagnates and the available network bandwidth per core increases.

To reduce the load on the CPU, some networking equipment include the possibility for Remote Direct Memory Access (RDMA). Figure 2 compares what happens when a client application sends a packet in a normal network compared to one with RDMA support. Without RDMA, the client machine's CPU first needs to copy the packet's content (e.g., an HTTP request) from an application buffer to a DMA buffer. The client machine's oper-

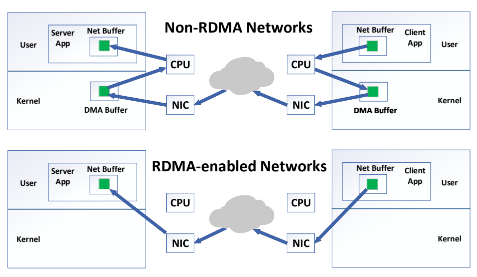

Figure 2: RDMA allows zero-copy network communication.

ating system then signals the NIC that the packet is ready for network transfer. The NIC then reads the packet using DMA and sends it over the wire. On the server side, the server's NIC receives the packet from the wire and copies it to a DMA buffer that is pre-configured to the NIC. It then signals the server's CPU that a packet has arrived. The CPU then copies the packet's content to the server application's buffer.

With RDMA, there is no need to involve the CPU on both client and server for packet transfer. The server and client applications both configure DMA buffers to the NIC through interfaces that are provided by the operating system. When the client application wants to send a packet to a server application, it directly writes it to its buffer. It then signals its NIC that the packet is ready for transfer. The NIC then sends the packet over the wire. On the server side, the NIC receives the packet and directly writes it to the buffer that has previously been configured by the server application. The server application can then be notified that a new packet has arrived or it can poll its own buffer. RDMA can boost existing protocols such as NFS [46] and new applications can use its functionalities to achieve better performance. Examples include databases [43], distributed hash tables and in-memory key-value stores [22, 23, 33, 34, 44].

RDMA's prevalence Data centers and cloud providers such as Google [45] and Microsoft [1, 62, 20] use RDMA to improve the performance of their clusters. Microsoft very recently announced RDMA support for SMB file sharing in the workstation edition of Windows [5], suggesting RDMA-enabled networks are spreading into the workstation market. Cloud providers are already selling virtual machines with RDMA support. For example, Microsoft Azure [3] and ProfitBricks [8] provide offerings with high-speed RDMA networks.

3 Threat Model

We consider attackers that generate and send legitimate traffic through a high-speed network to a target server. A common example is a client that sends requests to a cloud or data center machine that runs a server application. We assume that the target machine is vulnerable to Rowhammer bit flips [51, 60]. We further assume that the target system benefits from IOMMU protection. With IOMMU, the server's NIC is not allowed to write to memory pages that are not part of the pre-configured DMA areas by the server application. The end goal of the attacker is to bypass RDMA's security model by modifying bits outside of memory areas that are registered for DMA in order to compromise the system.

4 Bit Flipping with Network Packets

To investigate the possibility of triggering bit flips over the network, we built the first Rowhammer test tool that scans for bit flips by repeatedly sending or receiving packets to/from a remote machine, called Throwhammer. Throwhammer is implemented using 1831 lines of C code and runs entirely in user-space without requiring any special privileges. We will make this tool available so that interested parties can check for remote bit flips.

4.1 Throwhammer's Implementation

Throwhammer makes use of RDMA capabilities for transferring packets efficiently. Throwhammer has two components: a server and a client process running on two nodes connected via an RDMA network. On the server side, we allocate a large virtually-contiguous buffer and configure it as a DMA buffer to the NIC. We set all bits to one when checking for one-to-zero bit flips and do the reverse when checking for zero-to-one bit flips.

On the client side, we repeatedly ask the server's NIC to send us packets with data from various offsets within this buffer. Given the remote nature of our attack, we cannot make any assumption on the physical addresses that map our target DMA buffers and cannot rely on side channels for inferring this information [28]. Fortunately, on the server side, the Linux kernel automatically turns the memory backing our RDMA buffer into huge pages with its `khugepaged` daemon. This allows us to perform double-sided Rowhammer similar to Rowhammer.js [29] and Flip Feng Shui [51]. Periodically, we check the entire buffer at the server for bit flips.

To make the best possible use of the network capacity, we spawn multiple threads in Throwhammer. At each round, two *aggressor* addresses are chosen and all the threads send/receive packets that read from these two addresses for a pre-defined number of times. We make no effort in synchronization between these threads, so multiple network packets may hit the row buffer. While we leave potential optimizations for selecting aggressor addresses more carefully and better synchronization to fu-

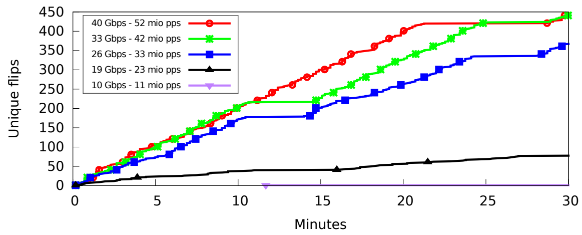

Figure 4: Number of unique Rowhammer bit flips on Hynix DIMMs over time using different network configurations.

ture work, we show that Throwhammer already can trigger bit flips in 10 Gbps networks and above.

4.2 Results

Testbed We use two machines each with 8-core Haswell i7-4790 processors connected using Mellanox ConnectX-4 single port NICs as our evaluation testbed. Note that these cards are already old: at the time of this paper's submission, two newer generations of these cards (ConnectX-5 and ConnectX-6) are available, but we show that it is already possible to trigger bit flips with our older generation cards. We experiment with different DIMMs and varying network performance.

DIMMs We chose two pairs of DDR3 DIMMs configured in dual-channel mode, one from Hynix and one from Corsair. These DIMMs already show bit flips when we run the open source Rowhammer test [6]. We configured our NICs in 40 Gbps mode and ran Throwhammer for 30 minutes. Figure 3 shows the number of unique bit flips as a function of time over these two sets of DIMMs on the server *triggered by transmitting packets*. We could flip 464 unique bits on the Hynix DIMMs and 185 unique bits on the Corsair DIMMs in 30 minutes. While these bit flips are already enough for exploitation, we believe that it is possible to trigger many more bit flips with a more optimized version of Throwhammer.

Network performance To understand how the network performance affects bit flips, we used the Hynix modules. We first configured our NICs in 10 Gbps Ethernet which can be saturated with 2 threads. We then configured our NICs in 40 Gbps Ethernet which can be saturated with 10 threads. The number of bit flips depends on the number of packets that we can send over the network (i.e., how many times we force a row to open) rather than the available bandwidth. For example, to trigger a bit flip that happens by reading 300,000 times from each aggressor address in the refresh window of 64 ms locally, in perfect conditions (e.g., proper synchronization) we need to be able to transmit $\frac{1000}{64} \times 300,000 \times 2 = 9.375$ million packets per second (pps). Unfortunately our NICs do not provide an option to reduce the bandwidth (or pps for that matter) in between 40 Gbps and 10 Gbps. We can however use fewer threads to emulate what the number of bit flips in networks that provide a bandwidth between 10 Gbps and 40 Gbps (e.g., Amazon EC2 [2]). We measure the pps for each configuration and use it to extrapolate the network bandwidth. Figure 4 shows the number of unique bit flips in different configurations as a function of time. With 10 Gbps, we managed to trigger one bit flip after 700.7 seconds, showing that commodity networks found in companies or university LANs are fast enough for triggering bit flips by transmitting network packets. Starting with faster networks than 10 Gbps, Throwhammer can trigger many more bit flips during the 30 minutes window. Again, we believe a more optimized version of Throwhammer can potentially generate more bit flips, especially on 10 Gbps networks.

5 Exploiting Bit Flips over the Network

We now discuss how one can exploit remote bit flips caused by accessing RDMA buffers quickly. The exploitation is similar to local Rowhammer exploits: the attacker needs to force the system to store sensitive data in vulnerable memory locations before triggering Rowhammer to corrupt the data in order to compromise the system. We exemplify this by building an end-to-end exploit against RDMA-memcached, a key-value store with RDMA support [32].

5.1 Memcached architecture

Memcached stores key/value pairs as *items* within memory *slabs* of various sizes. By default, the smallest slab class size is 96 bytes, with the largest being 1 MB. Memory allocated is broken up into 1 MB sized chunks and then assigned into slab classes as necessary. For rapid retrieval of keys, memcached uses a hash table, with colliding items chained in a singly-linked list.

The main data structure used for storing key/value *items* is called `struct _stritem`, as shown in Figure 5a. The first 50 bytes are used to store item metadata, while the remaining space is used to store the key and the value. Items are chained together into two lists. A

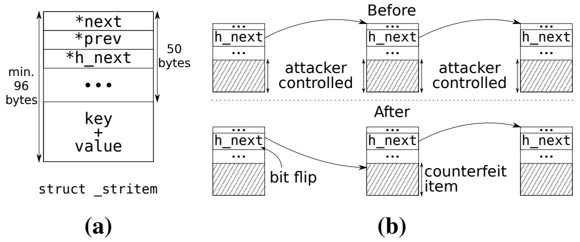

Figure 5: Memcached Exploit.

first doubly linked list (LRU, identified by the next and prev pointers) is updated during GET hits by relinking recent items at the head, and is traversed when freeing unused items. A second singly linked list (hash chain, identified by the h_next pointer) is traversed when looking up keys with colliding hashes. Another notable field is nbytes, the length of the value. *Slabs* come in fixed number of classes decided at compile-time with their metadata stored in a global data structure named slabclass. Crucially for our purposes, this data structure contains slots, a pointer to (a list of) "free" items which are used for subsequent SET operations.

5.2 Exploiting memcached

The attack progresses in four steps. In the first step, we search for bit flips using GET requests. Once we find an exploitable bit flip, we perform memory massaging [51] to land a target struct _stritem on the memory location with a bit flip. In the third step, we corrupt the hash chain to make a h_next value point to a counterfeit item that we encode inside a valid item. Our counterfeit item provides us with limited read and write primitives, using program logic triggered by GET requests. Finally, we target our limited write primitive towards the slabclass data structure, escalating it to arbitrary write and code execution. We describe each of the steps in more detail next.

Finding exploitable bit flips We spray the entire available memory with 1 MB sized key-value items with values made out of binary value one (when looking for 1 to 0 bit flips). Filling up all the available memory makes sure that some key-value items eventually border on the initial 16 MB RDMA buffers. Our experiments show that this is always the case. The attacker now remotely hammers the initial 16 MB RDMA buffers to trigger bit flips in the pages that belong to the adjacent rows where some of the 1 MB items are now stored. After that, the attacker reads back the items with GET requests to find out which bit offsets have been corrupted. We now discuss which offsets are exploitable.

Our target is corrupting the hash chain (i.e., the h_next pointer of a struct _stritem). As shown in Figure 5b, this allows us to pivot the h_next pointer to a counterfeit item that we encode inside a legitimate item — similar to Dedup Est Machina [15] and GLitch [24]. Assuming we can reuse a 1 MB item for smaller items, we have to see which size class we should pick for our target items so that one of the items' h_next pointer lands on a memory location with a bit flip. We do this analysis for every bit flip to see whether we can find a suitable size class for exploitation.

There are two challenges that we need to overcome for this strategy to work: first, we need to be able to chain many items together and second, we need to force memcached to reuse memory backing the 1 MB item with an exploitable bit flip for smaller items of the right size for corrupting their h_next pointer. We discuss how we overcome these challenges next.

Memory massaging We first need to craft memcached items with different keys which hash to the same value. Items with colliding keys make sure that the h_next pointer always points to an item that we control. Memcached uses the 32 bit Murmur3 hash function on the key to find the slot in a hashtable. This hash function is not cryptographically secure and we could easily generate millions of colliding 8 byte keys.

The simplest way to address the second challenge, is to issue a DELETE request on the target 1 MB item. We previously calculated the exact size class that would allow us to land an h_next pointer on a location with a bit flip. We can reassign the memory used by the deleted 1 MB item to the slab cache of the target item's size class using the slabs reassign command from the memcached client. Even without slabs reassign, we can easily trigger the reuse by just creating many items of the target size. The LRU juggler component in the memcached watches for free chunks in a slab class and reassigns any free ones to the global page pool.

While it is possible to deterministically reuse 1 MB items after an exploitable bit flip in a complete implementation of RDMA-memcached, the current version of RDMA-memcached does not support DELETE or slabs reassign. In these cases, we can simply spray the memory with items with a size that maximizes the of probability of corrupting the h_next pointer. We later report on the success rate of both attacks.

Corrupting the target item Once we land our target item on the desired location in memory, we re-trigger the bit flip by transmitting packets from the RDMA buffers. This causes the corruption of the target item's h_next pointer. With the right corruption, the pointer will now point inside another item whose key/value contents we control. By carefully crafting a counterfeit header inside the value area, we gain either a limited read or write capability. Issuing a GET request on our counterfeit item will now retrieve nbytes contiguous bytes from memcached's address space, provided the memory is mapped. Attempting to read unmapped memory is handled gracefully with an error being returned to the client, preventing unwanted crashes. If our counterfeit item is not LRU-linked (i.e., `next=prev=NULL`), the `GET` handler returns without any additional side-effects. A linked item, however, will trigger a relink operation on the next `GET`. By controlling the `next (n)` and `prev (p)` pointers and taking advantage of the unlink step, we gain a limited write primitive, where `*p=n` and `*(n+8)=p`, if `p` and `n` are respectively non-NULL.

Escalation The RDMA-memcached binary is not compiled as a Position Independent Executable (PIE); hence, we know the starting address of the `.data` and `.got` sections. Using this information, we point our write primitive at the `slabclass` data structure, aiming to overwrite the `slots` pointer of a particular class. We set up our counterfeit item with `next=&(slabclass[i].slots)-8`, where `i` is the slab class corresponding to our intended payload's size, and with `prev` to the target address of our choosing. The first `GET` operation on our counterfeit item will trigger the unlinking procedure which overwrites the `slots` pointer with `prev`, with the side effect of writing `next` to `*prev`. The next `SET` on our chosen class will store the new item in memory at the target address. Since we control the key and value of this new item, this gives us an arbitrary write primitive. We can further use our arbitrary write to corrupt the GOT to redirect the control flow and achieve code execution.

Results For the deterministic attack, we can successfully exploit 1.17% of 0 to 1 and 1.15% of 1 to 0 all possible bit flips. On the Hynix DIMMs, it takes us 5.1 minutes to find an exploitable bit flip and on the Corsair DIMMs it takes us 19.2 minutes to find an exploitable bit flip. With the non-deterministic attack, the best size class for spraying is items of size 384 bytes with 0.2% of the 0 to 1 bit flips resulting in a successful exploitation and 0.5% of them resulting in a crash. The results are similar with 1 to 0 bit flips.

6 Isolated Memory Allocation with ALIS

We now present an effective technique for defending against remote Rowhammer attacks using DRAM-aware allocation of network buffers. We first briefly discuss the main intuition behind our allocator, ALIS, before describing the associated challenges. We then show how ALIS overcomes these challenges for arbitrary physical-to-DRAM address mappings.

6.1 Challenges of Finding Adjacent Rows

The main idea behind ALIS is simple: given that Rowhammer bit flips happen in victim rows adjacent to aggressor rows, we need to make sure that all accessible rows in an isolated buffer are separated from the rest of system memory by at least one *guard row* used to absorb said bit flips. The implementation of this idea, however, is not simple because finding all possible victim rows along with their neighbors is not straightforward.

Given that bit flips happen on the DRAM ICs, ALIS should isolate rows in the DRAM address space. Recall from §2.1 that the DRAM address space is defined using the <channel, DIMM, rank, bank, row, column> hextuple. We use the term *row* to refer to memory locations addressed by <channel, DIMM, rank, bank, row, *>, where channel, DIMM, rank, bank and row are all fixed values. Given a singular row R at DRAM address <C, D, Ra, B, R, *> to be isolated, our aim is to allocate all DRAM addresses <C, D, Ra, B, R - 1, *> and <C, D, Ra, B, R + 1, *> (i.e., rows R - 1 and R + 1) as guard.

A common assumption made by both Rowhammer attacks [12, 15, 29, 51, 59] and defenses [12, 16] is that rows sharing the same row address (i.e., <*, *, *, *, row, *> memory locations) are contiguously mapped in physical memory. That is to say, while accessing physical memory addresses in an ascending order, the memory controller would activate the same numbered row across all its available banks, ranks, DIMMs and channels before moving on to the next. This assumption, however, does not hold for most real-world settings, since memory controllers have considerable freedom in translating physical addresses to DRAM addresses. One such example is presented in Figure 6a, which shows physical-to-DRAM address translation on an AMD CPU with 4 GB of single-rank memory [10]. Another example is shown in Figure 6b, with a non-linear physical address space to DRAM address space translation on an Intel Haswell CPU with dual-channel, dual-ranked memory with rank-mirroring [54]. As a result, existing attacks can become much more effective in finding bit flips if they take the translation between physical and DRAM address spaces into account. Similarly, current defenses only protect against bit flips caused by existing attacks that do not take this translation into account.

A correct solution must therefore be conservative in its assumptions about physical to DRAM address translation. In particular, we cannot assume that the contents of a DRAM row will be mapped to a contiguous area of physical memory. Similarly, we cannot assume that a physical page frame will be mapped to a single DRAM row. As an example of the latter, Figure 6c shows the physical to DRAM address space translation on an AMD CPU with channel-interleaving enabled by default [10].

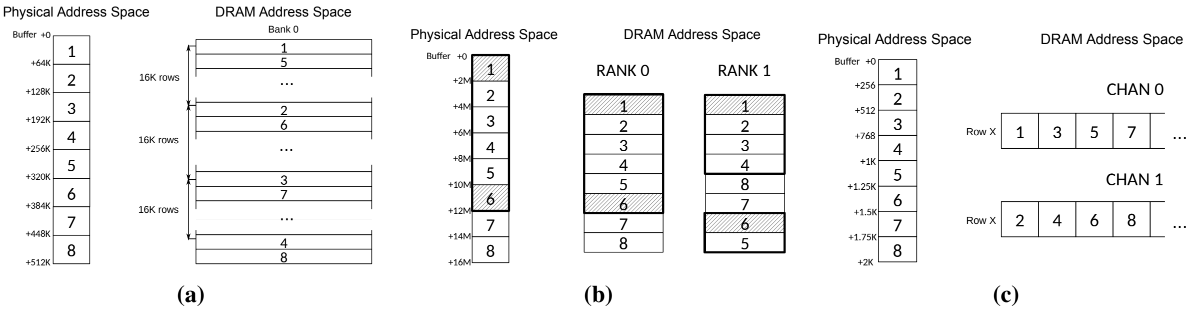

Figure 6: Examples of nonlinear DRAM address mappings taken from real systems [10, 49, 54].

6.2 Design

We now discuss how ALIS addresses these challenges. We define the *row group* of a page to be the set of rows that page maps onto. Similarly, the *page group* of a row is the set of pages with portions mapped to that row. In addition, in the context of a user-space process, we say a page is allocated if it is mapped by the system's MMU into its virtual address space. Likewise, we say a row is *full* if all pages in its page group are allocated, and *partial* if only a strict subset of these are allocated. If no page is allocated we call a row *empty*.

ALIS requires a physical to DRAM address mapping that satisfies the following condition: any two pages of an arbitrary row's page group have identical row groups themselves. If this condition holds, we can prove the following two properties:

(1) Enumeration property: To list all rows accessible by owning pages in a page group, it is sufficient to list any such page's row group.

(2) Fullness property: Rows that share page groups have the same allocation status — a row is full, partial or empty if and only if all rows in its pages' row group are respectively full, partial or empty.

For the interested reader we present a formal description of these properties, along with sufficiency criteria and proof that they hold for common architectures in [7].

Assuming a mapping where these properties hold, we now discuss how ALIS allocates isolated RDMA buffers.

6.3 Allocation Algorithm

Preparatory Steps. Initially, ALIS reserves a buffer and *locks* it in memory, so that any virtual memory mappings are not changed through the course of allocation or usage. Subsequently, ALIS translates the physical pages that back the reserved buffer into to their respective DRAM addresses. Translating from physical addresses to DRAM addresses is performed using mapping functions either available through manufacturer documentation [10] or previously reverse-engineered [49]. At the end of this step, we have a complete view of the allocated buffer in DRAM address space.

Pass 1: Marking. ALIS iterates through the rows of the buffer in DRAM address order and marks all (allocated) pages of a row as follows: Partially allocated rows have their pages marked as UNSAFE. Completely allocated (i.e. full) rows preceded or followed by a partially allocated or empty row are marked EDGE. Due to the fullness property we can be certain that any partial row groups have their pages marked UNSAFE at the first occurrence of one of its members in the enumeration. We can therefore be certain that a row, once concluded safe, will not be marked otherwise later. In addition, the enumeration property guarantees that if an edge row is found later in the pass, such as block 4 in Figure 6b, previous rows containing the same pages will be correctly "backmarked" as EDGE.

Pass 2: Gathering. ALIS now makes a second pass over the DRAM rows, searching for contiguous *row blocks* of unmarked pages, bordered on each side by rows with marked EDGE. We add each of these row blocks to a list while marking all their pages as USED. At the end of this step we have a complete list of all *guardable* memory areas immediately available for allocation. Note these row blocks are isolated from each other and all other system memory by a padding of at least one guard row.

Pass 3: Pruning. In this final cleanup pass, ALIS iterates through allocated pages, unmapping and returning to the OS pages that aren't marked as USED, freeing up any non-essential memory locked by the previous steps.

Reservation and Mapping. ALIS can now use the data structure obtained in the previous steps to allocate isolated buffers using one or more row blocks. Applications can map the (physical) pages in these buffers into the virtual address space at desired locations to satisfy the allocation request.

6.4 Implementation

We have implemented ALIS on top of Linux as a user-space library using 2518 lines of C code. ALIS reserves memory by mapping a file descriptor associated with anonymous shared memory (i.e., a `memfd` on Linux). ALIS uses the `/proc/self/pagemap` interface [35], to translate the buffer's virtual addresses to physical addresses. Finally, ALIS maps particular page frames into the process' virtual address space using the `mmap` system call by providing specific offsets into the `memfd` to specific virtual addresses using the `MAP_FIXED` flag. These mechanisms allow ALIS to seamlessly replace memory allocation routines used by applications with an isolated version. ALIS supports translation between the physical address space to the DRAM address space for the memory controller of all major CPU architectures.

7 Protecting Applications with ALIS

In this section, we show how we used ALIS to protect two popular applications that provide distributed key-value services, namely memcached [32] and HERD [34] against remote Rowhammer attacks. One key observation is that there are a few different ways to allocate space for the RDMA buffer. Since we are interested in isolating the memory used as the RDMA buffer for containing RDMA bit flips, it is crucial to understand the way each application manages memory for its RDMA buffers. Our allocator is capable of handling common cases such as when the memory is allocated with `mmap` or `posix_memalign` while it can be extended to support additional constructs. We now discuss the specifics of the applications which we tried with our custom allocator. We evaluate the performance of both systems when deployed using our custom allocator in §8.2.

7.1 Memcached

Many large-scale Internet services use DRAM-based key-value caches like memcached. Usually, memcached serves as a cache in front of a back-end database. Memcached with RDMA support [32] provides lower latency and higher throughput compared to the original memcached. This is done by introducing traditional RDMA-enabled set and get APIs. Given that memcached is a popular application, exploitable bit flips caused over the network as we discussed in §5 can affect many users.

RDMA-memcached is not open-source. We hence reverse engineered its binary to discover that it uses `posix_memalign` for allocating the RDMA buffers. Total size of these RDMA-buffers is approximately 5 MB. Unfortunately, instead of using the standard libc-provided `posix_memalign`, memcached-rdma uses its own statically-linked implementation. We hence needed to perform a simple binary instrumentation to instead jump to our implementation of `posix_memalign` which allocates isolated buffers.

7.2 HERD

HERD [34] is a key-value store that leverages RDMA to deliver low latency and high throughput. Unlike similar systems, HERD has been designed with RDMA in mind. The system offers clean RDMA primitives, and heavily relies on RDMA to reduce round-trip times, reduce latency, and maximize throughput. As a case-study, HERD is ideal, since simply turning RDMA off is not an option; the system is primarily designed around the concept of RDMA. Thus, if anyone needs to take advantage of the performance of HERD, they additionally need to secure its RDMA buffer, otherwise its users run the security risks of remote Rowhammer attacks.

HERD's initializer process uses `shmget` to allocate the RDMA buffer and share it with its worker process. While we could extend ALIS to support `shmget`, instead we opted to declare a global variable in HERD's initializer process to store allocated the RDMA buffer address and pass it to the worker process. This required modifying 10 lines of code in HERD.

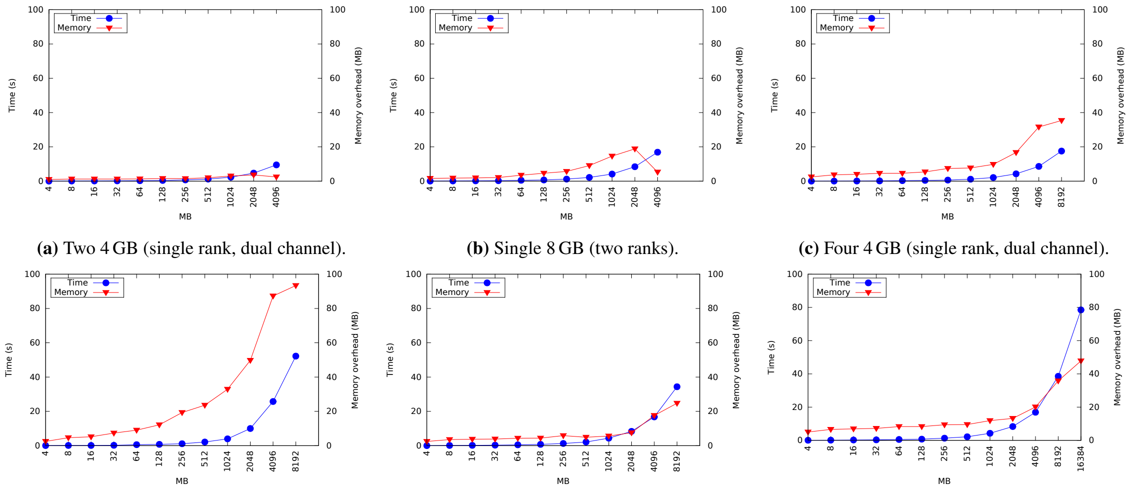
8 Evaluation

We use the same testbed that we used in §4 for our evaluation. Firstly we made sure ALIS was indeed protecting our system from bit flips. We modified Throwhammer's client to allocate isolated RDMA buffers using ALIS. Hammering remotely for extended periods of time with different strategies did not generate any bit flips outside the RDMA buffers unlike previously, thus enforcing the RDMA security model (§3).

We now evaluate in detail the memory overhead and performance impact of protecting applications.

8.1 Allocation Overhead

To calculate the overhead of ALIS, we wrote a simple test program that allocates an isolated buffer of a given size and reports how long it took for the allocation to succeed. Note that in most cases, we only pay this (modest) overhead once at application initialization time. Given that ALIS pools these allocations, in cases where an application re-allocates these buffers (e.g., [9, 46]), the subsequent allocations of the same size will be fast. We also collected statistics from our allocator on the number of extra pages that we had to allocate for guard rows.



(a) Two 4 GB (single rank, dual channel). **(b)** Single 8 GB (two ranks). **(c)** Four 4 GB (single rank, dual channel).

(d) Two 8 GB (two ranks, single channel). **(e)** Two 8 GB (two ranks, dual channel). **(f)** Four 8 GB (two ranks, dual channel).

Figure 7: The allocation time and memory overhead of isolating RDMA buffers of various sizes in different configurations.

Configurations We experimented with all possible configurations including multiple DRAM modules, channels, and ranks. We assume that up to half of the memory can be used for RDMA buffers, but nothing stops us from increasing this limit (e.g., 80%). We run each measurement 5 times and report the mean value.

Figure 7 shows two general expected trends in all configurations: 1. the allocation time increases as we request a larger allocation due to the required extra computation, 2. the amount of extra memory that our allocator needs for guard rows increases only modestly as we allocate larger safe buffers. In fact, the relative overhead becomes much smaller as we allocate larger buffers.

We also make a number of other observations:

1. The size of installed memory does not affect the allocation performance (Figure 7a vs. Figure 7c),
2. Increasing the number of ranks and channels increases the allocation time.
3. The number of ranks increases the allocation time more than the number of channels (Figure 7a vs. Figure 7b and Figure 7c vs. Figure 7d). Given that column address bits slice the DRAM address space into finer chunks than the channel bits, our allocator requires more computation to find safe memory pages when rank mirroring is active.

In general, allocating larger buffers slightly increases the amount of memory required for isolating the buffers given that our allocator stitches multiple safe *blocks* together to satisfy the requested size. Interestingly, as we allocate more memory, the allocator requires fewer areas and in some cases, this reduces the amount of memory required for guard rows (Figure 7a and Figure 7b).

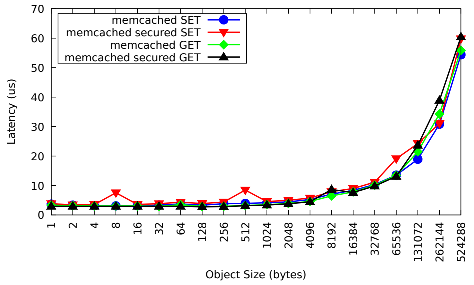


Figure 8: Secured memcached performance.

8.2 RDMA Performance

We now report on the performance implications of using ALIS on RDMA-memcached and HERD (§7). We use the same testbed that we used in our remote bit flip study (§4) and use the benchmarks provided by the applications. The benchmark included in RDMA-memcached measures the latency of SET and GET requests with varying value sizes. Figure 8 shows that our custom allocator only introduces negligible performance overhead in memcached-rdma. This is expected because ALIS only introduces a small overhead during initialization.

The benchmark included with HERD reports the throughput of HERD in terms of number of requests per second. Our measurements show that isolating RDMA buffers in HERD reduces the performance by 0.4% which is negligible. The original HERD paper [34] achieves the throughput of 26 million requests per second by using multiple client machines and a server machine with two processors. The authors of HERD verified that our throughput baseline is expected with our testbed. Hence, we conclude that ALIS does not incur any runtime overhead while isolating RDMA buffers.

9 Related work

Attacks Rowhammer was initially conceived in 2014 when researchers experimentally demonstrated flipping bits in DDR3 for x86 processors by just accessing other parts of memory [36]. Since then, researchers have proposed increasingly sophisticated Rowhammer exploitation techniques, on browsers [52, 15, 29], clouds [14, 51, 60], and ARM-based mobile platforms [59]. There have also been reports of bit flips on DDR4 modules [41, 59]. Finally, recent attacks have focused on bypassing state-of-the-art Rowhammer defenses [27, 56].

In all of these instances, the attacker needs to find a way to trigger the right bit flips that can alter critical data (page tables, cryptographic keys, etc.) and thus affect the security of the system. All these cases assume that the attacker has local code execution. In this paper, we showed how an adversary can induce bit flips by merely sending network packets.

Defenses Although we have plenty of advanced attacks exploiting bit flips, defenses are still behind. We stress here that for some of the aforementioned attacks that affect real products, vendors often disable software features. Linux kernel disabled unprivileged access to `pagemap` [35] in response to Seaborn's attack [52], Microsoft disabled deduplication [21] in response to the Dedup Est Machina attack [15], Google disabled the ION contiguous heap [58] in response to the Drammer attack [59] and further disabled high-precision GPU timers [4] in response to the GLitch attack [24]. A similar reaction to Throwhammer could be potentially disabling RDMA, which (a) in not realistic, and (b) does not solve the problem entirely. Therefore, we presented ALIS, a custom allocator that isolates a vulnerable RDMA buffer (and can in principle isolate any vulnerable to hammering buffer in memory). ALIS is quite practical, since, compared to other proposals [12, 16], it is completely implemented in user-space, compatible with existing software, and does not require special hardware features.

More precisely, CATT [16] can only protect kernel memory against Rowhammer attacks. We showed, however, that it is possible to target user applications with Rowhammer *over the network*. Furthermore, CATT requires kernel modification which introduce deployment issues (especially in the case of data centers). In particular, it applies a static partitioning between memory used by the kernel and the user-space. The kernel, however, often needs to move physical memory between different zones depending on the currently executing workload. In comparison, our proposed allocator is flexible, does not require modification to the kernel, and unlike CATT, can safely allocate memory by taking the physical to DRAM address space translation into account.

Another software-based solution, ANVIL [12] also lacks the translation information for implementing a proper protection. It relies on Intel's performance monitoring unit (PMU) that can capture precisely which physical addresses cause many cache misses. By accessing the neighboring rows of these physical addresses, ANVIL manually recharges victim rows to avoid bits to flip. An improved version of ANVIL with proper physical to DRAM translation can be an ideal software defense against remote Rowhammer attacks. Unfortunately, Intel's PMU (or AMD's) does not capture precise address information when memory accesses bypass the cache through DMA. Hence, our allocator can provide the necessary protection for remote DMA attacks (or even local DMA attacks [59]) while processor vendors extend the capabilities of their PMUs.

10 Conclusion

Thus far, Rowhammer has been commonly perceived as a dangerous hardware bug that allows attackers capable of executing code on a machine to escalate their privileges. In this paper, we have shown that Rowhammer is much more dangerous and also allows for remote attacks in practical settings. Remote Rowhammer attacks place different demands on both the attackers and the defenders. Specifically, attackers should look for new ways to massage memory in a remote system. Meanwhile, defenders can no longer prevent Rowhammer by banning local execution of untrusted code. We showed how an attacker can exploit remote bit flips in memcached to exemplify a remote Rowhammer attack. We further presented a novel defense mechanism that physically isolates the RDMA buffers from the rest of the system. This shows that while it may be hard to prevent Rowhammer bit flips altogether without wide-scale hardware upgrades, it is possible to contain their damage in software.

Varys

Protecting SGX Enclaves From Practical Side-Channel Attacks

Oleksii Oleksenko[†], Bohdan Trach[†], Robert Krahn[†], Andre Martin[†],

Abstract

Numerous recent works have experimentally shown that Intel Software Guard Extensions (SGX) are vulnerable to cache timing and page table side-channel attacks which could be used to circumvent the data confidentiality guarantees provided by SGX. Existing mechanisms that protect against these attacks either incur high execution costs, are ineffective against certain attack variants, or require significant code modifications.

We present **Varys**, a system that protects unmodified programs running in SGX enclaves from cache timing and page table side-channel attacks. Varys takes a pragmatic approach of strict reservation of physical cores to security-sensitive threads, thereby preventing the attacker from accessing shared CPU resources during enclave execution. The key challenge that we are addressing is that of maintaining the core reservation in the presence of an untrusted OS.

Varys fully protects against all L1/L2 cache timing attacks and significantly raises the bar for page table side-channel attacks—all with only 15% overhead on average for Phoenix and PARSEC benchmarks. Additionally, we propose a set of minor hardware extensions that hold the potential to extend Varys' security guarantees to L3 cache and further improve its performance.

1 Introduction

Intel Software Guard Extensions (SGX) enclaves provide a shielded environment to securely execute sensitive programs on commodity CPUs in the presence of a privileged adversary. So far, no successful direct attack on SGX has been reported, i.e., none that compromises SGX's security guarantees. However, numerous works demonstrate that SGX is vulnerable to several types of side channel attacks (SCAs), in particular, traditional cache timing and page table SCA that reveal page-level memory accesses [9, 39, 21, 47, 43, 45, 24], as well as speculative attacks [29, 12] that use the side channels as a way of retrieving information. Although Intel explicitly excludes side channels from the SGX threat model, SCAs effectively circumvent the SGX confidentiality guarantees and impede SGX adoption in many real-world scenarios. More crucially, a privileged adversary against SGX can mount much more powerful SCAs compared to the unprivileged one in canonical variants of the attacks. For example, a malicious OS can dramatically reduce the noise levels in cache timing attacks via single-stepping [24] or by slowing down the victim.

In this paper, we investigate *practical* ways of protecting SGX programs from page table and cache timing SCAs. Specifically, we focus on the case where unmodified general-purpose applications are executed in enclaves in order to protect their secrets, as it is the case with Haven [4], Graphene-SGX [11], or SCONE [3].

We postulate that a *practical* solution should have low performance overheads, require no modifications to application source code, and impose no restrictions on the application's functionality (such as restricting multithreading). We assume that recompilation of source code is acceptable as long as it does not require code changes.

Existing mitigation techniques, however, fall short of satisfying our requirements. Traditional hardening techniques against cache timing attacks [5, 23] require rewriting the application; recent defenses [22] based on Intel TSX technology also require code changes; memory accesses obfuscation approaches, such as DR.SGX [8], incur high performance cost (at least 3× and up to 20×); T-SGX [40] prevents controlled OS attacks, but it is ineffective against concurrent attacks on page tables and caches. Déjà Vu [14] protects only against page table attacks and is prone to false positives.

In *Varys*, we strive to achieve both application performance and user convenience while making page table and cache timing SCAs on enclaves much harder or entirely impossible to mount. The basic idea behind Varys design is *trust but verify*. A potentially malicious OS is *requested* to execute the enclave in a *protected environment* that prevents all known cache timing and page fault attacks on

SGX enclaves. However, the Varys trusted runtime inside the enclave verifies that the OS fulfills the request.

Our main observation is that all published page table and L1/L2 cache timing attacks on SGX require either (1) a high rate of enclave exits, or (2) control of a sibling hyperthread on the same CPU core with the victim. Consequently, if an enclave is guarded against frequent asynchronous exits and executes on a dedicated CPU core without sharing it with untrusted threads, it would be protected against the attacks. The primary challenge that Varys addresses is in maintaining such a protected environment in face of a potentially malicious OS. It achieves this goal via two mechanisms: *asynchronous enclave exits monitoring* and *trusted reservation*.

First, Varys monitors when asynchronous enclave exits (AEX) occur (e.g., for scheduling another process on the core or handling an exception) and restricts the frequency of such exits, terminating the enclave once the AEX frequency bound is exceeded. Varys sets the bound to the values that render all known attacks impossible. Notably, the bound is much higher than the frequency of exits in an attack-free execution, thereby minimizing the chances of false positives as we explain in §4.

Second, Varys includes a mechanism for *trusted core reservation* such that the attacker cannot access the core resources shared with the enclave threads while they are running, nor can it recover any secrets from the core's L1 and L2 caches afterward. For example, consider an in-enclave execution of a multi-threaded application with two threads. Assuming a standard processor with hyperthreading (SMT), all it takes to prevent concurrent attacks on L1/L2 caches is to guarantee that the two enclave threads always run *together* on the same physical core. As a result, the threads occupy both hardware threads of the core, and the attacker cannot access the core's caches. Note that this simple idea prevents any concurrent attacks on core's resources shared between its hyperthreads, such as branch predictor and floating point unit. It also prevents exit-less SCAs on page table attributes [43] because they require attacker's access to the core's TLB—available only if the attacker thread is running on that core. Additionally, to ensure that the victim leaves no traces in the caches when de-scheduled from the core, Varys explicitly evicts the caches when enclave threads are preempted.

While conceptually simple, the implementation of the trusted reservation mechanism is a significant challenge. An untrusted OS may ignore the request to pin two enclave threads to the same physical core, may re-enable CPU hyperthreading if disabled prior to enclave execution, and may preempt each of the enclave threads separately in an attempt to break Varys's defense.

Our design offers *a low-overhead mechanism for trusted core reservation under an untrusted OS*. Application threads are grouped in pairs, and the OS is *requested* to co-locate these pairs on the same physical CPU core. The trusted application threads are instrumented (via a compiler pass) to *periodically verify* that they are indeed co-scheduled and running together on the same core. Varys terminates the enclave if co-scheduling is violated or if any of the threads in the pair gets preempted too often. To reduce the frequency of legitimate exits and lower the false positives, Varys uses exitless system calls [3] and in-enclave thread scheduling such that multiple application threads can share the same OS thread. Moreover, Varys configures the OS to reduce the frequency of interrupts routed to the core in order to avoid interference with attack-free program execution. However, if the OS ignores the request, this will effectively lead to denial of service without compromising the enclave's security.

Varys primarily aims to protect multi-threaded programs by reserving complete cores and scheduling the application threads on them, i.e., protection against SCAs translates into an allocation policy that allocates or frees computing resource with a granularity of one core. We believe that Varys exercises a reasonable trade-off between security and throughput for services that require the computational power of one or more cores. For single-threaded applications Varys pairs the application thread with a service thread to reserve the complete core.

Due to the lack of appropriate hardware support in today's SGX hardware, Varys remains vulnerable to timing attacks on Last Level Cache (LLC) as we explain in §8. We suggest a few minor hardware modifications that hold the potential to solve this limitation and additionally, eliminate most of the runtime overhead. These extensions allow the operating system to stay in control of resource allocations but permit an enclave to determine if its resource allocation has changed.

Our contributions include:

- Analysis of attack requirements.
- A set of measures that can be taken to protect against these attacks using existing OS features.
- Varys, an approach to verifying that the OS correctly serves our request for a protected environment.
- Implementation of Varys with 15% overhead across PARSEC [7] and Phoenix [38] benchmark suites.
- Proposal for hardware extensions that improve Varys's security guarantees and performance.

2 Background

2.1 Intel SGX

Intel Software Guard Extensions is an ISA extension that adds hardware support for Trusted Execution Environments. SGX offers creation of *enclaves*—isolated memory regions, with code running in a novel enclave execution mode. Also, Intel SGX provides a local and remote attestation systems that is used to establish whether the software is running on an SGX-capable CPU.

SGX has hardware-protected memory called Enclave Page Cache (EPC). Accesses to the EPC go through the Memory Encryption Engine (MEE), which transparently encrypts and applies MAC to cache lines on writes, and decrypts and verifies cache lines on reads. Access permissions of the pages inside an enclave are specified both in page tables and in EPC Metadata, and permissions can be only restricted via page tables. The enclave's memory contents in the caches are stored as plaintext.

Enclaves can use more virtual memory than can be stored by the EPC. In this case, EPC paging will happen when a page not backed by physical memory is accessed. The CPU, in coordination with the OS kernel, can evict a page to untrusted memory. Currently, the EPC size available to user applications is around 94 MB.

2.2 Side-channel attacks

In this work, we focus mainly on cache timing and page table attacks as they provide the widest channel and thus, are the most practical to be used to attack enclaves.

Cache timing attacks [36, 32, 27, 25, 2, 48] infer the memory contents or a control flow of a program by learning which memory locations are accessed at fine granularity. The adversary uses the changes in the state of a shared cache as a source of information. In particular, she sets the cache to a predefined state, lets the victim interact with the cache for some time, and then reads from the cache again to determine which parts were used by the victim. Accordingly, for this attack to work, the adversary has to be able to access the victim's cache.

Page table attacks reveal page-level access patterns of a program. They are usually considered in the context of trusted execution environments as they are possible only if privileged software is compromised, hence they are also called *controlled-channel attacks* [47].

These attacks can be classified into *page-fault based* and *page-bit based*. Page-fault based attacks [47, 41] intercept all page-level accesses in the enclave by evicting the physical pages from the EPC. Page-bit based attacks [45, 43] use the *Accessed* and *Dirty* page table bits as an indication of access to the page, without page faults. However, these bits are cached in a TLB, so to achieve the required fidelity, the adversary has to do both, i.e., to clear the flags and to flush the victim's TLB.

3 Threat Model

We assume the standard SGX threat model. The adversary is in complete control of privileged software, in particular, the hypervisor and the operating system. She can spawn and stop processes at any point, set their affinity and modify it at runtime, arbitrarily manipulate the interrupt frequency and cause page faults. The adversary can also read and write to any memory region except the enclave memory, map any virtual page to any physical one and dynamically re-map pages. Together, it creates lab-like conditions for an attack: it could be running in a virtually noise-free environment.

4 System footprint of SGX SCAs

In this section we analyze the runtime conditions required for the known SCAs to be successful. Varys mitigates the SCAs by executing an enclave in a protected environment and preventing these conditions from occurring.

Cache attacks [36, 42, 32, 2, 48, 50, 10, 17] can be classified into either *concurrent*, i.e, running in parallel with the victim, or *time-sliced*, i.e., time-sharing the core (or a hyperthread) with the victim.

Time-sliced cache attacks $\Longrightarrow$ high AEX rate. For a time-sliced attack to be successful, the runtime of the victim in each time slice must be short; otherwise, the cache noise will become too high to derive any meaningful information. For example, the attack described by Zhang et al. [49] can be prevented by enforcing minimal runtime of 100us [44], which translates into 10kHz interrupt rate. It is dramatically higher than the preemption rate under normal conditions—below 100Hz (see §5.3). If the victim is an enclave thread, its preemption implies an asynchronous enclave exit (AEX).

Concurrent cache attacks $\Longrightarrow$ shared core. The adversary running in parallel with the victim must be able to access the cache level shared with it. Thus, L1/L2 cache attacks are not possible unless the adversary controls a sibling hyperthread.

We note that with the availability of the Cache Allocation Technology (CAT) [26], the share of the Last Level Cache (LLC) can also be allocated to a hardware thread, preventing any kind of concurrent LLC attacks [31]. However, this defense is ineffective for SGX because the allocation is controlled by an untrusted OS. We suggest one possible solution to this problem in §8.

Page-fault page table attacks $\Longrightarrow$ high AEX rate. These attacks inherently increase the page fault rate, and consequently AEX rate, as they induce page faults to infer the accessed addresses. For example, as reported by Wang et al. [45], a page table attack on EdDSA requires approximately 11000 exits per second. In fact, high exit rates have been already used as an attack indicator [40, 22].

Interrupt-driven page-bit attacks $\Longrightarrow$ high AEX rate. If the attacker does not share a physical core with the victim, these attacks incur a high exit rate because the attacker must flush the TLB on a remote core via Inter-Processor Interrupts (IPIs). The rate is cited to be around 5500Hz [43, 45]. While lower than other attacks, it is still above 100Hz experienced in attack-free execution (§5.3).

Exit-less page-bit attacks $\Longrightarrow$ shared core. The only way to force TLB flushes without IPIs is by running an adversary sibling hyperthread on the same physical core to force evictions from the shared TLB [45]. These attacks involve no enclave exits, thus are called *silent*.

In summary, all the known page table and L1/L2 cache timing SCAs on SGX rely on (*i*) an abnormally high rate of asynchronous enclave exit, or/and (*ii*) an adversary-controlled sibling hyperthread on the same physical core. The only exception is the case when the victim has a slowly-changing working set, which we discuss in §7.2. These observations drive the design of the Varys system we present next.

5 Design

Varys provides a *side-channel protected execution environment* for SGX enclaves. This execution environment ensures that neither time-sliced nor concurrent cache timing as well as page table attacks can succeed. To establish such an environment, we (*i*) introduce a trusted reservation mechanism, (*ii*) combine it with a mechanism for monitoring enclave exits, and (*iii*) present a set of techniques for reducing the exit rate in an attack-free execution to avoid false positives.

5.1 Trusted reservation

The simplest way to ensure that an adversarial hyperthread cannot perform concurrent attacks on the same physical core would be to disable hyperthreading [33]. However, doing so not only hampers application performance but may not be reliably verified by the enclave: One can neither trust the operating system information nor can one execute the CPUID instruction inside of enclaves.

An alternative approach is to allow sharing of a core only by benign threads. Considering that in our threat model only the enclave is trusted, we allow core sharing only among the threads from the same enclave. We can achieve this goal by dividing the application threads in pairs (if the number of threads is odd, we spawn a dummy thread) and requesting the OS to schedule the pairs on the same cores. Since we do not trust the OS, we ensure collocation by establishing a covert channel in the L1 cache as follows.

The idea is to determine whether the threads share L1 cache or only last level cache. The later would imply the threads are on different physical cores. We refer to the procedure that determines the threads co-location on the core as *handshake*. To perform the handshake, we establish a simple covert channel between the threads via L1: One of the two threads writes a dummy value to a shared memory location, thus, forcing it to L1. Then, the sibling thread reads the same memory location and measures the timing. If the reading is fast (up to 10 cycles per read), both threads use the same L1 cache, otherwise (more than 40 cycles) they share only LLC, implying they are on different cores. If the threads indeed run on different cores, the OS did not satisfy the scheduling request made by Varys. We conclude that the enclave is under attack and terminate it. Since the current version of SGX does not provide trusted fine-grain time source, we implement our own as we explain in §6.2.

Of course, immediately after we established that the two threads are executing on the same core, the operating system could reschedule these threads on different cores. However, this rescheduling would cause an asynchronous enclave exit (AEX), which we detect via AEX monitoring as we discuss next.

5.2 AEX monitoring

To detect an asynchronous enclave exit, we monitor the SGX State Save Area (SSA). The SSA is used to store the execution state of an enclave upon an AEX. Since some parts of the enclave execution state are deterministic, we can detect an AEX by overwriting one of the SSA fields with an invalid value and monitoring it for changes.

For example, in the current implementation of SGX, the EXIT_TYPE field of an SSA frame is restricted to values 011b and 110b [26]. Thus, if we write 000b to EXIT_TYPE, SGX will overwrite it with another, predefined value at the next AEX. To detect an AEX, we periodically read and compare this field with the predefined value. Note that it is not the only SSA field that we could use for this purpose; many other registers, such as Program Counter, could be used too.

Now that we have a detection mechanism, it is sufficient to count the AEX events and abort the application if they are too frequent. Yet, to calculate the frequency, we need a trusted time source which is not available inside an enclave. Fortunately, precise timing is not necessary for this particular purpose as we would only use the time to estimate the number of instructions executed between AEXs. It is possible to estimate it through the AEX monitoring routine that our compiler pass adds to the application. Since it adds the routine every few hundred LLVM IR instructions, counting the number of times it is called serves a natural counter of LLVM IR instructions. In Varys, we define the AEX rate as number of AEXs per number of executed IR instructions.

Even though IR instructions do not correspond to machine instructions, one IR instruction maps on average to less than one x86-64 machine instruction[1]. Thus, we overestimate the AEX rate, which is safe from the security perspective.

Originally, we considered using TSX (Transactional Synchronization Extensions) to detect AEXs—similar to the approach proposed by Gruss et al. [22]. The main limitation of TSX is, however, that it does not permit

[1] In our experience with Phoenix and PARSEC benchmark suites, calling the monitoring routine every 100 IR instructions resulted in the polling period of 70–150 cycles.

non-transactional memory accesses within transactions. Hence, a) handshaking is not possible within a TSX transaction—this would lead to a transaction abort, and b) the maximum transaction length is limited and we would need to split executions in multiple transactions.

5.3 Restricting Enclave Exit Frequency

Ensuring that protected applications exit as rarely as possible is imperative for our approach. If the application has a high exit rate under normal conditions, not only does it increase the overhead of the protection, but also makes it harder to distinguish an attack from the attack-free execution. In the worst case, if the application's normal exit rate is sufficiently high (i.e., more than 5500 exits/second, see below), the adversary does not have to introduce any additional exits and can abuse the existing ones to retrieve information. Therefore, we have to analyze the sources of exits and the ways of eliminating or reducing them.

Under SGX, an application may exit the enclave for one of the following reasons: when the application needs to invoke a system call; to handle system timer interrupts, with up to 1000 AEX/s, depending on the kernel configuration; to handle other interrupts, which could happen especially frequently if Varys runs with a noisy neighbor (e.g., a web server); to perform EPC paging when the memory footprint exceeds the EPC size; to handle minor page faults, which could happen frequently if the application works with large files.

We strive to reduce the number of exits as follows. We use asynchronous exit-less system calls implemented, for example, in Eleos [35] and SCONE [3] (which we use in our implementation). Further, we combine asynchronous system calls with user-level thread scheduling inside the enclave to avoid reliance on the OS scheduling. We avoid the timer interrupt by setting the timer frequency to the lowest available —100 Hz—and enabling the DynTicks feature. Regular interrupts are re-routed to non-enclave cores. Last, we prevent minor page faults when accessing untrusted memory via `MAP_POPULATE` flag to `mmap` calls.

To evaluate the overall impact of these changes, we measure the exit frequencies of the applications used in our evaluation (see §7 for the benchmarks' description). The results are shown in Figure 1.

As we see, the rate is (i) relatively stable across the benchmarks and (ii) much lower than the potential attack rate of more than 1000 exits per second. Specifically, the attack presented by Van Bulck et al. [43] has one of the lowest interrupt rates among the published time-sliced attacks. We ran the open-sourced version of the attack and observed the rate of at least 5500 exits per second, which is in line with the rate presented in the paper. Correspondingly, if we detect (see §6.2) that the AEX rate is getting above 100 Hz, we can consider it a potential attack and take appropriate measures. To avoid false positives, we could set the threshold even higher—around 2kHz—without compromising security (see §7.2).

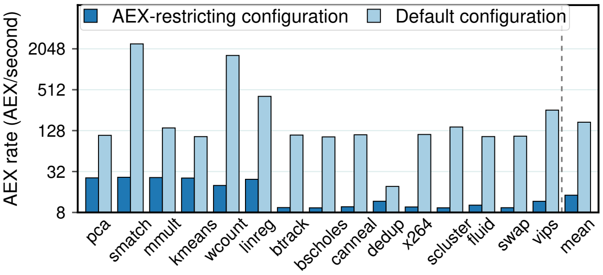

Figure 1: AEX rates under normal system configuration and with re-configured system.

```
while(true):
  wait_for_request()
  if (secret == 0): response = ∗a
  else: response = ∗b
```

Figure 2: An example of code leaking information in cache side-channel even with low frequency of enclave exits. If a and b are on different cache lines and the requests are coming infrequently, it is sufficient to probe the cache at the default frequency of OS timer interrupts.

5.4 Removing residual cache leakage

As we explained in §4, even with low frequency of enclave exits some leakage will persist if the victim has a slowly changing working set. Consider the example in Figure 2: the replies to user requests depend on the value of a secret. If requests arrive infrequently (e.g., 1 per second), restricting the exit frequency would not be sufficient; even if we set the bar as low as 10 exits per second (the rate we achieved in §5.3), the victim will touch only one cache line and thus, will reveal the secret.

To completely remove the leakage at AEX, we should flush the cache before we exit the enclave. This would remove any residual cache traces that an adversary could use to learn whether the enclave has accessed certain cache lines. Unfortunately, this operation is not available at user-space on Intel CPUs [26] nor do we have the possibility to request a cache flush at each AEX. Moreover, Ge et al. [18] have proven that the kernel-space flush commands do not flush the caches completely. `CLFUSH` instruction does not help either as it flushes a memory address, not the whole cache set. Thus, it cannot flush the adversary's eviction set residing in a different virtual address space, as it is the case in Prime+Probe attacks.

Instead, on each enclave entry, we write a dummy value to all cache lines in a continuous cache-sized memory region (e.g., 32KB for L1), further called *eviction region*. In case of L1, for which instruction and data are disjoint, we also execute a 32KB dummy piece of code to evict the instruction cache. This way, regardless of what the victim

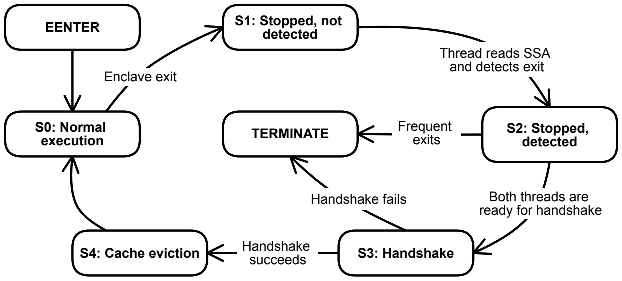

Figure 3: State diagram of a Varys-protected application.

does in between the exits, external observer will see that all the cache sets and all the cache ways were accessed and no information will be leaked.

6 Implementation

We implement Varys as an LLVM compiler pass that inserts periodic calls to a runtime library. We use SCONE to provide us with asynchronous system calls as well as in-enclave threading such that we minimize the need for an application to exit the enclave.

6.1 LLVM compiler pass

The cornerstone of Varys is the enclave exit detection. As discussed in §5.2, it requires all application threads to periodically poll the SSA region. Although we implement the checks as a part of a runtime library (§6.2), calls to the library have to be inserted directly into the application. To do this, we instrument the application using LLVM [30].

The goal of the instrumentation pass is to call the library and do the SSA polling with a predictable and configurable frequency. We achieve it by inserting the following sequence before every basic block: We increment a counter by the length of the basic block (in LLVM IR instructions), call the library if the counter reached a threshold, and skip the call otherwise. If the basic block is longer than the threshold, we add several calls. This way, the checks will be performed each time the application executes a given (configurable) number of IR instructions. We also reserve one of the CPU registers for the counter, as it is manipulated every few instructions and having the counter in memory would cause much higher overheads.

A drawback of SSA polling is that it has a blind zone. If a malicious OS preempts a thread multiple times in a very short period of time, they may happen before the counter reaches the threshold and the thread checks the SSA value. Hence, they will be all counted as a single enclave exit. This allows an adversary to launch stealthy cache attacks on small pieces of code by issuing occasional series of frequent preemptions. Yet, this vulnerability would be hard to exploit because the blind zone is narrow—on the order of dozens of cycles, depending on the configuration—and the adversary must run in tight synchronization with the victim to retrieve any meaningful information.

Optimization. Adding even a small piece of code to every basic block could be expensive as the blocks themselves are often only 4–5 instructions long. We try to avoid this by applying the following optimization.

Consider a basic block B0 with two successors, B1 and B2. In a naive version, in the beginning of each basic block we increment the IR instruction counter by the length of the corresponding basic block. However, if B0 cannot jump into itself, it will always proceed to a successor. Therefore, it is sufficient to increment the counters only in the beginnings of B1 and B2 by, accordingly, `length(B0)+length(B1)` and `length(B0)+length(B2)`. If B1 or B2 have more than one predecessor, it could lead to overestimation and more frequent SSA polling, which only reduces the blind zone.

6.2 Runtime library

Most of Varys' functionality is contained in a runtime library implementing the state machine in Figure 3.

When a program starts, it begins *normal execution* (S0). As long as the program is in this state, it counts executed instructions thus simulating a timer.

When one of the threads is interrupted, the CPU executes an AEX and overwrites the corresponding SSA (S1). As its sibling thread periodically polls the SSA, it eventually detects the exit. Then, if the program has managed to make sufficient progress since the last AEX (i.e., if the IR instruction counter has a large enough value), it transfers to the *detected* state (S2). Otherwise, the program terminates. To avoid false positives, we could terminate the program only if it happens several times in a row.

In S2, the sibling declares that the handshake is pending and starts busy-waiting. When the first thread resumes, it detects the pending handshake, and the pair enters state S3. If the handshake fails, the program is terminated[1]. Otherwise, one of the threads evicts L1 and L2 caches, and the pair continues normal execution.

Software timer. To perform cache measurements during the handshake phase, we need a trusted fine-grained source of time. Since the hardware time counter is not available in the current version of SGX, we implement it in software (similar to Schwarz et al. [39]). We spawn an enclave thread incrementing a global variable in a tight loop, giving us approximately one tick per cycle.

However, the frequency of the software timer is not reliable. An adversary can abuse the power management features of modern Intel CPUs and reduce the timer tick frequency by reducing the operational frequency of the underlying core. If the timer becomes slow enough, the handshake will be always succeeding. To protect against

[1] In practice, timing measurements are noisy and the handshake may fail for benign reasons. Therefore, we retry it several times and consider it failed only if the timing is persistently high.

```
.align 64
label1: jump label2 // jump to the next cache line
.align 64
label2: jump label3
```

Figure 4: A code snippet evicting cache lines in the L1 instruction cache. For evicting a 32 KB cache, the pattern is repeated 512 times.

it, we measure the timing of a constant-time operation (e.g., a series of in-register additions). Then, we execute the handshake only if the measurement matches the expected value.

Instruction cache eviction. Writing to a large memory region is not sufficient for evicting L1 or L2 caches. L1 has distinct caches for data (L1d) and instructions (L1i), and L2 is non-inclusive, which means that evicting L2 does not imply evicting L1i. Hence, the attacks targeting execution path are still possible.

To evict L1i, we have to execute a large piece of code. The fastest way of doing so is depicted in Figure 4. The code goes over a 32 KB region and executes a jump for each cache line thus forcing it into L1i.

L2 cache eviction. Evicting L2 cache is not as straightforward as L1 as it is physically-indexed physically-tagged (PIPT) [46]. For the L2 cache, allocating and iterating over a continuous virtual memory region does not imply access to continuous physical memory, and therefore does not guarantee cache eviction. A malicious OS could apply cache colouring [6, 28] to allocate physical pages in a way that the vulnerable memory locations map to one part of the cache and the rest of the address space—to another. This way, the vulnerable cache sets would not be evicted, and the leakage would persist.

With L2 cache, we do two passes over the eviction region. The first time, we read the region to evict the L2 cache. The second time, we read and measure the timing of this read. If the region is continuous, the first read completely fills the cache and the second read should be relatively fast as all the data is in the cache. However, if it is not the case, some pages of the eviction region would be competing for cache lines and evicting each other, thus making the second read slower. We use this as an indicator that L2 eviction is not reliable and we should try to allocate another region. If the OS keeps serving us non-continuous memory, we terminate the application as the execution cannot be considered reliable anymore.

6.3 SCONE

We base our implementation on SCONE [3], a shielding framework for running unmodified application inside SGX enclaves. Among other benefits, SCONE provides two features that make our implementation more efficient and compact. First, it implements user-level threading, which significantly simplifies thread pairing. As the number of enclave threads is independent of the number of application threads and fixed, it suffices to allocate and initialize thread pairs at program startup. Second, it provides asynchronous system calls. They not only significantly reduce the rate of enclave exits but also make this rate more predictable and application agnostic.

We should note, that Varys is not conceptually linked to SCONE. We could have avoided user-level threading by modifying the standard library to dynamically assign thread pairs. The synchronous system calls are also not an obstacle, but they require a mechanism to distinguish different kinds of enclave exits.

7 Evaluation

In this section, we measure the performance impact of Varys, the efficiency of attack detection and prevention, as well as the rate of false positives.

Applications. We base our evaluation on the Fex [34] evaluation framework, with PARSEC [7] and Phoenix [38] benchmark suites as workloads. The following benchmarks were excluded: *raytrace* depends on the dynamic X Window System libraries not shipped together with the benchmark; *freqmine* is based on OpenMP; *facesim* and *ferret* fail to compile under SCONE due to position-independent code issues. Together with the benchmarks, we recompile and instrument all the libraries they depend upon. We also manually instrument the most frequently used *libc* functions so that at least 90% of the execution time is spend in a protected code. We used the largest inputs that do not cause intensive EPC paging as otherwise, they could lead to frequent false positives.

Methodology. All overheads were calculated over the native SGX versions build with SCONE. The reported results are averaged over 10 runs and the "mean" value is a geomean across all the benchmarks.

Testbed. We ran all the experiments on a 4-core (8 hyperthreads) Intel Xeon CPU operating at 3.6 GHz (Skylake microarchitecture) with 32 KB L1 and 256 KB L2 private caches, an 8 MB L3 shared cache, 64 GB of RAM, and a 1TB SATA-based SSD. The machine was running Linux kernel 4.14. To reduce the rate of enclave exits, we configure the system as discussed in §5.3.

7.1 Performance Evaluation

Runtime. Figure 5 presents runtime overheads of different Varys security features. On average, the overhead is ~15%, but it varies significantly among benchmarks.

A major part of the overhead comes from the AEX detection, which we implement as a compiler pass. Since the instrumentation adds instructions that are not data dependent on the application's data flow, they can run in parallel. Therefore, they highly benefit from instruction

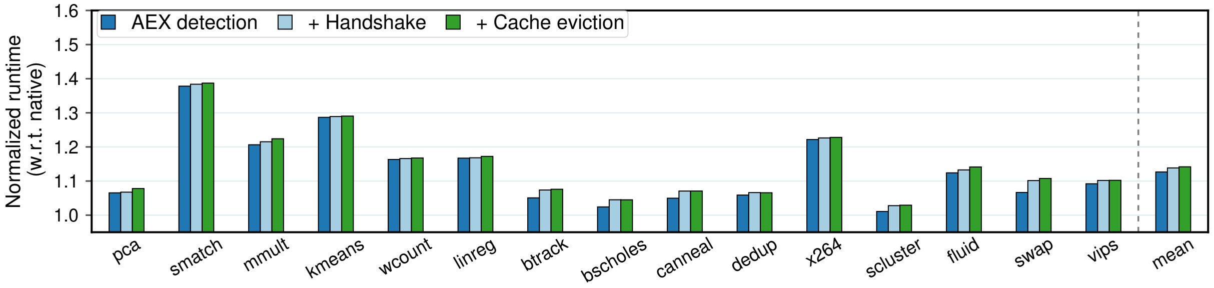

Figure 5: Performance impact of Varys security features with respect to native SGX version. Each next bar includes all the previous features. (Lower is better.)

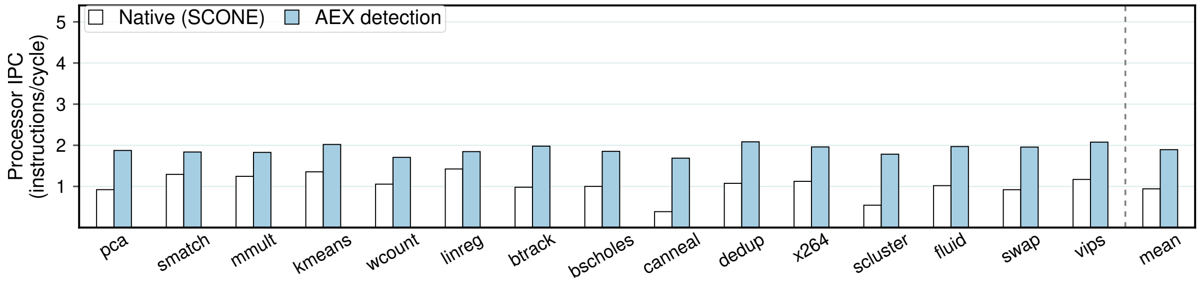

Figure 6: IPC (instructions/cycle) numbers for native and protected versions.

level parallelism (ILP), which we illustrate with Figure 6. The applications that have lower ILP utilization in the native version (e.g., *canneal* and *stream cluster*) can run a larger part of the instrumentation in parallel, thus amortizing the overhead.

Since we apply instrumentation per basic block, another factor that influences the overhead is the average size of basic blocks. The applications dominated by long sequences of arithmetic operations (e.g., *linear regression*) tend to have longer basic blocks and lower number of additional instructions (53% in this case), hence the lower overhead. At the same time, the applications with tight loops on the hot path cause higher overhead. Therefore, *string match* has higher overhead than *kmeans*, even though they have approximately the same level of IPC.

The second source of overhead is trusted reservation. It does not cause a significant slowdown because the handshake protocol is relatively small, including ten memory accesses for the covert channel and the surrounding code for the measurement. The overhead could be higher as the headshake is synchronized, i.e., two threads in a pair can make progress only if both are running. Otherwise, if one thread is descheduled, the second one has to stop and wait. Yet, as we see in Figure 5, it happens infrequently.

Finally, cache eviction involves writing to a 256 KB data region and executing a 32 KB code block. Due to the pseudo-LRU eviction policy of Intel caches, we have to repeat the writing several times (three, in our case). Together, it takes dozens of microseconds to execute, depending on the number of cache misses. Fortunately, we evict only after enclave exits, which are infrequent under normal conditions (§5.3) and the overhead is low.

Multithreading. As Varys is primarily targeted at multithreaded applications, it is crucial to understand its impact on multithreaded performance. To evaluate this parameter, we measured the execution time of all benchmarks with 2, 4, and 8 threads with respect to native versions with the same number of threads. Mind that these are user-level threads; the number of underlying enclave threads is always 4. The results are presented in Figure 7.

Generally, Varys does not have a significant impact on multithreaded scaling. However, there are a few exceptions. First, larger memory consumption required for multithreading causes EPC paging, thus increasing the AEX rate and sometimes even causing false positives. We can see this effect in *dedup* and *x264*: the higher AEX rate makes the flushing more expensive and eventually leads to false positives with higher numbers of threads. For the same reason, we excluded *linear regression*, *string match*, and *word count* from the experiment.

Another interesting effect happens in multithreaded *kmeans*. The implementation of *kmeans* that we use frequently creates and joins threads. Internally, `pthread_join` invokes memory unmapping, which in turn causes a TLB flush and an enclave exit. Correspondingly, the more threads *kmeans* uses, the more AEXs appear and the higher is the overhead.

Case Study: Nginx. To illustrate the impact of Varys on a real-world application, we measured throughput and latency of Nginx v1.13.9 [1] using ab benchmark. Nginx was running on the same machine as previous experiments

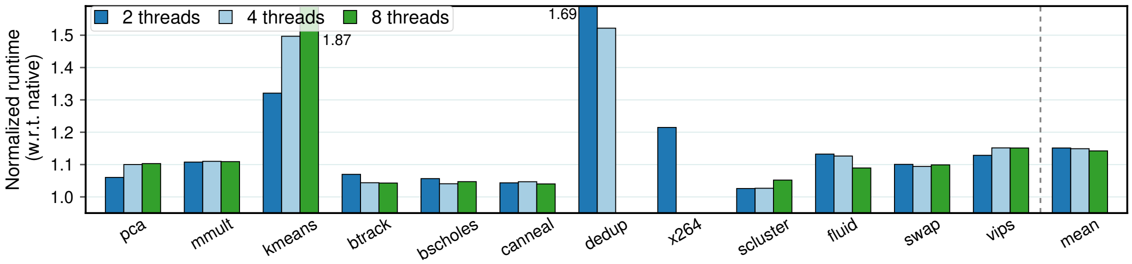

Figure 7: Runtime overhead with different number of threads. (Lower is better.)

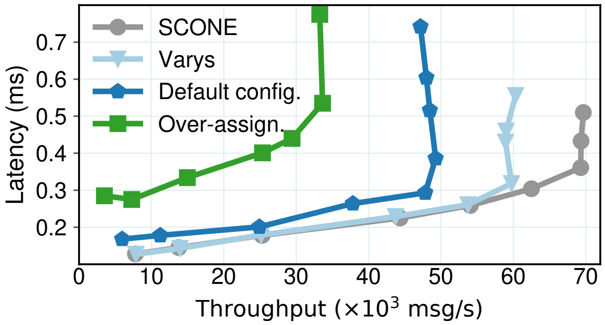

Figure 8: Throughput-latency plots of Nginx. Varys: low-exit system configuration, Default conf.: default configuration of Linux, Over-assign.: another process is competing for a core with Nginx.

Time threshold, SW timer ticks	**False positives, %**	**False negatives, %**
140	4.0	0.0
160	0.0	0.0
250	0.0	0.1

Table 1: Rate of false positives and false negatives depending on the value of handshake threshold. The threshold is presented for 10 memory accesses.

and the load generator was connected via a 10Gb network. The results are presented in Figure 8.

In line with the previous measurements, Varys reduces the maximum throughput by 19% if the system is configured for a low AEX rate. Otherwise, the AEX rate becomes higher, cache flushing has to happen more frequently and the overhead increases. The higher rate comes from two sources: disabling DynTicks increases the frequency of timer interrupts and disabling interrupt redirection adds exits caused by network interrupts. Finally, the "Over-assignment" line is the throughput of Nginx in the scenario, when we do not dedicate a core exclusively to Nginx and assign another application that competes for the core (in our case, we use *word_count* from Phoenix). Since the Nginx threads are periodically suspended, the cost of the handshake becomes much higher as both threads in a pair have to wait while one of them is suspended.

7.2 Security Evaluation

Violation of trusted reservation. To evaluate how effective Varys is at ensuring trusted reservation (i.e., if a pair of threads is running on the same physical core), we performed an experiment that emulates a time-sliced attack. We launch a dummy Varys-protected application in normal configuration (all threads are correctly paired) and then, at runtime, change affinity of one of the threads. Additionally, to evaluate the rate of false positives, we run the application without the attack. As trusted reservation is implemented via a periodic handshake, the main configuration parameter is the time limit distinguishing cache hits from cache misses.

The results are presented in Table 1. False negatives represent the undetected attacks and false positives—the cases when there was no attack, but a handshake still failed. The results are aggregated over 1000 runs.

As we see, trusted reservation can be considered reliable if the limit is set to 160 ticks of the software timer (§6.2). The fact that we neither have false positives nor false negatives is caused by the difference in timing of L1 and a LLC cache hits. If the threads are on the same core, the handshake will have timing of 10 L1 cache hits. Yet, if they are on different cores, the only shared cache is LLC and all 10 accesses would miss both L1 and L2.

Increased rate of AEX. To evaluate Varys's effectiveness at detecting attacks with high AEX frequencies, we ran a protected application under different system interrupt rates and counted the number of aborts (i.e., detected potential attacks). For the purity of the experiment, the victim was a dummy program that does not introduce additional AEXs on top of the system interrupts. In each of the measurement, we tested several limits on minimal runtime (MRT), inverse of the AEX rate. Similar to the previous experiment, we had 1000 runs.

The results are presented in Table 2. Here, the "Normal rate" is 100Hz (see §5.3); "Low-AEX attack" is 5.5kHz as in the attacks from Wang et al. [45] and Van Bulck et al. [43]; "Common attack" is 10kHz which corresponds to the rate required for cache attacks. We can see that

MRT, IR instructions	**Normal execution**	**Low-AEX attack**	**Common attack**
60M	0.2%	100%	100%
62M	1.2%	100%	100%
64M	10%	100%	100%

Table 2: Varys abort rate depending on the system interrupt rate and on the value of minimum runtime (MRT).

for (Set in L1_Cache_Sets):
  for (Very Long):
    for (CLine in CacheLine1..CacheLine8):
      Read(Set, CLine)
```

Figure 9: An example of worst-case victim for a defense mechanism based solely on interrupt frequency.

if we set the threshold on the number of IR instructions between enclave exits to 60 millions, it achieves both low level of false positives (0.2%) and detects all simulated attack attempts.

Residual cache leakage. For small applications (i.e., applications with small or slowly changing working set), cache leakage may persist even after we limit the frequency of enclave exits.

As a worst case, we consider the following application (see Figure 9): it iterates over cache sets, accessing all cache lines in a set for a long time. With such applications, limiting the interrupt frequency will not help, because even a few samples are enough to derive the application state. We use this application to evaluate effectiveness of the cache eviction mechanism proposed in §5.2.

We use a kernel module to launch a time-slicing cache attack on the core running the victim application. The attack delivers an interrupt every 10 ms, and does an L1d cache measurement on all cache sets. We normalize the results into the range of $[0,1]$. Additionally, we disables CPU prefetching both for the victim and attack code to reduce noise. Essentially, it is a powerful kernel-based attack that strives to stay undetected by Varys.

The results of the measurements are on Figure 10a. Without eviction, the attack succeeds and the state of application can be deducted even with a few samples. Then, we apply Varys with L1i and L1d cache eviction to the application (Figure 10b). Even though the amount of information leaked decreases greatly, we can still distinguish some patterns in the heatmap due to residual L2 cache leakage. When we enable L2 eviction in Varys, the results contain no visible information about the victim application (Figure 10b).

8 Hardware Extensions

Many parts of Varys's functionality could be implemented in hardware to improve its efficiency and strengthen the security guarantees. In this section, we propose a few such extensions. We believe that introducing such a functionality would be rather non-intrusive and should not require significant architectural changes.

8.1 Userspace AEX handler

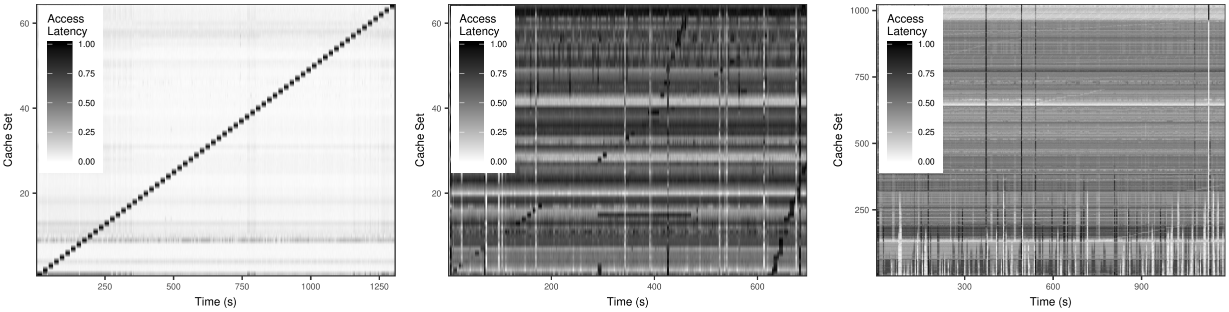
Varys relies on the SGX state saving feature for detection of enclave exits. However, this approach has certain drawbacks: it requires the application to monitor the SSA value, thus increasing the overhead, and it introduces a window of vulnerability (§6.1). An extension to the AEX protocol could solve both of the issues.

Normally during an AEX, the control is passed to the OS exception handler, which further transfers control to the userspace AEX handler, provided by the user. The user AEX handler then executes `ERESUME` instruction, which re-enters the enclave. However, there is no possibility for an in-enclave handler. Our proposed extension adds a hardware triggered callback to the `ERESUME` instruction, specified in the `TCS: TCS.eres_handler`. After each `ERESUME` executed by unprotected code, the enclave is re-entered, and the control is passed to code located at the address `TCS.eres_handler`. To continue executing interrupted in-enclave code, the `ERESUME` handler will execute the `ERESUME` instruction once again, this time, inside the enclave. Note that calling `ERESUME` inside of an enclave is right now not permitted. One difficulty of this extension would be an AEX during the processing of a handler. We would allow recursive calls since handlers could be designed to deal with such recursions.

8.2 Intel CAT extension

Although Intel CAT could be used to prevent concurrent LLC attacks, the OS has complete control over the CAT configuration, which renders the defense ineffective. It can be solved by associating the CAT configuration registers with *version numbers* that are automatically incremented each time the configuration changes. The application could check the version number in the AEX handler after each AEX and thus easily detect the change. In case, no support for AEX handlers is added, the application could perform periodic checks within the enclave instead.

To estimate the potential impact of the extension, we ran an experiment where Nginx was protected by Varys and had a slice of LLC exclusively allocated to it (see Figure 11). As we see, allocating 4 and 2 MB of cache did not cause a significant slowdown for the given workload. The difference in throughput comes mainly from the larger eviction region: Varys had to flush 4 MB instead of 256 KB. However, allocating this large part of the cache can significantly reduce the overall system performance. At the same time, if we try a more modest allocation, we risk causing a much higher rate of cache misses, which is what happened with the 1 MB allocation in our experiment.



(a) No eviction.

(b) L1 eviction.

(c) L2 eviction.

Figure 10: An experiment proving the effectiveness of cache eviction. Without eviction, we can easily see the program behavior. With L1 eviction, the L2 residual leak exposes some information. With L2 eviction, no visible information is exposed. Graphs have different time scales due to different overhead from L1/L2 measurement and presence of eviction mechanism. Color reflects normalized values, with different absolute minimum and maximum values for every graph.

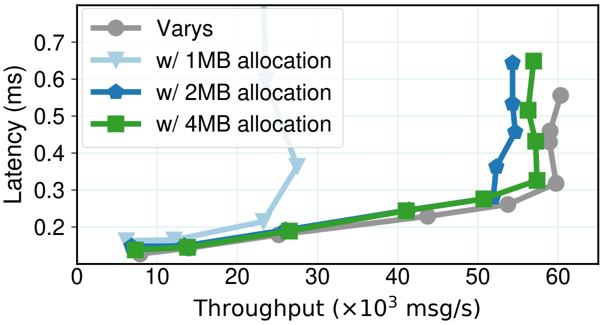


Figure 11: Impact of different cache allocation sizes on throughput and latency of Nginx protected by Varys.

8.3 Trusted HW timer

Since the hardware timer (RDTSC/P instruction) is not available in SGX1, we use a software timer, which wastes a hyperthread. SGX2 is going to introduce the timer, but we cannot rely on it either as privileged software can overwrite and reset its value.

We see two ways of approaching this problem: We may introduce a monotonically increasing read-only timer which could be used as-is. Alternatively, we could introduce a version number that is set to a random value each time the timer is overwritten. To ensure the timer correctness, the application would have to compare the version of this register before and after the measurement.

9 Related Work

The idea of restricting minimal runtime was proposed by Varadarajan et al. [44], although they relied on features of privileged software. Similarly, Déjà Vu [14] relies on measuring execution time of execution paths at run-time.

T-SGX [40] uses Transactional Synchronization Extensions (TSX) to detect and hide page faults from the OS. It protects against page fault attacks, but not page-bit and cache timing attacks. Cloak [22] strives to extend T-SGX guarantees to cache attacks by preloading sensitive data, but requires source code modifications.

Concurrently with our work, an alternative approach to establishing thread co-location was proposed in HyperRace [13]. It uses data races on a shared variable as a way of distinguishing L1 from LLC sharing. Accordingly, it does not require a timer thread.

Zhang et al. [51] and Godfrey at al. [19] employ flushing as a defense against cache attacks, and Cock [15] proposed to used lattice scheduling [16] as an optimization. All of them rely on privileged software.

Among the alternatives, Racoon [37] builds on the idea of oblivious memory [20] and makes enclaves' memory accesses independent of the input by introducing fake accesses, but requires manual changes in code. Dr. SGX [8] automates the obfuscation. Shinde et al. [41] make the accesses deterministic at the page level. Both introduce high overheads (in the range of 3–20×).

10 Conclusion

We presented Varys, an approach to protecting SGX enclaves from side channel attacks. Varys protects from multiple side channels and causes low overheads. Conceptually, Varys protects against side channels by limiting the sharing of core resources like L1 and L2 caches. We have shown that implementing it in software is possible with reasonable overhead. With additional hardware support, we would not only expect a more straightforward implementation of Varys but also lower overhead and protection against a wider range of side channel attacks, including LLC-based ones.

Abstract

The Linux Audit system is widely used as a causality tracking system in real-world deployments for problem diagnosis and forensic analysis. However, it has poor performance. We perform a comprehensive analysis on the Linux Audit system and find that it suffers from high runtime and storage overheads due to the large volume of redundant events. To address these shortcomings, we propose an in-kernel cache-based online log-reduction system to enable high-performance audit logging. It features a multi-layer caching scheme distributed in various kernel data structures, and uses the caches to detect and suppress redundant events. Our technique is designed to reduce the runtime overhead caused by transferring, processing, and writing logs, as well as the space overhead caused by storing them on disk. Compared to existing log reduction techniques that first generate the huge raw logs before reduction, our technique avoids generating redundant events at the first place. Our experimental results of the prototype KCAL (Kernel-supported Cost-effective Audit Logging) on one-month real-world workloads show that KCAL can reduce the runtime overhead from 40+% to 15-%, and reduce space consumption by 90% on average. KCAL achieves such a large reduction with 4% CPU consumption on average, whereas a state-of-the-art user space log-reduction technique has to occupy a processor with 95+% CPU consumption all the time.

1 Introduction

Understanding system provenance is an important and challenging task, especially in forensic analysis and problem diagnosis. A common approach is to perform operating system-level audit logging, which is one of the core functionalities required in enterprise-level infrastructures. The Linux Audit system is the most widely used audit system. It resides in the kernel, collects information for predefined kernel events, and records them in log files. Following incidents, investigators use automated tools (e.g., ausearch) to analyze audit logs to search for suspicious system objects (e.g., files, sockets) and subjects (e.g., processes), and identify causal dependencies among them. Such information is critical to locating root causes and assessing damages. Then they use such information to hunt for suspicious activities such as policy violations. In practice, the Linux Audit system has been known to have poor performance, and other researchers have been working on improving the Linux Audit system for a long time. Many works [8, 9, 22, 24, 31, 41, 42] proposed enhancement or alternative designs to provide fast logging infrastructures or highly compressed logs. However, existing solutions do not fundamentally solve the high space and runtime overhead problems. And this motivates us to deeply analyze and understand the overhead problems in the Linux Audit framework.

In this paper, we first describe a comprehensive analysis on the Linux Audit system, and show that the runtime and the storage overheads are essentially caused by transferring and processing huge raw logs that contain substantial redundancies. Previous research failed to solve the problems because methods required first generating the redundant logs. Our key idea is *to remove redundancies inside the kernel so that we can prevent the huge raw logs from being generated at the first place.* Inspired by hardware/software cache system designs, we propose KCAL, a kernel-level, cost-effective, memory-cache-based audit logging system. It caches important dependencies and events, and detects redundancy on the fly using the caches. If redundant events indicated by cache hits are detected, they are immediately discarded. Only events that introduce new system objects/subjects or new dependencies are retained. Dependency caches and event caches are distributed in individual kernel data structures. The caches are carefully designed such that the kernel memory consumption is kept reasonably low, avoiding perturbation of normal kernel functionality. In summary, in this paper, we make the following contributions:

- We describe a comprehensive analysis on the Linux Audit system, which revealed that the root cause of its high runtime and storage overheads is the need to transfer, process, and store the huge raw log, and identify this can be solved by removing the redundant events.
- We propose a kernel-level, cache-based, log-reduction system. The key idea is to prevent the kernel from generating redundant raw logs in the first place. The design features a multi-layered and distributed cache scheme that leverages the autonomous execution sub-structures (i.e., units) in individual processes (e.g., sub-executions serving individual requests in Apache), and indexes largely scattered syscall events belonging to the same object.
- We built a prototype KCAL based on the Linux Audit system. Our experimental results showed that KCAL is capable of reducing the runtime overhead from 40+% to 15-%, log files by 90+%, and it does not introduce significant memory pressure on the existing kernel. The comparison with the state-of-the-art, user-space log-reduction technique ProTracer [24] shows that ProTracer fully occupies an idle processor with 95% constant CPU consumption whereas KCAL only requires 4% CPU consumption on average.

2 Motivation and Related Works

2.1 Audit Logging Systems

There are many existing audit logging systems [2, 5, 7, 24, 28, 31] from commercial companies and research communities. Prior works [13, 14, 16, 35, 37, 43] proposed many different general logging infrastructures. Some of them [11, 27, 28, 34] monitor the whole file system at the `inode` level, while others [31, 36] leverage the Linux Security Module (LSM) to monitor operations on kernel data structures. Many of the techniques [12, 17, 18, 19, 20] use record-and-replay techniques to record system wide events for system replay. They require logging of syscalls including the concrete values such as the content of files or packets. Hence, they tend to be expensive and are mostly used in single application execution. Bates *et al.* provide a general and secure framework for writing a provenance system at the operating system level. Among these provenance systems, the Linux Audit framework [2] is the most practical and widely used. The framework provides a general logging infrastructure that allows the integration of plugins to enhance the system. As such, it is widely used and has been adopted by many other research projects and real-world products [3, 4, 6].

Linux Audit Architecture. Figure 1 shows the architecture of the Linux Audit framework. It contains a few user-space utilities (brown boxes) and a kernel component. The kernel component contains a number of filters (blue circles). Based on the execution order, i.e., before/during/after the syscall processing logic, the filters are named `User/Task/Exit`, respectively. The `Exclude` filter defines exceptions to the filtering rules; namely, any syscall that falls into the `Exclude` category will not be filtered. The `auditctl` program helps administrators manage filters. If these filters determine that a syscall needs to be recorded, the kernel component sends the information to the user-space daemon program `auditd` through the `Netlink` device. `Auditd` collects syscall records and writes them to the log file.

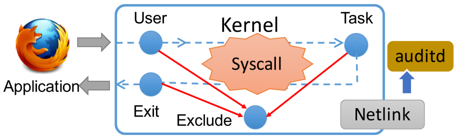

Figure 1: The audit framework architecture

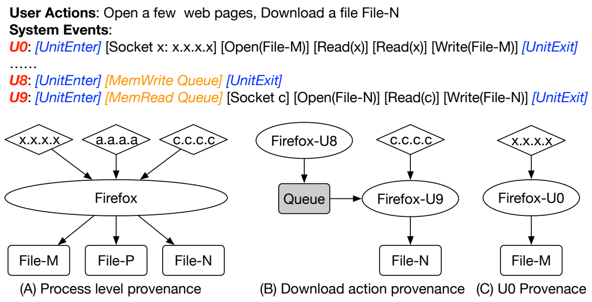
State-of-the-Art Causality Analysis. An important feature of an audit logging system is the dependency analysis support. As demonstrated by previous researchers [21,23], the Linux Audit system suffers from the *dependency explosion* problem because of the large number of fan-outs in process-level analysis. Process execution partitioning techniques [21, 23] were proposed to enable fine-grained dependency analysis in audit logging, and to help remove redundant log information. They partition process executions into *execution units*. Each execution unit is a part of the whole process execution serving a specific task. MPI [23] partitions process execution based on user-defined tasks, e.g., individual tabs in Firefox. BEEP [21] partitions process execution based on event-handling loop, namely, and an execution unit is essentially an iteration of the event handling loop. Execution units are considered largely autonomous. Therefore, *an output syscall event in a unit is considered only dependent on the preceding input events within the same unit unless there are dependencies across units (e.g., through in-memory data structures)*. In contrast, Linux Audit considers that an output event depends on all the preceding events in the same process, causing numerous bogus dependencies [14,18,20,21]. An execution unit is delimited by a special `UnitEnter` event indicating the start of the unit, and a `UnitExit` event denoting the end in these systems. An execution unit may depend on another through variable reads/writes. Such variables/data-structures are treated as Inter-Process Communication (IPC) objects, and exposed to the audit system via the `MemWrite` and `MemRead` syscall events [21, 23].

Figure 2 shows an example of using Firefox to open webpages and download a file (File-N). It also shows the simplified log events. In each line, we show the events



User Actions: Open a few web pages, Download a file File-N
System Events:
U0: *[UnitEnter]* [Socket x: x.x.x.x] [Open(File-M)] [Read(x)] [Read(x)] [Write(File-M)] *[UnitExit]*
......
U8: *[UnitEnter]* *[MemWrite Queue]* *[UnitExit]*
U9: *[UnitEnter]* *[MemRead Queue]* [Socket c] [Open(File-N)] [Read(c)] [Write(File-N)] *[UnitExit]*

(A) Process level provenance (B) Download action provenance (C) U0 Provenace

Figure 2: Comparison of different dependency granularity

that belong to a unit marked with the unit ID. Without unit information, we will get a graph shown in (A). The file object File-M (transitively) depends on all the socket read by Firefox before the write to the file, which introduces many bogus dependencies. With partitioning, the events are properly grouped. For example, the first unit, *U0* represents a unit for opening a web page. It creates a socket, fetches a page, stores it, and then renders it on screen. The dependency relationship is shown in (C). The multiple page loading tasks are separated to units, and the resulting provenance graph is accurate. Downloading in Firefox causes explicit dependencies between units (*U8*, *U9*). *U8* first inserts the download request to a queue, and then *U9* fetches it from the queue and downloads the file. These units are connected through `MemWrite`/`MemRead` events as shown in (B).

2.2 Linux Audit System Performance

To motivate our technique, we perform a few experiments to measure the overhead of Linux Audit and explain the limitations of existing overhead reduction techniques. We run 20 virtual machines with Ubuntu 14.04 as the guest OS on the Kernel-based virtual Machine (KVM) platform, and each virtual machine has two cores and 4 GB main memory. The machines are classified into two categories: servers running server programs (e.g., HTTP server Apache, FTP server ProFTPd), and clients running client programs (e.g., Firefox and Vim) for daily use. Each group has 10 virtual machines.

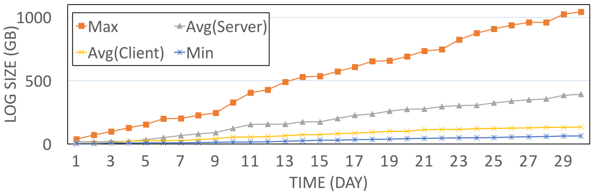


Figure 3: The audit framework log sizes growth in 30 days

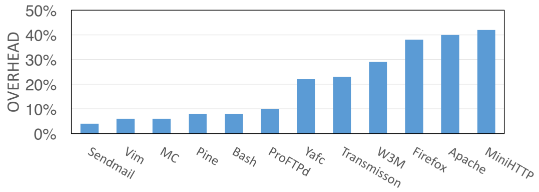

Figure 4: The audit framework runtime overhead

Figure 3 shows the log size growth along time. We configure the audit system to only record 60 provenance-related syscalls [24, 31]. These system calls are related to process creation/termination, file/socket creation/read-/write/deletion and IPCs and so on. Observe that in the worst case, a machine generates 1100+GB log in 30 days. Even in the best case, 60 GB log is generated within 30 days. On average, a server machine can generate about 130GB data per day, whereas a client machine generates about 5GB data per day. The data is also consistent with previous research [22, 41]. Such a large volume of data causes many problems. First, it is expensive to store or transmit log files. By default, the audit log is stored on the local disk and consumes substantial storage space. It can be sent to external servers for storage and inspection, but this incurs runtime overhead, network traffic, and maintenance efforts on servers. Second, processing such large files can be extremely challenging. It may take hours to days to answer a provenance query as it requires searching through log files in the size of GBs to TBs. The situation becomes worse in the enterprise environment, where there are hundreds to thousands of inter-connected machines, which increases the problems associated with storing, correlating, and processing audit logs. Compressing the log is one way to reduce the storage overhead, but causes more runtime overhead for compressing/decompressing the logs to investigate an attack. Zhang *et al.* [41] also demonstrated that in an enterprise environment, using databases to store the logs is also very challenging in such scenarios.

Figure 4 shows the runtime overhead (caused by Linux Audit) for a few programs including both server programs like Apache and client programs like Vim. We leverage existing workloads to test the performance if possible. For programs that support batch mode (e.g., Vim), we write scripts to test the performance. Some of the programs generate frequent system calls (e.g., Apache), and naturally cause higher runtime overhead. As we can see, the overhead for some programs like Vim is tolerable. But for I/O intensive programs such as browsers and server programs, the overhead can be rather high.

Understanding the Overheads. The Linux Audit framework has three parts: the kernel part (filtering rules etc.), the `Netlink` data transmission channel, and the user space logger (i.e., `auditd`). Figure 5 shows the runtime overhead of each component. Similar observations are made on both Hard Disk Drives (HDDs) and Solid State

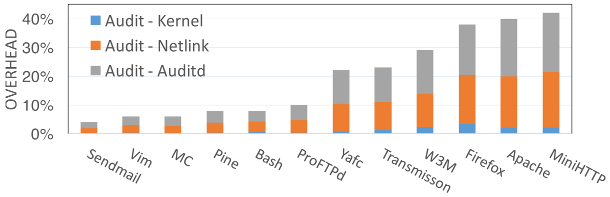

Figure 5: Audit framework runtime overhead

Drives (SDDs). The graph tells us the kernel filters are relatively lightweight, and the other two parts, `Netlink` and `auditd`, are the dominant factors of the overhead. `Netlink` provides a socket-like channel for transmitting data, and `auditd` is responsible for writing the log data to disk. The major factor that affects the time spent on these two components is the size of log data that needs to be processed (transferred/written). Considering the amount of data we need to handle (Figure 3), it is understandable these two parts dominate the overhead. As such, we can say *the root cause of both runtime and storage overheads is the large amount of data generated by the Linux Audit framework*.

2.3 Log Redundancy

Previous works addressed the storage overhead problem by shrinking the log size. Most of them [10, 15, 25, 29, 30, 32, 33, 38, 39, 40] generated the dependency graph first, and then used various graph visualization or compression algorithms to help causality analysis. These techniques ignore the importance of reducing the redundancy of audit logs, and cannot solve the runtime overhead problem caused by such redundancy.

Existing Linux Audit generates highly redundant logs. Based on our analysis (see §4), over 89% log entries are redundant. Previous research [22, 24, 41] has also presented similar observations. Thus pruning the log could improve the performance of the Linux Audit system. Some existing works [8, 41] suggest removing redundancy by various analysis techniques, e.g., rule-based filtering. However, this requires human effort to create and maintain the rules. ProTracer [24] leverages execution partitioning for log reduction. It has a kernel module, which simply receives syscall events, filters them, and then sends the remaining event records including unit-related events to the user-space daemon, which consists of multiple processes. These processes run in parallel to remove redundant events. The ProTracer views system objects as taints and monitor their propagation during execution by performing syscall level taint analysis while processing the log. Each unit/object is associated with a taint set denoting the set of data sources that it depends on. The causalities denoted by the taint sets (instead of individual events) are emitted to the log. Therefore events leading to the same taint set are essentially reduced.

All these techniques first generate the full-fledged log and then reduce it. It is the huge raw log that causes the substantial overhead. These techniques cannot be applied in the kernel space because it has rather limited resources that prevents loading and processing huge raw logs. For instance, the parallel (tainting-based) processing required by ProTracer cannot be ported to the kernel space due to its high CPU consumption (See data in §4). An ideal solution is to *prevent redundant log entries from being generated by the kernel in the first place*. This is the motivation behind KCAL, a kernel-supported log cache and reduction system.

3 Design

3.1 Overview

We propose a cache-based, cost-effective audit logging system inside the kernel called KCAL. It leverages execution partitioning and is orthogonal to the underlying partitioning scheme. Any partitioning scheme [21, 23] that generates unit boundary syscalls and cross-unit memory dependency events can be seamlessly integrated with KCAL, and we use BEEP. Upon a new syscall event, KCAL determines if there is a cache hit, which means the new event reveals the same causal information as some event(s) that have been recorded before and hence can be safely discarded. Since the cache is positioned at the kernel, redundant log events are prevented from being generated in the first place, leading to highly succinct raw logs without any information loss. KCAL is not a monolithic caching system like traditional memory caches because different subjects/objects have diverse life times and various numbers of associated syscall events distributed in their life spans. Due to the nature of audit logging, we cannot be certain if events belonging to a subject/object are redundant before it is closed or terminated. A monolithic cache design would require complex data structure support for indexing and removing sparse and highly distributed log events. Therefore, we propose a distributed cache design so each process/object (e.g., a file) has its own cache storing associated events, and these caches are encapsulated as part of the kernel data structures. Figure 6 shows the overall architecture of KCAL.

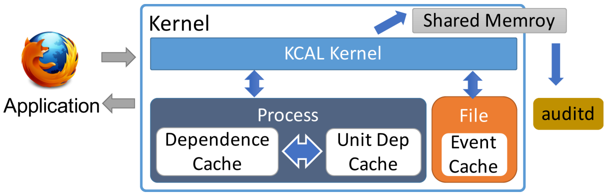

Figure 6: Overview of KCAL architecture

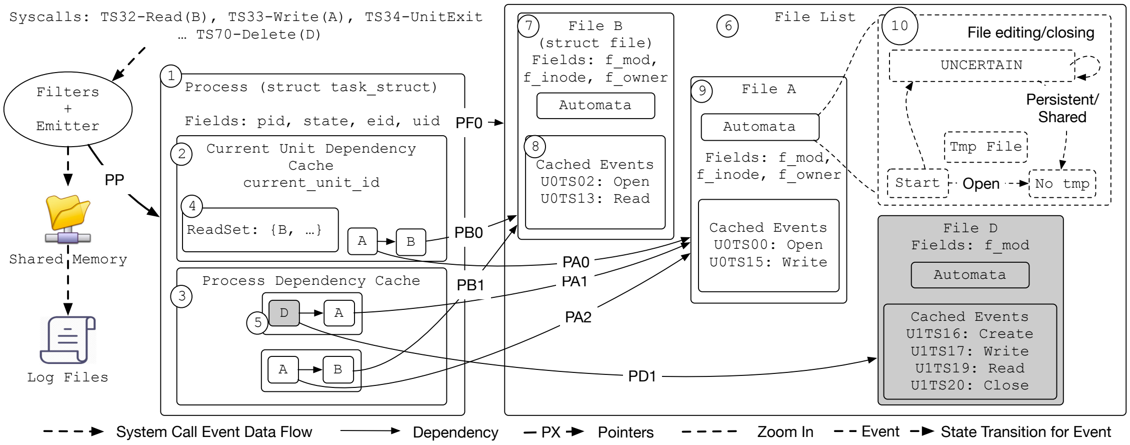

Figure 7: Overview of KCAL

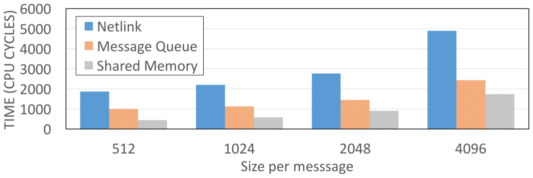

Figure 8: Performance of 3 data channels (kernel to user-space)

First, we enhance the Linux Audit module with an online cache-based log-reduction algorithm, and modify the kernel data structures for processes and objects (e.g., files and sockets) to insert caches. Second, we use shared memory instead of `Netlink` as the transfer channel.

In-kernel Architecture and Workflow. Figure 7 shows a simplified view of the kernel part of KCAL. The first modification is in the `task_struct` data structure (①), which stores process specific information such as the *pid*. We add more pointer fields. The first one is a pointer to a unit dependency cache (box ②). The cache uses a *ReadSet* to store the objects that have been read by the current unit (box ④), and also maintains the detected dependencies in the current unit (e.g., $A \rightarrow B$ shown inside ②). Each object in the cache also has a pointer (e.g., PA0 and PB0) to the corresponding kernel data structure instance such as a `File` structure. The second pointer points to a process-level dependency cache (box ③), which stores the dependencies detected in this process (box ⑤) by aggregating the unique dependencies from individual units. The unit cache is needed for in-unit redundancy and the process cache is for cross-unit redundancy.

We also enhance the kernel data structures representing objects (resources). For example, we enhance the `File` data structure that contains file-specific information, such as its inode, by adding two pointers. The first one points to a cache that stores the syscall events operating on the object with timestamps (box ⑧). Redundant events are removed at the unit/process level before being added to the object cache. We do not directly send these events to the user space but rather cache them because all the events in the object cache may be deemed redundant if the resource is determined as temporary. More details will be discussed in §3.3. The second pointer points to an automaton used to detect if the resource is temporary (box ⑨). Box ⑩ shows the states and the transitions. Details will be discussed in §3.3. KCAL does not cause any compatibility issues as it does not change the meanings of existing fields in these data structures. More importantly, our method is general, and one could easily use stand-alone hash tables that map a process/object to its auxiliary data structures and avoid touching any kernel data structures. As we will show in §4, although KCAL is mainly kernel based, its perturbation to the normal kernel functionalities is negligible due to its small memory footprint and limited instrumentation inside the kernel.

The Linux Audit module is enhanced with an on-the-fly reduction algorithm that interacts with the caches to determine if an event is redundant. When a syscall event occurs, it first goes through the filters. Non-provenance related syscalls like time-related system calls are filtered out. The remaining syscalls (i.e., reads/writes) are passed to the reduction component. This component checks if there is a cache hit for the dependency represented by the event. Note the caches are accessible through the `current` variable, which points to the `task_struct` of the current process that contains direct or transitive pointers to multiple layers of caches. If hit, the event is safely discarded. Otherwise the dependence is inserted to the dependence cache, and the event is inserted to the event cache of the object that is being operated on. Eventually, non-redundant events will be emitted to the shared memory and saved to the disk by the user-space component.

Transfer Channels. `Netlink` provides a socket-like communication method between the kernel space and the user space and was widely adopted by SELinux as it provides a simpler interface and better performance as compared with its competitors (printk, ioctl etc.). We compare three general ways of transferring bulk data from the kernel space to the user space: `Netlink`, message queues, and shared memory. Figure 8 shows the performance comparison of these channels. The X-axis represents the size of each message. We use four configurations: 512, 1024, 2048, and 4096 bytes. For each message size, we generate 10,000 random messages and perform the experiments 10 times. The Y-axis is the performance measured by the average time (CPU cycles) used to transfer one message. Shared memory has the best performance. In the past, due to the memory size limits made it practical to use shared memory as the transfer channel as it requires reserving a memory pool, but this is no longer a problem in modern computers.

3.2 Redundancy in the Linux Audit Log

Our definition of *redundancy* is with respect to the attack investigation, which is based on a causal graph according to the latest *Open Provenance Model* (OPM) [26]. OPM standardizes the forensic analysis procedure and is the most widely adopted provenance model. A causal graph is generated by first starting from a given subject or object (e.g., a suspicious file) and then performing *forward/backward* traversal along dependencies to find all the reachable subjects and objects. Backward traversal is used when the inspector wants to trace back the root cause of an attack starting from some observed symptom. In contrast, forward traversal is used when the inspector has already identified the root cause and now wants to understand the damage caused by the attack. It starts with the root cause and finds all the affected subjects/objects. In this context, *we consider an event redundant if the derived causal graph contains the same dependency information with and without the event.* That is, we can reach the same set of objects and subjects with and without the event. As such, an event is redundant if it leads to some dependency that was induced in a previous unit. This is because the previously recorded events and the entailed dependence render the same reachability. Events denoting the same dependency may be in the same or different execution units, and they are referred as in-unit redundancy and cross-unit redundancy, respectively.

Another type of redundancy is what we call *temporary files*. We define the term *temporary file* from the provenance analysis perspective. A *temporary file* is a file that is created, edited, and deleted by the same owner and during its whole life cycle; the file is not “shared” with any other process. These files only temporarily exist in the system and are used internally by applications. For example, editors with auto-saving features often use a temporary file to keep the newly edited contents to support recovery. These files are deleted when the user saves the file explicitly. Another example is that browsers like Firefox use a large number of temporary files to store downloaded web elements. The browser regularly removes such files to save space. Temporary files do not lead to useful forensic information as they do not have interactions with other system objects or subjects and can be removed. Many programs use temporary files because they need to save a large amount of contents locally, and memory is not sufficient for them to do so. From the provenance point of view, the temporary files are a part of the program execution just like the runtime variables in memory. As all the information source and sink points are the same, it can be viewed part of the program execution.

Our definition of *temporal files* is different from that of traditional temporary files that usually refers to the files in the `tmp` file system. Many of these files can interact with other processes and generate new provenance information, and thus the corresponding events are not redundant according to our design. For example, Firefox has one `open with` option for many types of files such as torrent files in its download dialog. It will first download the selected file (e.g., one torrent file), and then open the file using the system default program for this file type. In this case, the downloaded file is stored in the `tmp` file system, but it will be kept in our design as it is read by another process, which is new provenance information.

Therefore, KCAL guarantees the information completeness from the provenance graph point of view. Namely, the log files before and after reduction will output the same provenance graph for the same provenance query. As a provenance tracking system, it does not guarantee information completeness for other audit purposes such as the total number of syscalls in a time range.

3.3 Redundancy Reduction

In this section, we explain the details of the KCAL design. There are three important design choices: *a two-layer dependency cache (the unit layer and the process layer) for a process*, *a distributed event cache for objects*, and methods for *handling cross-unit memory dependencies.*

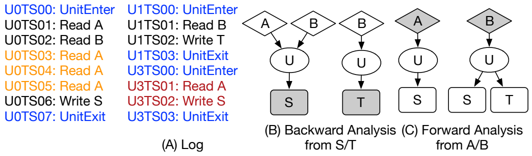
Two-layer Dependency Cache For Process. As shown in Figure 7, we cache two-layer dependencies for a process, the dependencies detected in the current unit (box ②) and those in the whole process (box ③). The former is to remove in-unit redundancy, and the latter is to reduce cross-unit redundancy.

- *In-unit Redundancy.* Read/write syscalls use buffers with limited sizes to transfer data. To load/edit a file larger than the buffers, an application has to issue a sequence of read/write syscalls. For example, Vim reads a file piece by piece and adds the pieces to the in-memory content tree. This produces a sequence of events in the audit log (without reduction) containing tens to hundreds of read syscalls on the target file in the same execution unit. These syscalls denote the same dependency and are redundant. Such redundancy is detected by the unit cache in KCAL. KCAL only keeps one instance of them. At the first read event, the object is added to the `ReadSet`. If it is already in the `ReadSet`, the event is simply discarded. When a write event happens, it is considered dependent on all the objects in the `ReadSet` as the information from these objects can affect the content it writes. KCAL checks if these dependencies are present in the unit-dependency cache. If not, it adds the write event and the read events of objects in the unit cache to the event caches of the corresponding objects. Otherwise, the event is discarded.

- *Cross-unit Redundancy.* Processes usually perform repeated actions on the same system objects. Some of them are because of repeated user actions. For example, editors usually work on a few files for a long time with repeated editing operations. And some of them are due to built-in application functionalities. For example, Firefox writes to the `recovery.js` file every 15 seconds (through a unit) to support purpose. As a result, the same dependency can appear in the log file across different units repeatedly, leading to *cross-unit redundancy*.

An example in Figure 9 on the left-hand-side, (A) shows the simplified log entries. There are three units. Unit 0 (`U0`) reads File-A, File-B, and writes File-S; `U1` reads File-B and writes File-T; and `U3` reads File-A and writes File-S. The blue entries are the `UnitEnter`/`UnitExit` events. The yellow entries are the in-unit redundant events. In particular, `U0` keeps loading contents from File-A. Events `U0TS03` to `U0TS05` all represent the same action, and are redundant. The red entries are the cross-unit redundant events. In this case, the causal dependency between File-A and File-S in `U3` is already detected in `U0`, and hence is redundant. The graphs in (B) show the generated backward analysis graphs starting from File-S and File-T (in gray), and the graphs in (C) represent the generated forward analysis graphs starting from File-A and File-B (in gray). Events `U3TS01` and `U3TS02` do not induce any new dependencies and removing them does not affect the reachable objects and subjects in both forward and backward analyses. Without the execution partitioning, File-T would depend on File-A because the process loads File-A before writing to File-T. As shown later in §4, our reduced logs generate the same casual graphs as using the original BEEP logs (with redundancy reduction).

Distributed-event Cache. In KCAL, dependencies are cached in processes and syscall events are cached in objects. KCAL features a distributed-event cache mechanism in which each object caches the syscall events that operate on the object. They are not transferred to the user space for storage until the object is no longer needed or the process terminates. This is to handle the substantial redundancy caused by temporary files (defined in §3.2).



```

(A) Log

(B) Dependencies (edges label: timestamp)

Figure 10: Cross-unit memory causality example

We detect temporary files using the automaton shown in box ⑩ in Figure 7. Each `File` data structure maintains its own state. At first, when a file is opened by the owner process, KCAL checks the creator of the file. If the file exists and was created by another process, it is marked as a non-temporary file. Otherwise, it can potentially be a temporary file (i.e., the *UNCERTAIN* state). Normal file editing operations by the owner such as read/write/close do not change the state of the file. Any operation from a different process indicates that information propagates beyond the current process through the file, and hence the file must not be temporary. If the file is deleted by its owner without being read/edited by other processes, it is temporary. If the file is not deleted by its owner process (and hence is persistent), it is not temporary.

As KCAL cannot be certain if a file is temporary or not until the file is deleted, edited by other processes, or the owner process terminates, it buffers all the events for a file it created (after redundancy reduction) in the cache associated with the file until either condition is satisfied. Then, KCAL discards all the events in the cache or emits them to the user space. The emission order of events may be different from the temporal order due to the distributed caching. It is not problematic, however, as all events have global time stamps.

Cross-unit Memory Causality. As mentioned earlier, there may be dependencies across units caused by variables or data structures. For example, in Vim's built-in clipboard, a piece of memory (known as *registers*) is used to support copy/cut-and-paste operation across units.

Existing execution partitioning schemes generate special syscalls `MemWrite`/`MemRead` to denote the write/read operations on cross-unit, dependency-inducing variables, respectively. The nature of these memory operations is very similar to file reads and writes. Hence, KCAL models these events in a similar way. Particularly, each unique memory location is considered as a separate object. The difference is we do not remove events that cause the same memory dependencies across units. Instead, KCAL treats the memory object as a new object each time it is redefined. This is because each memory write to a location is considered as a complete redefinition of the memory object, which is different from a file write. For such an object, each read only depends on the latest write.

For example, in the syscall sequence in Figure 10, unit `U1` receives a request through the memory queue from `U0` at location `M` and then forwards another request to `U2` through a different memory location `N`. KCAL detects a dependency from `N` to `M`. Later, the same procedure happens again and hence the same dependence is detected inside unit `U8`. The same memory locations are observed due to memory reuse, and we cannot unify the multiple instances of the memory locations and throw away the memory events in `U8`. Otherwise, bogus dependencies would be introduced. In the shown example, `D` only depends on `C`. If the dependency introduced by `U8` is removed and the two `M` nodes are unified, `D` would depend on `{C,A}`. In KCAL, the variables `M, N` associated with `U8` and the ones associated with `U1` are treated as a new set of system objects even though they are using the same memory addresses. KCAL leverages existing execution partitioning techniques and existing execution partitioning techniques only instrument a very small number of memory operations through sophisticated analysis [21,23]; and hence, the number of memory events generated at run time is small.

3.4 Implementation and Discussion

KCAL is implemented on the long-supported Linux kernel 3.19 and the Linux Audit framework 2.3. By default, each system object cache size is 32 events. The number of dependencies a process can cache is capped at 256, and the number of dependencies a unit can cache is 8. These values are configurable in KCAL. If the cache is full, and we use the Least Recently Used (LRU) cache replacement policy to evict entries. It is important to note *the consequence of cache eviction is merely that some redundancy cannot be removed. It does not affect information completeness*. The study of the effect of various cache sizes can be found in §4.

KCAL is a provenance tracking system built on top of the Linux Audit framework. The audit log message format is still the same. This makes it compatible with existing audit log processing tools such as `aureport` and `ausearch`. On the other side, the generated messages are for provenance tracking only, and the number of such messages is significantly reduced. This will affect audit tools that calculate the sysall frequencies or concretely analyze individual syscalls such as `aureport`. Also, KCAL modifies the Linux kernel source code including many data structures. As a result, porting it to other kernel versions requires extra human effort. We also port our prototype from Linux kernel 3.19 to kernel 3.2, and most of the patches can be directly applied. The new modification is less than 10 lines. We expect that the porting efforts will be limited as long as the kernel data structure change is not significant. KCAL also depends on existing execution partitioning techniques such as BEEP [21] or MPI [23]. Without the execution partitioning support, cross-unit redundancies cannot be removed, which affects the reduction effectiveness (see §4).

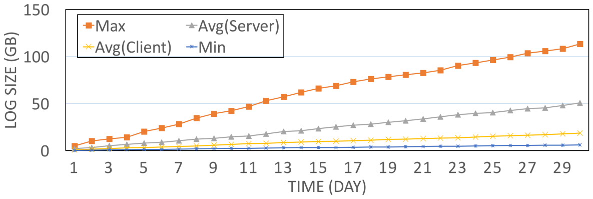

Figure 11: The space overhead of KCAL in a month

4 Evaluation

We evaluate our prototype to answer the following research questions (RQ):
RQ1: How efficient is KCAL? (§4.1)
RQ2: Can KCAL remove the redundancy while keeping the accuracy of the forensic analysis? (§4.2, §4.3)
RQ3: What are the rationales of our design choices, and what are the benefits? (§4.4)

4.1 KCAL Performance

Space Overhead. The space overhead is shown in Figure 11. The experimental environments and workloads are the same with the ones in §2. The orange shows the growth of log size for the machine that has the maximum size. In our case, the log file is less than 120GB after 30 days, while the old log size was almost 1TB without our technique (Figure 3). The gray line represents the average log size for the server machines, and the yellow line shows the average log size for the client machines. Compared with the original audit log (Figure 4), the log size is less than 10%. The workloads also include many applications that do not have the execution partitioning instrumentation, and thus do not benefit from log reduction. The blue lines show the log size of the machine that has the minimal log size. The log now is only about 6GB for 30 days. This shows that KCAL generates much smaller log files than the Linux Audit system.

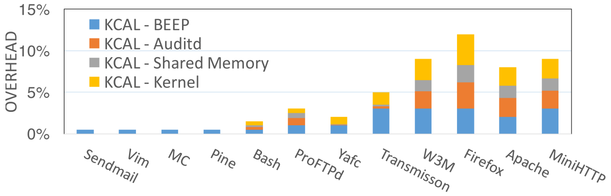

Figure 12: The KCAL runtime overhead analysis

Runtime Overhead. We used the same configuration and the same set of applications with the experiments used in §2 to measure the runtime overhead. Figure 12 shows the results. The bottom bars show the runtime overhead caused by the instrumentation, and the upper bars show the overhead caused by KCAL. For most client programs, the overhead caused by KCAL is less than 1%. The overhead for server programs is about 5% to 10%. This is because a server program needs to serve many clients at the same time, causing a large number of dependencies. Firefox has the most significant overhead, about 15%. This is because Firefox dynamically creates and terminates hundreds of threads, and uses many sockets and files for DNS queries, browsing history, cache, page preferences, and so on. It generates more events within the same duration compared with other applications, leading to higher overhead.

4.2 KCAL Log Reduction Effects

Table 1 summarizes the effects of using our log-reduction algorithm. The first two columns show the experimental environment. The third column shows the number of raw audit logs. We also present the number of log events and the corresponding percentage of in-unit redundancy (columns 4-5), cross-unit redundancy (columns 6-7), and temporary files (columns 8-9). The last two columns show the number of log entries and the percentages after reduction. We first ran the system on five machines for one month, collected the numbers (rows 3-7), and calculated the average (row 8, in gray). For different settings and runs, the reduction effects are different. Some of them have substantial in-unit redundancy (machines 1,2) while others have more cross-unit dependency (machines 4,5). Overall, KCAL keeps only 8% to 14% of the original logs, and on average the number is 11%. We also collected the reduction effects for some representative applications. The results are shown in rows 9-20 in Table 1. For different programs, the effects of the algorithm are significantly different. For example, most server programs do not have temporary files. On the contrary, browsers like Firefox use temporary files a lot. Server programs, especially FTP servers, need to read large files, and generate a huge number of in-unit redundant events, while this is not true for most client programs. For many programs like Vim, the dependency relationships are simple because they work on a limited number of system objects, and we can reduce the events to a very small number. For other programs like Bash, most of their events are related to process manipulations, which cannot be reduced. Thus, most of the logged events are kept. These process-related events will not be cached as they cannot be reduced, and they will not flood the cache. KCAL directly generates such reduced logs from the kernel, leading to substantial savings in raw log transfer from the kernel to the user space and in log processing compared to existing user-space reduction techniques [22, 24, 41].

4.3 Support for forensic analysis

We also performed a few experiments to verify the correctness of our log-reduction algorithm and the benefit for forensic analysis. We reproduced the attack cases used by previous research works [21, 23] and compared the generated graphs and the analysis time. In another set of experiments, we randomly selected 100 objects, and performed backward analysis to identify all of its dependencies. The results are summarized in Table 2. We show the number of nodes and edges in the graphs, the size of the log file, and the analysis time spent using the Linux Audit log, BEEP log, and KCAL log measured by log size. Note that BEEP logs are usually 10-30% larger than the Linux Audit logs due to the additional unit-related events. The last row shows the average number of nodes and edges, the average size of the log files, and the average analysis time for the randomly selected objects. We manually inspected and compared the graphs. The results show that all generated graphs contain the needed and complete information. The graphs generated by the Linux Audit framework usually contain redundant nodes/edges (representing wrong dependencies), whereas graphs generated by the other two methods generated the same graphs. This shows our reduction algorithm is lossless. Because of the complex dependency relationships, it takes far longer time to perform the analysis on the Audit log. BEEP benefits from simpler dependency relationships, but it spends more time inspecting the large number of log entries and checking and updating the dependency sets for each event including many redundant operations. The KCAL log provides simplified and accurate provenance information, enabling faster forensic analysis.

4.4 Understanding KCAL

Cache Behavior. Table 3 shows summarized data for cache behaviors. It shows the name of applications (column-1), the average/maximum number of dependencies in unit cache (column-2), the average/maximum num-

Table 1: KCAL log reduction effects

ber of dependencies in process cache (column-3), and the average/maximum number of events cached in a system object (column-4). From the table, it is clear that the number of dependencies in the unit cache is quite small thanks to execution partitioning. The number of dependencies in the process caches varies for different applications. In most cases, the number of dependencies is less than 200. Firefox is the only one that reaches the size limit (256) and triggers the cache replacement. For the cache in each object, the average number is less than 10 events for most programs. Even for the maximum values, the average number is still less than 32 (the cache size).

To understand the behaviors of the caches, we ran Apache and Firefox, and counted the number of dependencies they cached over time. We set the process cache bound to a large number to observe the cache pressure. Figure 13 shows the results. For Apache, we used the ab benchmark [1] with 10 concurrent clients to generate the workload. For Apache, the number of dependencies varies in a small range and remains < 70. This is because each request has just a few read/write operations on the requested file and the socket (with the client), and cached dependencies are discarded when the corresponding files and sockets are closed. For Firefox, we performed two different experiments. The first one was a normal browsing. The blue line shows the result of this experiment. Firefox uses many system objects when it loads pages. After loading the page, many dependencies can be discarded as sockets are closed and temporary files are deleted. In our test scenario, the number of dependencies (in the process dependency cache) is around 150. The other experiment used a script to open a new web page in a new tab every second. The gray line shows the results. At the beginning, each new page caused a peak, and the script opened pages more frequently than the normal user. The number of dependencies is hence larger. After 10 minutes with 500+ pages opened, Firefox reached its capacity. The number of dependencies in the cache becomes flat. Even in this extreme situation, the number of dependencies is still reasonable due to the elimination of redundant and bogus dependencies.

Kernel Memory Consumption. Figure 14 shows the maximum kernel memory footprint caused by KCAL for each application. Since our cache sizes are fixed,

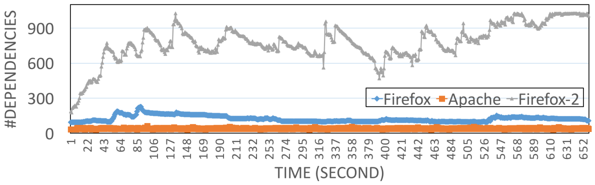

Figure 13: Number of dependencies in process dep. cache

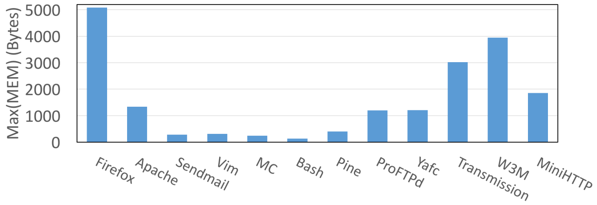

Figure 14: Max memory usage for individual applications

the memory overhead for each process including all its opened system resources (e.g., files/sockets) is fixed at 4224 bytes. In comparison, the original `task_struct` itself is 3520 bytes and it has a lot of pointers for opened system resources. One of its pointer fields `mm` pointing to a `mm_struct` is 952 bytes. Depending on the total number of system objects accessed to a process, the total memory footprint may vary a lot. However, since the number of events cached in an object tends to be small (Table 3), the kernel memory consumption is reasonably small, which ensures that KCAL does not perturb normal kernel functionalities.

Cache Size vs. Reduction Rate. The dependency cache sizes affect the reduction rate because evicting caches can result in keeping some redundant events. Previous experimental results indicate a small cache size is sufficient for many programs. In this experiment, we chose Firefox, whose dependency caches, especially the process cache, vary a lot over time, and we tested the effects of using different cache sizes. The results are presented in Figure 15. Even when the cache size is small, KCAL can still reduce many redundant events such as in-unit redundancies. With larger cache sizes, KCAL is able to detect and remove more cross-unit dependencies. If the cache is large enough (e.g., 1200 entries), all redundant dependencies are detected and the reduction rate is flat.

Comparison with State-of-the-Art ProTracer ProTracer can achieve a high reduction rate with a low runtime overhead (7% according to [24]). However, since ProTracer demands first generating the raw log before reduction, it requires parallel user-space processes to load and reduce the raw log. As a result, although its runtime overhead is low, the CPU consumption is substantial, because tainting on the large raw log files. Here we use the `ab` benchmark as an example to compare the CPU consumption of the two systems. Figure 16 shows the results.

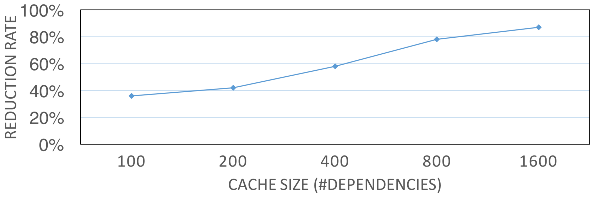

Figure 15: KCAL reduction results with different cache sizes

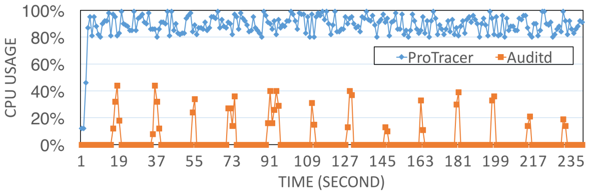

Figure 16: CPU consumption of ProTracer and KCAL

As seen in the graph, ProTracer uses the CPU consistently, and consumes almost all the cycles. In contrast, KCAL uses the CPU periodically. The average consumption is 4%. Even for the peaks, the CPU usage is about 40%, much less than ProTracer. This is because KCAL avoids generating the huge raw log in the first place and hence examines far fewer events for the same workload. In fact, ProTracer has to be pinned to a CPU to achieve the low runtime overhead. In contrast, KCAL's user-space processes just run as normal processes.

5 Conclusion

We analyzed the Linux Audit system and found the root cause of its high runtime and space overheads is its redundancy events. To solve this problem, we propose KCAL, a kernel-supported, cost-effective audit logging system for causality tracking. It caches dependencies and system events in the kernel and performs online log redundancy reduction. KCAL removes the overhead caused by transferring, processing, writing, and storing the redundant events. Our evaluation shows that KCAL can significantly reduce the log sizes and speed up the system.

EPTI: Efficient Defence against Meltdown Attack for Unpatched VMs

Zhichao Hua, Dong Du, Yubin Xia, Haibo Chen, Binyu Zang

Abstract

The Meltdown vulnerability, which exploits the inherent out-of-order execution in common processors like x86, ARM and PowerPC, has shown to break the fundamental isolation boundary between user and kernel space. This has stimulated a non-trivial patch to modern OS to separate page tables for user space and kernel space, namely, KPTI (kernel page table isolation). While this patch stops kernel memory leakages from rouge user processes, it mandates users to patch their kernels (usually requiring a reboot), and is currently only available on the latest versions of OS kernels. Further, it also introduces non-trivial performance overhead due to page table switching during user/kernel crossings.

In this paper, we present EPTI, an alternative approach to defending against the Meltdown attack for unpatched VMs (virtual machines) in cloud, yet with better performance than KPTI. Specifically, instead of using two guest page tables, we use two EPTs (extended page tables) to isolate user space and kernel space, and unmap all the kernel space in user's EPT to achieve the same effort of KPTI. The switching of EPTs is done through a hardware-support feature called *EPT switching* within guest VMs without hypervisor involvement. Meanwhile, *EPT switching* does not flush TLB since each EPT has its own TLB, which further reduces the overhead. We have implemented our design and evaluated it on Intel Kaby Lake CPU with different versions of Linux kernel. The results show that EPTI only introduces up to 13% overhead, which is around 45% less than KPTI.

1 Introduction

The recently discovered Meltdown [16] and Spectre [14] vulnerabilities allow unauthorized processes to read data of privileged kernel or other processes, which brings severe security threat especially to cloud platforms. Currently, Intel has released micro-code patches to fix the Spectre vulnerability. However, in order to fix the Meltdown vulnerability, which is much more serious and easier to exploit, users are required to apply a kernel patch named KPTI (kernel page table isolation) [30] that uses two page tables to host kernel and user programs to isolate kernel address space from any user process. While this patch can effectively defend the Meltdown attacks, it brings three issues, which leaves thousands of millions of unpatched machines in danger.

First, the patch has to be applied manually by every user. In cloud environment, although the cloud administrators can patch the host OS, they cannot directly patch guest OS running in VMs (virtual machines) since they are not allowed to do so. For example, Amazon "recommend that customers patch their instance operating systems to address process-to-process or process-to-kernel concerns of this issue" [12]. However, many cloud users are not capable of doing such system maintenance.

Second, the patch may depend on specific versions of kernel, especially for Linux. Till now, Linux community just released version 4.15 that contains the patch. The patch may not work on some early versions of kernel like 4.4 [28]. It is expected to take a long time before the patch can be applied to all the versions of Linux kernel.

Third, the patch may incur non-trivial performance slowdown. The KPTI patch makes the kernel and user process use different page tables, which causes TLB-flush during the switching between user-mode and kernel-mode and thus increases the rate of TLB miss. Prior evaluation results show that for some system-call intensive workload, the performance penalty may be high as 30% in VMs [22]; our own experiments confirmed such performance slowdown (Section 6).

In this paper, we present an alternative approach to defending against Meltdown attack for VMs in cloud. Our approach, namely EPTI, can be applied to unpatched guest VMs without users' awareness and can achieve better performance than KPTI at the same time. First, instead of using two gPTs (guest page tables) as in KPTI, EPTI uses two EPTs (extended page tables), namely EPT_k and EPT_u, to run the kernel and user processes, correspondingly. The guest kernel and user still share one gPT, but in user mode, the gPT entries for mapping kernel address space are set to zero in EPT_u, which forbids any translation of address within kernel space to mitigate the Meltdown attack. Second, we leverage one of Intel's hardware features for virtualization, named *EPT switching*, to switch the two EPTs within the VM itself without causing any VMExit. We use binary instrumentation to insert two trampolines at the entrance and exit of guest kernel to do the EPT switching, which does not require kernel's source code and has little (if any) dependence on kernel versions. Third, through a detailed micro-architectural analysis, we find that EPT switching can be more efficient than gPT switching. Since each EPT has its own TLB, when switching the EPTs there will be no TLB flushing by hardware, which is the main reason of performance degradation of KPTI. We also adopt several optimizations to minimize the number of VMExits to further reduce the overhead. Fourth, EPTI can be seamlessly deployed in the cloud by combining with live VM migration [5]: a host can migrate away all the guest VMs, patch the host hypervisor with EPTI, and then migrate all the VMs back.

We have implemented EPTI on KVM and use unmodified Ubuntu distribution as guest VM for evaluation. We conduct a detailed security analysis as well as evaluation to show that our EPTI can achieve the same security guarantee as KPTI. We also evaluate real-world benchmarks to measure the performance overhead. The results show that the *average* performance overhead on server applications of EPTI is about 6%, which is 45% lower than KPTI whose *average* overhead is 11%.

To summarize, this paper makes the following contributions:

- An EPT-level isolation of kernel's and user's address spaces to defend against Meltdown attack for unpatched guest VMs.
- Several optimizations to achieve better performance than the current solution KPTI.
- A prototype of our design on real hardware for performance and security evaluation.

2 Motivation and Background

2.1 Meltdown Attack and KPTI

The Meltdown vulnerability was published in January 2018, known to affect Intel's x86 CPU, ARM Cortex-A75 [16] and some versions of PowerPC processor [11]. Through this attack, a malicious user application can steal contents of kernel memory in two steps. Step-1: to access kernel address *A* and to leverage its data as an index to access the cache; step-2: to get the data through cache covert channel. The key problem here is that the Step-1 is executed reordered and will be canceled eventually, but the cache layout is affected without rollback. Since the kernel will typically map all the physical memory within its memory space, the malicious application can potentially get all of the memory contents.

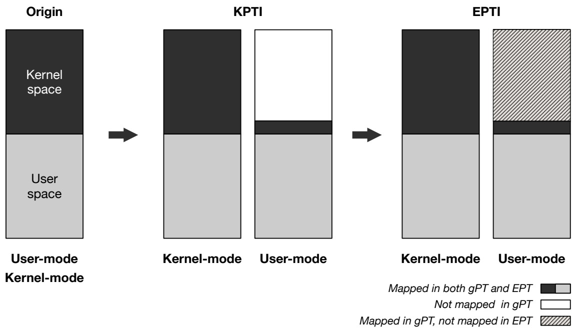

Figure 1: Page table isolation. For a VM, KPTI uses two gPTs and one EPT, while EPTI uses one gPT (since VM is not patched) and two EPTs.

KPTI (kernel page table isolation) [30] is based on KAISER (kernel address isolation to have side-channels efficiently removed) [19], which is proposed to defend against the Meltdown attack. This patch separates user space and kernel space page tables entirely, as shown in Figure 1. The one used by kernel is the same as before, while the one used by application contains a copy of user space and a small set of kernel space mapping with only trampoline code to enter the kernel. Since the data of kernel are no longer mapped in the user space, a malicious application cannot directly de-reference kernel's data address, and thus cannot issue Meltdown attack. KPTI has been merged to the mainstream Linux kernel 4.15, which was released on 28 Jan, 2018. However, the patch still has problems on previous Linux kernel versions. For example, it is reported that some Ubuntu user "just got the Meltdown update to kernel linux-image-4.4.0-108-generic but this does not boot at all" [28]. Considering the patch needs to be applied manually by system administrators, it may take a long time before most of the machines getting the patch deployed.

2.2 Overhead of KPTI

KPTI introduces performance overhead since both entering-kernel and exiting-kernel require additional page table switching. The switching is done by loading the CR3 register, which takes around 300 cycles. Meanwhile, since TLB (translation lookaside buffer) will be flushed during CR3 changing, the performance will further be affected due to higher TLB miss rate. There

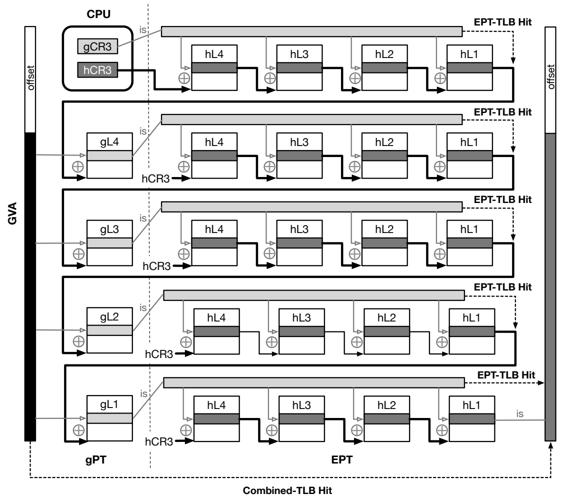

Figure 2: Process of translating GVA to HPA in an x86-64 guest VM. The gCR3 of CPU points to gPT and hCR3 points to EPT.

are many reports on evaluations of KPTI's overhead, which show that KPTI could lead to significant performance cost (up to 30%), particularly in syscall-heavy and interrupt-heavy workloads [30, 25, 18].

On processors that support PCID (process-context identifiers) feature, a TLB flush can be avoided and the performance overhead of KPTI can be reduced. PCID is a 12-bit tag of page table and is saved as a part of a TLB entry. For two page tables with different tags, their TLB entries can co-exist in the CPU and no TLB flush is needed when switching between the two page tables. Existing report shows that after enabling PCID, the overhead of KPTI on PostgreSQL's read-only test on Intel Skylake processor reduces from 17-23% to 7-17% [18]. However, Linux does not support PCID until version 4.14 released on 12 Nov 2017.

2.3 gPT, EPT and TLB

In native environment, PT (page table) is used for translating virtual address to physical address. In virtualization environment, the guest VM (virtual machine), running in non-root mode, only controls its GVA (guest virtual address) to GPA (guest physical address) mapping by gPT (guest page table). The hypervisor, running in root mode, controls each VM's GPA to HPA (host physical address) mapping through a hPT (host page table), which is called EPT (*extended page table*) on Intel platform [1].

Figure 2 shows the procedure of GVA-to-HPA translation on an x86-64 machine with 4 level gPT and EPT. The value of guest CR3 and addresses inside gPT are GPAs, while the value of EPTP and address inside EPT are HPAs. When CPU walks the gPT, it needs to translate all the GPA of needed gPT pages to HPA through EPT.

In order to minimize memory footprint during page walk, the processor has two types of TLB in virtualized environment: EPT-TLB and combined-TLB. The EPT-TLB is used for accelerating translation from GPA to HPA, while the combined-TLB stores entries of translation from GVA to HPA.

2.4 EPTP Switching with *VMFUNC*

VMFUNC is an Intel hardware virtualization extension, which provides VM functions for guest VMs, running in non-root mode, to directly invoke without VMExit. Currently, there is only one VM function provided by *VMFUNC*, named "EPTP switching", which allows software (either in the kernel mode or user mode) in guest VM to load a new EPTP (EPT pointer). Guest can only switch to the EPEP from a list of valid EPTP values configured by the hypervisor. The EPTP switching is supported on all Intel CPUs starting from Haswell architecture.

Performance of EPTP switching: We compare the latency of loading CR3 and EPTP switching. Writing the same value to the CR3 in guest VM costs around 300 cycles, with PCID enabled. While the "EPTP switching" takes about 160 cycles (two different EPTP values, but have the same mappings).

TLB behavior of EPTP switching: We further test the TLB behavior of EPTP switching and find how CPU constructs address mapping in TLB for different EPTs. The operations performed with one EPT will not affect other EPTs, Table 1 shows test results. In the table, "Invalid both EPTs' TLBs then fill EPT-0's TLB" means we first invoke *invlpg* instruction (which is used to flush TLB) in both EPT-0 and EPT-1, and then access the target memory in EPT-0. After that, we access the target memory again in both EPT-0 and EPT-1, and test the access latency. The result means that the EPT-0's is filled while the EPT-1's is not. We also test whether invoking flush TLB operations (write CR3 and *invlpg*) in one EPT will influence the other's TLB or not. We find that both of them flush other EPT's TLB.

3 System Overview

EPTI has three goals:

- **Goal-1**: To achieve the same security level as KPTI.
- **Goal-2**: To support protection on unpatched VMs seamlessly.
- **Goal-3**: To get better performance than KPTI.

[1] The hPT of AMD is called NPT (*nested page table*). Since the Meltdown attack only affects Intel's processor, we use "EPT" instead of "hPT" in the rest of the paper.

Table 1: TLB behaviors of different EPTs during *VMFUNC*.

Action	Access again in EPT-0	Access again in EPT-1	Conclusion
Invalid both EPTs' TLBs then fill EPT-0's TLB	3-5 cycles	120+ cycles	Each EPT has its own mapping in TLB.
Fill both EPTs' TLBs then write CR3 in EPT-0	120+ cycles	120+ cycles	Writing CR3 will flush TLB of all EPTs.
Fill both EPTs' TLBs then *invlpg* in EPT-0	120+ cycles	120+ cycles	*invlpg* will flush TLB of all EPTs.

We first construct two EPTs for each guest VM: EPT_k for kernel and EPT_u for user. The mapping of EPT_k is the same as original EPT (but with different permissions, which will be introduced later), so that the kernel will run just as before. When user applications are running, we need to ensure that they cannot access (even speculatively) any data in the kernel address space.

One intuitive way is to remove all the mappings of HPA of pages used by guest kernel in EPT_u, so that all kernel pages are not mapped when a user process is running. However, this solution does not work since typically Linux kernel will map *the entire GPA* to its GVA space, which is known as *direct mapping*, as shown in Figure 3. It means that we have to remove all of the GPA mappings from EPT, which will also disable the execution of user processes.

Instead, we just remap all the *gPT's pages that map kernel space* in EPT_u to a zeroed page, as shown in Figure 3. Thus, once a user process tries to access kernel address using its GVA, the GVA will never be translated to GPA since the CPU cannot find the corresponding mapping in gPT (refer to the left part of Figure 2). The security guarantee is the same as KPTI (**Goal-1**).

Next, we need to find a way to switch the EPTs at appropriate points. When a user process traps to kernel, the processor should immediately switch to EPT_k by *VMFUNC*. It also switches to EPT_u before the kernel returns to user process. In Linux kernel, there are limited entry points and exit points. The entry points can be located through IDT (interrupt descriptor table) and some specific MSRs (model-specific registers) [2]. The exit points must contain specific instructions (e.g., *sysretq*). Thus, we use *binary instrumentation* to re-write the kernel code on-the-fly to insert two pieces of trampoline code at the entry and exit points, which are mainly used to do the EPT switching. Leverage this method, EPTI can be used together with live migration to seamlessly protect a guest without rebooting it. More details are described in Section 4.3 (**Goal-2**).

In order to unmap the kernel space in EPT_u, we need to track which gPT pages are used for mapping kernel space, and zero them in EPT_u. EPTI tracks the gL3 pages, which are used to translate kernel GVA, and zero them (details in Section 4). We further present our optimizations in Section 5 to reduce the number of VMExits and get better performance (**Goal-3**).

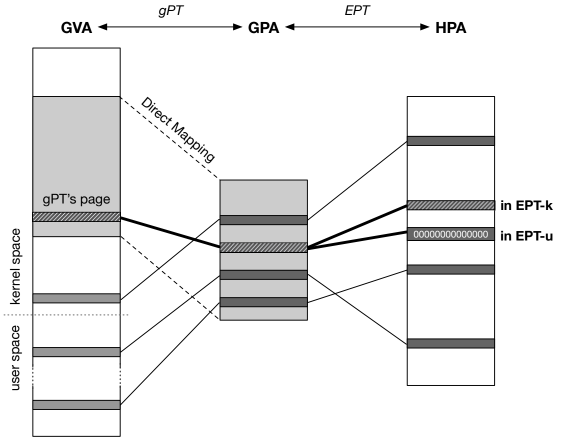

Figure 3: The difference of mapping of EPT_u and EPT_k.

Challenges: There are still many challenges on security and performance in the above design. For example, since it is allowed for a user process to invoke *VMFUNC*, a malicious process may try to switch to EPT_k before issuing Meltdown attack. We will describe our design with more details and present solutions to these challenges in the following text.

4 Design of EPT Isolation

In this section, we introduce the basic design of EPTI. Firstly, we need to construct the EPT_u, which removes all the kernel address mappings. Then, we introduce the basic method of how to track kernel gPT pages and add trampoline code for EPT switching. Finally we construct the EPT_k so that a malicious user cannot switch to it.

4.1 Zeroing gPT for Kernel Space in EPT_u

We remove all the GVA-to-GPA mappings of kernel address space in user mode by zeroing the gPT pages used for address translation in EPT_u. As shown in Figure 3, to zero a gPT page, we remap it to a new zeroed physical page in EPT_u. There are 4 page levels (from gL4 to gL1) in a 64-bit Linux kernel which uses 48-bit virtual address. Since each process has different gL4 pages , to minimize the modification to EPT_u, we only zero the gL3 pages used for kernel address translation (gPT structure is shown in Figure 5).

[2] E.g., IA32_LSTAR controls syscall entry.

After zeroing the gL3 pages for kernel space in EPT_u, accessing kernel memory from user mode will trigger a guest page fault since the target GVA is not mapped (although Meltdown attack can bypass permission check, it cannot access non-mapped pages). Since the kernel runs in EPT_k, it can never fill the zeroed gL3 page in EPT_u and the attacker's user process can never access the kernel memory (even speculatively).

4.2 Tracking gPT Pages in EPT_k

In order to zero all the gL3 pages that map kernel space in EPT_u, EPTI first needs to track all the gL3 pages for the kernel. Specifically, by setting the *CR3_LOAD_EXITING* bit in *VMCS* (virtual machine control structure), when a guest kernel changes CR3 it will trap to the hypervisor, which will then walk through the gPT to get a list of all gL3 pages for kernel space mapping. Meanwhile, the guest kernel may allocate new gL3 pages and add them to gL4. In order to track new kernel gL3 pages, all the gL4 pages will be mapped as read-only in EPT_k, so that each time a guest kernel adds a new gL3 page to gL4, it will trap to the hypervisor to update the monitored gL3 page list. We will present some optimization of tracking in Section 5.

4.3 Trampoline for EPT Switching

Listing 1 EPT switching to EPT_k

```
1:  SWITCH_EPT_K:
2:   SAVE_RAX_RCX
3:   movq $0, %rax
4:   movq $0, %rcx
5:   vmfunc
6:   RESTORE_RAX_RCX
```

The trampoline code contains instructions for EPT switching. Listing 1 shows the assembly code for switching from EPT_u to EPT_k. The *%rax* and *%rcx* contain the *VMFUNC index* and arguments passed to the *VMFUNC*. Line 3 means to call the first *VMFUNC* function (EPTP switching, index 0), and line 4 means to switch to EPT-0. Both *%rax* and *%rcx* are caller-saved, so the values need to be saved and restored in the trampoline. The process of *SWITCH_EPT_U* is similar but in the other direction.

Since the trampoline code is used to switch between EPT_k and EPT_u, it needs to be invoked in both EPTs. We need to ensure that: (1) the trampoline is executable in both EPTs and (2) there is a suitable place to store the caller-saved registers.

Mapping trampoline as executable in both EPTs: In EPT_u, only one page with the trampoline code will be mapped in the kernel space. To ensure that, EPTI remaps all the gPT pages (except gL4), which are used to translate the GVA for the trampoline, to new host physical pages. Then all the entries of these pages are set to zero, except those that used for mapping the trampoline (as shown in Figure 4). Entries of the guest IDT and the syscall entry MSR (IA32_LSTAR) will be changed to point to the trampoline code. In EPT_k, EPTI inserts the trampoline code to the end of direct map region of guest kernel, and re-writes the binary of kernel to change the exit points to *jmp* instructions that transfer control to the trampoline.

Saving caller-saved registers: Since *VMFUNC* will not save any register by hardware (which makes it fast), the trampoline code cannot use any register before saving them. One challenge to save these caller-saved registers is to support multi-core. For single CPU core, the value of %rax and %rcx can be saved to a memory page with a fixed address. However, for multi-core, one core may overwrite the saved register values of another core since they write to the same address.

Linux solves this problem by using *gs*-based per_cpu value. During system boot, it allocates a per_cpu memory region for each core. The base addresses of these regions will be recorded through *gs* registers of different cores after entering the kernel (through *swapgs* instruction) [3]. The following access of per_cpu values is performed by *%gs:index*. EPTI cannot leverage this method because: (1) it needs to know some specific semantics of the kernel and (2) it needs to map kernel's per_cpu region into EPT_u.

EPTI provides a per_vCPU memory page to save and restore the caller-saved registers. Specifically, a memory page is mapped into the kernel space in both EPT_u and EPT_k. To enable concurrent accesses from multiple cores, the page will be mapped to different physical pages for different vCPUs, so that when one vCPU saves %rax and %rcx, the values are written to its own page. In our implementation, we modify gPT to map this page to an unused GPA (e.g., the GPA out of the guest's DRAM range). In the EPTs for different vCPUs, we map this GPA to different HPA. In both EPT_k and EPT_u of one vCPU, it is mapped to the same HPA.

Seamless protection: Combined with live migration, EPTI can seamlessly protect a guest VM without rebooting it. The cloud provider can migrate away all the VMs, update the host hypervisor to enable EPTI and migrate all the VMs back. To resume a VM on EPTI, we need to: (1) map the trampoline into the guest; (2) rewrite the entries for interrupts and syscalls (stored in IDT and MSR), as well as the exit points (contain specific instructions e.g., sysretq), to jump to the trampoline; (3) enable the trapping of gPT and guest EPTP switching.

[3] The *swapgs* instruction exchanges the current *gs* value with the value stored in MSR_KERNELGSbase.

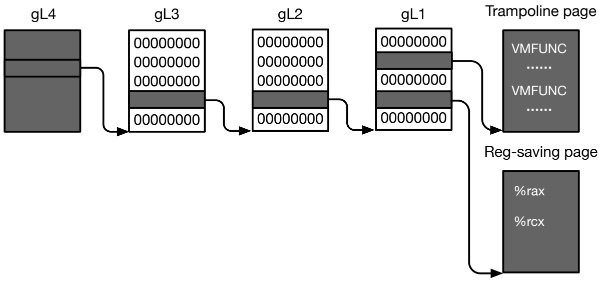

Figure 4: Contents of kernel space of EPT_u, which includes trampoline code page, register saving page, and gPT for mapping these two pages.

4.4 Malicious EPT Switching

The above design relies on an assumption that only the kernel can switch EPT. Unfortunately, the *VMFUNC* instruction can be invoked in either guest kernel mode or guest user mode, which enables an attacker to maliciously switch to EPT_k by *VMFUNC*, issue Meltdown attack and switch back to EPT_u. To defend this attack, EPTI needs to make EPT_k useless for the user process.

By performing real Meltdown attacks, we find that although Meltdown can read the memory without access permission, it cannot fetch code without executable permission even in reorder-execution. Base on this observation, we map all user memory as execute-never in EPT_k. Thus, once the user maliciously switches to EPT_k, all its code will be non-executable.

Specifically, EPTI only maps the guest physical memory (including kernel's code and kernel modules) as executable in EPT_k, and all other guest physical memory is mapped as execute-never. The kernel code is loaded during system booting and will not be changed during execution, EPTI can detect all the corresponding GPAs by searching gPT. The kernel modules are loaded/removed dynamically during runtime, EPTI needs to monitor all the guest physical pages used for them. This is done by trapping all write operations on gPT pages which translates GVA-to-GPA mapping of kernel modules. Since Linux kernel reserves a fixed GVA region for kernel modules, trapping modifications to the corresponding gPT pages will only influence the performance of installing/removing kernel modules.

5 Optimizations

As mentioned in the previous section, EPTI needs to trap both the load-CR3 operation and the write-gL4 in guest VMs. These trapping methods have three performance problems:

- **Useless traps of load-CR3**: EPTI traps guest VM's load-CR3 operations for getting all the gPTs. In fact, EPTI only needs to trap the *new* gPTs, but most of the load-CR3 operations just load old gPTs, which causes a lot of useless VMExits.
- **Access/Dirty bits update**: To trap the modification of a gPT page, EPTI marks it as read-only in EPT_k. However, for each memory access (including read, write and fetch), the CPU will update the A/D bits (access/dirty bits) in the gPT entries which are used for translating the target GVA, even when the A/D bits are already set by previous operations. Thus, whenever the kernel accesses any of its data, it will trigger an EPT violation, which causes a huge number of VMExit.
- **Additional traps of write-gPT**: In Section 4.2, EPTI traps all write-gL4 operations to track all enabled gL3 for kernel space mapping. However, each process has one gL4 page, which means EPTI needs to trap thousands of gL4 pages. Since kernel address mappings are the same for each process, trapping all these gL4 can be optimized.

In this section, we give several optimizations to solve all these performance problems.

5.1 Selectively Tracking Guest CR3

EPTI leverages a hardware feature to reduce the number of VMExit caused by trapping loading old CR3. Intel provides four *CR3_TARGET_VALUE* fields in *VMCS*. A load-CR3 in guest does not cause a VMExit if its source operand matches one of these values. We write the CR3 value, which 1) causes more than *threshold A* VMExits per second or 2) totally causes more than *threshold B* VMExits, to the *CR3_TARGET_VALUE* (A and B can be configured by the VMM).

5.2 Setting gPT Access/Dirty-Bit

In order to eliminate VMExit when CPU setting A/D-bit, we need to allow CPU to write gPT while disallowing kernel to do so. We find that the access path of them are different: the kernel writes gPT through its GVA (using both gPT and EPT), while the CPU writes gPT through its GPA (using EPT only). Thus, EPTI maps gPT pages with write permission in the EPT to allow CPU updating the A/D bits. To trap kernel modifying a gPT page, we redirect the GVA of this page to a new GPA which is mapped as read-only in EPT_k. This is done by (1) modifying the gL1 entry that is used for GVA-to-GPA translation of the target gPT page and remapping the gPT page to a new GPA; (2) mapping the new GPA to the original HPA as read-only, which contains the target gPT page. Thus, only the write access to the gPT page from kernel will trigger a VMExit.

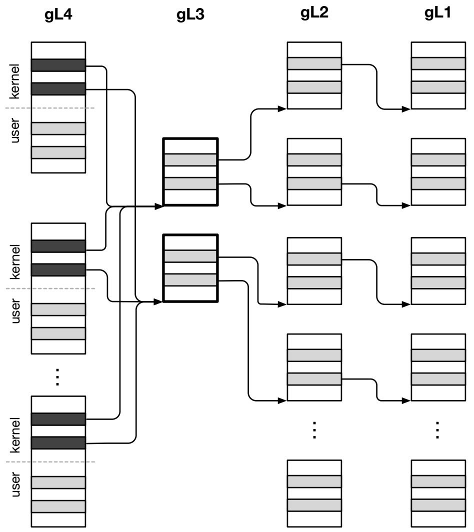

Figure 5: gPT of Linux. The kernel gL3 entries are shared by different gPTs.

5.3 Trapping gL3 Pages Instead of gL4

We adopt another optimization according to the following observations:

- *Most kernel virtual address regions are never changed.* Linux kernel reserve memory regions for different usages [4], and it never changes the mapping of most of these regions (e.g., direct map region is never changed).
- *Each gL3 pages can translate a large virtual space (512GB).* In a guest, it is almost impossible for the kernel to allocate so much virtual memory, so the number of kernel gL3 pages is rarely changed.
- In Linux kernel implementation, kernel only creates a new gL3 page when all entries of existing gL3 pages are in use, or the continuous free entries are not enough.

Based on the above observations, EPTI directly traps the modification of gL3 pages for kernel by default. When the last entry of a gL3 is used, which means the kernel may allocate a new gL3 page later, EPTI starts to trap the load-CR3 and write-gL4 until a new gL3 page is allocated. With this optimization, EPTI almost does not need to trap the operations of load-CR3 and write-gL4, which will reduce most (if not all) of VMExits.

6 Evaluation

In the evaluation, we try to answer these seven questions:

- *Question-1*: Can EPTI prevent Meltdown attacks?
- *Question-2*: How EPTI influences the performance of kernel critical operations (e.g., syscalls)?
- *Question-3*: How EPTI influences the performance of real server applications?
- *Question-4*: How EPTI influences the performance of multiple guest VMs?
- *Question-5*: How many VMExits are reduced by different optimizations of EPTI?
- *Question-6*: Can EPTI work on different kernel versions and how about the performance?
- *Question-7*: Can a guest VM be live migrated to hypervisor with EPTI and what is the performance?

6.1 Evaluation Environment

We do the evaluation on an x86-64 machine with an 8-core Intel Core i7-7700 CPU, 16GB memory and a Samsung 512GB SSD. We implemented EPTI with KVM based on Linux kernel 4.9.75 running in Ubuntu 14.04. We assigned 4 vCPUs (virtual CPUs) and 8GB memory to the guest VM, which runs an Ubuntu 16.04. The Linux kernel 4.9.75 is used as the guest kernel by default. In Section 6.4, we also test the overhead of multiple guest VMs. In Section 6.6, we test various kernel versions in the guest VM.

We isolate four physical cores on the host and each vCPU of the guest is pinned to a physical core. We use *virtio* to virtualize guest disk. During the evaluation, all the clients and server applications are running in the guest VM to reduce the influence of network.

In the performance evaluation, we test five systems: “Linux” (without KPTI), “KPTI” and EPTI with different optimizations, in which “EPTI-No” means EPTI with A/D bits updating, “EPTI-CR3” means applying A/D-bit updating and *CR3_TARGET_VALUE* to reduce VMExit caused by frequently loaded CR3, and “EPTI-CR3+L3” means applying all three optimizations.

6.2 Security Evaluation

First we implemented a PoC (proof of concept) of Meltdown attack, which has three steps: *step-1*: reads secret **S** from *kernel address*; *step-2*: uses **S** as an index to access memory (covert channel); and *step-3*: probes the cache and gets the value of **S**. The PoC also registers a signal handler of the segmentation fault to continuously perform the attack.

We use this PoC to steal *linux_proc_banner*, a value stored in kernel space (the PoC can also steal any other data in the kernel address space). It succeeds on Linux without KPTI, but is failed when using KPTI and EPTI. We then insert a *VMFUNC* in the PoC to make it switch to EPT_k just before step-1. The attack does not work

[4] e.g., In Linux with 48-bit VA, range from 0xffff880000000000 to 0xffffc7ffffffffff is used for direct map, and range from ffffc90000000000 to ffffe8ffffffffff is used for *vmalloc* and *ioremap*.

Table 2: Evaluation results of LMBench, in μs.

Operation	Linux	KPTI	EPTI-No	EPTI-CR3	EPTI-CR3+L3
Null syscall	0.04	0.16	0.12	0.12	0.12
Null I/O	0.07	0.2	0.17	0.17	0.16
Open/Close	0.70	0.93	0.84	0.84	0.83
Signal Handle	0.68	0.81	0.76	0.76	0.76
Fork syscall	72.9	79	80	80	75
Exec syscall	212	243	242	234	221
ctsw 16P/64K	6.07	7.37	7.66	7.66	6.39

on EPTI due to the defense mentioned in Section 4.4. We also try to pass a constant value through the covert channel after switching to EPT_k, which also fails.

The security evaluation shows that our system can successfully defend against existing Meltdown attacks, even if a malicious process switches to EPT_k first. Actually, a user process cannot execute any code in EPT_k. Logically, both EPTI and KPTI isolate the address space of user and kernel mode, so both of them can defend against Meltdown attacks.

6.3 Micro Benchmark

LMBench [21]: To answer *Question-2*, we use LMBench to test the time of some critical operations, e.g., syscall like *fork* and *exec*. As shown in Table 2, the *null* syscalls of unmodified Linux and KPTI take 0.04μs and 0.16μs, respectively. For EPTI, the time is about 0.12μs, which is smaller than KPTI due to the benefit of no-TLB-flushing of *VMFUNC*. The Null I/O, Open/Close and Signal Handle have the similar results as the *null* syscall. In all cases, EPTI performs better than KPTI. There is no difference between EPTI with different optimizations, because these operations do not involve load-CR3 or write-gL4.

For other three operations (*fork*, *exec* and context switch), EPTI-No and EPTI-CR3 take more time than EPTI-CR3+L3 because these operations contain many load-CR3 and write-gL4 operations. In LMBench, the EPTI-CR3 (optimized with *CR3_TARGET_VALUE*) has the same result with EPTI-No since a process is terminated before being identified as *trapping frequently*. The result of LMBench shows that both EPTI and KPTI have overhead on single critical operation, and the overhead of EPTI is smaller than KPTI.

SPEC_CPU 2006 [8]: We evaluate *all* of SPEC_CPU 2006 INT applications under five systems. As shown in Figure 6 (a), there is almost no overhead in both KPTI and EPTI, since these CPU-related applications rarely interact with the kernel.

6.4 Application Benchmark

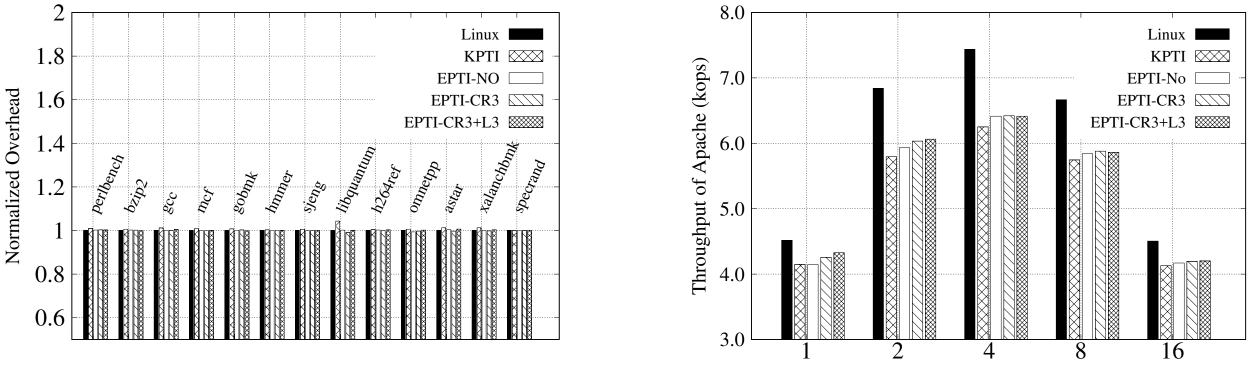
To answer that how EPTI influences the performance of server applications (*Question-3*), we evaluate the performance overhead of file system operations, databases and web servers.

Fs_mark [27] is used for evaluating file system performance. We configure it to continuously create 1MB files in the guest VM and use synchronization method 1 (call *fsync* before close a file), with different number of threads (each thread create 1000 files). The result is shown in Figure 7 (a), the KPTI has 6.5% overhead in single thread while our system has 1.1%. The overhead of both EPTI and KPTI are small because of the slow disk I/O performance for the guest.

Redis [24] is used for evaluating key-value store workloads. We use the standard redis-benchmark to test the throughput of *SET* and *GET* operation of Redis. The redis-benchmark is configured to use different numbers of threads (from 1 to 8) and the Redis runs with default configuration. Figure 7 (b) shows the result. The X-axis means the test operation and the number of threads used by the client (e.g., *SET-1* means *SET* operation with one thread). On the average, KPTI has about 12% of performance overhead while EPTI has 6%. In the worst case, KPTI has more than 20% overhead and our system has 12%.

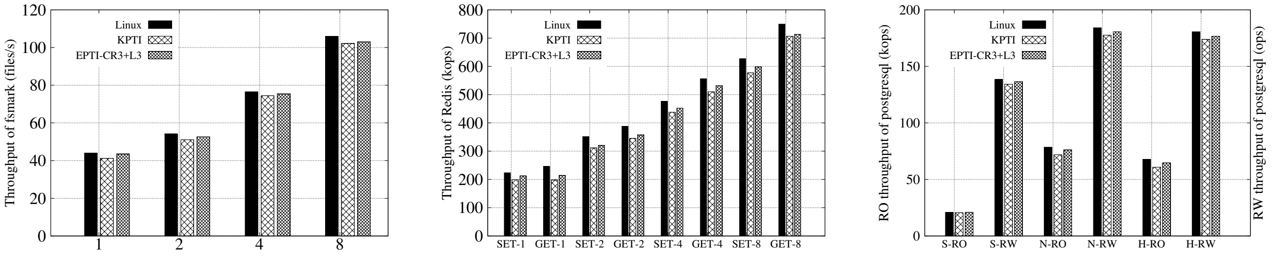
PostgreSQL [23] is a relational database. We test its performance with the *pgbench* (a benchmark provided by PostgreSQL based on TPC-B). We test the throughput of read-only and read-write transactions of PostgreSQL under three different loads: *single thread (S)*: using one database client; *normal (N)*: opening 4 test threads and 16 database clients; *heavy (H)*: opening 8 test threads and 64 database clients. The *pgbench* operates on a small database table with 1000 records. Each test is performed on a cleaned table and lasts for 60 seconds. The PostgreSQL is running with default configuration. The result is shown in Figure 7 (c). The unit of throughput of RO transaction is *kops* and the unit of RW is *ops*. Both KPTI and EPTI have small overhead for single thread *pgbench*. The overhead increases dramatically in the normal and heavy loads. In the Heavy-RO test, KPTI has about 12% overhead while our system has about 4%.

MongoDB [3] is a widely-used non-relational database. We use YSCB benchmark to test the performance of it with different workloads. Each workload is performed on a table with 10,000 records and we configure YCSB to use 32 test threads. The MongoDB uses the default configuration. We test all the standard workloads of YSCB (from workload-A to workload-F) and the result is shown in Figure 8 (a). On average, KPTI has about 7% performance overhead while our system has about 2%.



(a) SPEC_CPU INT **(b) Apache**

Figure 6: Figure (a) shows the overhead of all INT applications in SPEC_CPU 2006 benchmark, lower the better. Figure (b) shows the throughput of Apache with different number of clients, higher the better.



(a) fs_mark **(b) Redis** **(c) PostgreSQL**

Figure 7: Figure (a) shows the throughput of fs_mark with different threads. Figure (b) shows the throughput of SET and GET operations of Redis with different threads used by the client. Figure (c) shows the throughput of PostgreSQL under different workloads of RO (read-only) and RW (read-write) transactions. Higher the better.

Apache [1] is a widely-used web server. We use *ab* (apache benchmark) to test the throughput of Apache. It continuously downloads a 1MB static web page from the Apache, with different client threads (1 to 16). The Apache server uses default configuration (event mode). Figure 6 (b) shows the throughput of Apache. The performance drops after 4 client threads since we use 4 vCPUs in the VM. The overhead of KPTI is 15%-18%, while our system (EPTI-CR3+L3) has about 10% overhead.

Nginx [2] is a lightweight web server. We also test it by *ab* benchmark with a 1MB static web page and different threads (1 to 16). The Nginx server runs with default configuration. The throughput of Nginx is shown in Figure 8 (b). In the worst case, the overhead of KPTI is 18% and ours is 12%.

Multiple guest VMs: We evaluate the overhead of EPTI on multiple guest VMs (for *Question-4*). Each VM is configured to have 1 vCPU and 1GB memory, and all the VMs' vCPUs are pinned on 4 physical cores. We use linux 4.15 as the guest kernel, and run a Nginx server as well as an *ab* benchmark tool in each VM. The result is shown in Figure 9, the average overhead of KPTI is about 16% while our system is about 9%

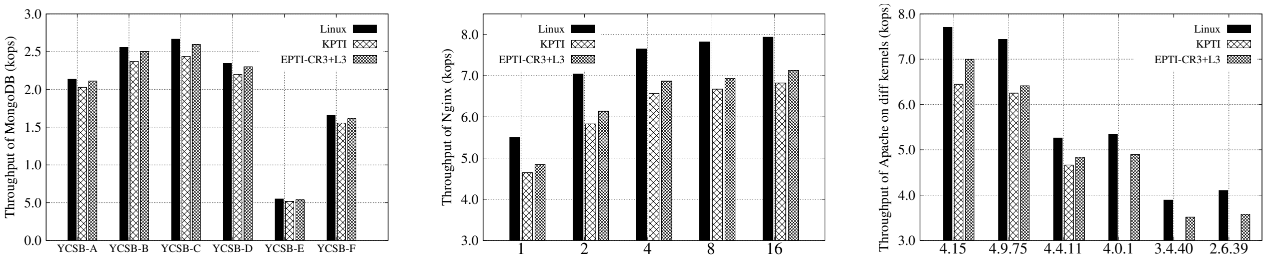
Table 3: Number of VMExit caused by EPTI.

Benchmark	EPTI-No	EPTI-CR3	EPTI-CR3+L3
Redis 1-thread	540	464	0
Redis 8-thread	385	315	0
Apache 4-thread	45406	225	0
Apache 32-thread	40149	623	0
Compile Kernel -j8	609659	551023	0

6.5 Breakdown of Optimizations

To answer how different optimizations reduce the number of VMExit of EPTI (*Question-5*), we test the performance of Apache on EPTI with different optimizations. Figure 6 (b) shows the result. In the best case (1 client thread), EPTI-No has about 9% performance overhead which is almost same as KPTI. EPTI-CR3 only has 5% overhead while EPTI-CR3+L3 has 4%.

To give a detailed breakdown of the performance improvement, we analyze the number of VMExits in EPTI with different optimizations. We calculate the total number of VMExits caused by EPTI of the whole guest in three scenarios: (1) running redis-benchmark to test Redis (1,000,000 operations with 1 or 8 threads); (2) running ab to download 1,000 1MB web pages (with 4 or



(a) MongoDB **(b) Nginx** **(c) Apache on different kernel versions**

Figure 8: Figure (a) and (b) show the throughput of MongoDB and Nginx, higher the better. For MongoDB, we test it with YSCB and X-axis means the different YSCB workloads. For Nginx, we test it by using ab benchmark with different threads. Figure (c) shows the throughput of Apache on different kernel versions, X-axis means the kernel version.

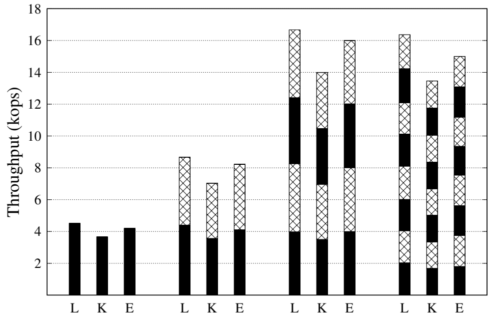


Figure 9: Throughput of Nginx on multiple guest VMs. (L means Linux, K means KPTI, E means EPTI-CR3+L3)

32 client threads); and (3) compiling Linux kernel 4.9.75 with "defconfig" (including kernel modules, "make -j8"). The result is shown in Table 3.

As shown in the table, the optimization of selectively trapping load-CR3 does not have much effect on Redis and kernel compilation, but is effective for Apache. This is because EPTI-CR3 can only reduce the VMExit caused by frequently loading CR3 value, while both Redis and redis-benchmark are single-process that have very few load-CR3 or write-gL4 operations. In kernel compilation, the Makefile creates a gcc process to compile each C file, which produces a huge number of processes with different CR3. Since each gcc process works for a short time, there is no long-term frequently-used CR3 which means the EPTI-CR3 cannot effectively reduce the number of VMExits (theoretically, the result of EPTI-CR3 can be improved by a better algorithm for replacing the value of *CR3_TARGET_VALUE*). On the contrary, Apache with event mode uses a few (typically 4) child processes to manage all the worker threads. Most of the VMExits are caused by loading the CR3 of Apache's child process, which can be optimized by storing their CR3 in *CR3_TARGET_VALUE*.

For all scenarios, there is no modification on kernel gL3, so the number of VMExit can be further reduced to 0 by EPTI-CR3+L3. The reason we still need both optimizations is that operation on kernel gL3 is highly OS dependent, while the optimization of selectively trapping CR3 is more general.

Table 4: VM live migration to host with EPTI, in *ms*.

	KVM w/o EPTI	KVM w/ EPTI
Total time	15779.5 ±1112.03	15782.6 ±1111.86
Downtime	6.1 ±0.82	9.2 ±1.03

6.6 Different Kernel Versions

To answer *Question-6* (could EPTI works on different kernel versions and how about their performance?), we test the performance of EPTI on different Linux kernel versions (selected from 2.6 to 4.15). We run Apache on them and use *ab* benchmark with 4 client threads to evaluate the throughput. The result is shown in Figure 8 (c). Our system has higher performance than KPTI in all the kernel versions (excluding kernels which do not have KPTI support). In the newest kernel 4.15, which enabled PCID, the performance of Linux w/o KPTI is improved obviously. However the KPTI of Linux 4.15 still has about 17% overhead, while our system has 10%.

6.7 VM Migration

To answer the last question, we test the total time and downtime of VM live migration, from a host without EPTI to one with EPTI. The source machine deploys an unmodified Linux kernel 4.9.75 with the same hardware configuration as mentioned, and the target is the one we use in previous evaluation. We use both the unmodified KVM and KVM with EPTI as the target hypervisor. A guest VM can be seamlessly migrated to a hypervisor with EPTI and the overhead is small. Table 4 shows the average migration time together with the stddev (test for 4 times). The downtime increases 3 ms which is caused by the scanning of code region in memory, preparing for two EPTs and binary writing.

7 Related Work

Besides the work mentioned, we now present the systems that also leverage similar hardware features for enhancing system security or performance.

KAISER [19] was proposed to defend against attacks on KASLR [10, 7, 13], which can also prevent Meltdown since it ensures no valid mapping to kernel space in user mode. It is later replaced by KPTI [30] and is merged to Linux kernel from version 4.15.

SecVisor [26] ensures lifetime kernel integrity via setting access permissions in NPT (Nested Page Table, from AMD, similar to Intel's EPT). TrustVisor [20] uses NPT to isolate memory regions used by a security task. CloudVisor [31] de-privileges the hypervisor to non-root mode and uses a separated EPT to host it. Thus, the hypervisor is isolated from guest VMs and is removed from the TCB (trusted computing base). InkTag [9] uses EPT to isolate the address space of a process. SeCage [17] leverages *VMFUNC* to provide two isolated execution environments, one for running security-critical code and the other for the normal code, to defend against attacks like heartbleed [29]. Similarly, MemSentry [15] creates domains (VMs) to hide secret data and uses *VMFUNC* to switch between different domains.

8 Discussion

Supporting x86-32: To support 32-bit linux, EPTI needs two steps, 1) trapping and modifying the gPT and 2) inserting the trampoline. The existing design can be used to trap and construct gPT for 32-bit linux. To add the trampoline, EPTI requires 8KB virtual address region within guest VM which should not be occupied by the VM itself. We could use technology like *shadow IDT* of ELI [6], which leverages extra pages of devices PCI BAR (base address register) in guest VM to insert additional pages.

Supporting five-level page table: 64-bit Linux also provides five-level page table (the root gPT is gL5). EPTI can trap all enabled gL4 pages and zero them in EPT_u to perform the user-kernel isolation. All the trap and zero methods are same as the four-level page table.

Supporting Windows: Technically, the design of EPTI can be applied to Windows or other OSes. All the kernel entries of Windows kernel can be detected by trapping the modification of IDT and MSRs, so that a trampoline can further be added. After that, EPTI can construct the EPT_u and EPT_k after knowing the virtual memory layout of Windows kernel.

Transparency to guest VMs: EPTI modifies the code and gPT of the guest. In current implementation, these modifications are not transparent to the guest VM. These modifications will not affect functionalities like VMI (virtual machine introspection) and kernel integrity check. For the VMI case, we keep the original address mapping with only different permission so the address translation in VMI can be done as before. For the kernel integrity check case, we do not change existing kernel code, so that its hash value will not be changed. Moreover, the VMM can make the modifications transparent to the guest. Features like *XnR* (execute-no-read) [4] can be used to prevent kernel from reading the trampoline code page while still allowing to execute the code, and the access to the modified gPT pages can also be trapped.

Compared with KPTI: EPTI has three advantages compared with KPTI: compatibility, performance and seamless deployment. Even when the KPTI is patched on all Linux versions, EPTI is still valuable for its low performance overhead and seamless deployment without guest rebooting.

9 Conclusion

The publish of Meltdown vulnerability makes public servers in danger, especially those in cloud. The KPTI solution requires server owners to apply the patch manually, which currently supports only a few of kernel versions and may introduce non-negligible performance overhead. This paper presents EPTI, a new solution to Meltdown vulnerability that can be applied to unpatched VMs and with less overhead. Specifically, our solution uses two EPTs (extended page tables) to isolate user space and kernel space, and unmaps all the kernel space in user's EPT to achieve the same effort of KPTI. EPTI leverages two hardware features to reduce the performance overhead: first, the switching of EPTs is done through a hardware-support feature called *EPTP switching* within guest VMs without hypervisor involvement. Second, *EPTP switching* does not flush TLB since each EPT has its own TLB, which further reduces the overhead. By leveraging live migration, EPTI can seamlessly protect a guest VM without rebooting it. We have implemented our design and evaluated on Intel Kaby Lake CPU with different versions of Linux kernel. The results show that EPTI only introduces up to 13% overhead, which is around 45% less than KPTI.

Abstract

In clouds where CPU cores are time-shared by virtual CPUs (vCPU), vCPUs are scheduled and descheduled by the virtual machine monitor (VMM) periodically. In each virtual machine (VM), when its vCPUs running I/O bound tasks are descheduled, no I/O requests can be made until the vCPUs are rescheduled. These inactivity periods of I/O tasks cause severe performance issues, one of them being the utilization of I/O resources in the guest OS tends to be low during I/O inactivity periods. Worse, the I/O scheduler in the host OS could suffer from low performance because the I/O scheduler assumes that I/O tasks make I/O requests constantly. Fairness among the VMs within a host can also be at stake. Existing works typically would adjust the time slices of vCPUs running I/O tasks, but vCPUs are still descheduled frequently and cause I/O inactivity.

Our idea is that since each VM often has active vCPUs, we can migrate I/O tasks to active vCPUs, thus mitigating the I/O inactivity periods and maintaining the fairness. We present vMIGRATER, which runs in the user level of each VM. It incorporates new mechanisms to efficiently monitor active vCPUs and to accurately detect I/O bound tasks. Evaluation on diverse real-world applications shows that vMIGRATER can improve I/O performance by up to 4.42X compared with default Linux KVM. vMIGRATER can also improve I/O performance by 1.84X to 3.64X compared with two related systems.

1 Introduction

To ease management and save energy in clouds, multiple VMs are often consolidated on a physical host. In each VM, multiple vCPUs often time-share a physical CPU core (aka. pCPU). The VMM controls the sharing by scheduling and descheduling the vCPUs periodically. When a vCPU is scheduled, tasks running on it become active and make progress. When a vCPU depletes its time slice, it is descheduled, and tasks on it become inactive and stop making progress.

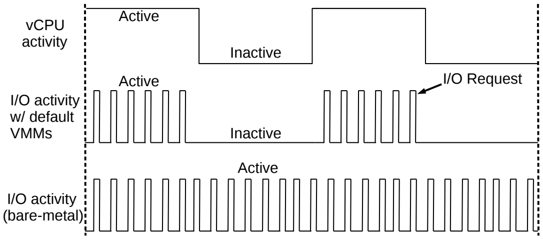

Figure 1: ***I/O inactivity*.**

vCPU inactivity leads to a severe I/O inactivity problem. After the vCPU is descheduled, the I/O tasks on it become inactive and cannot generate I/O requests, as shown in the first two curves in Figure 1. The inactive periods can be much longer than the latencies of storage devices. Typical time slices can be tens of milliseconds; the storage device latencies are a few milliseconds for HDDs and microseconds for SSDs. Thus, during the I/O inactive periods, I/O devices (both physical and virtual devices) may be under-utilized. The under-utilization becomes more serious with a higher consolidation rate (i.e., the number of vCPUs shared on each pCPU), because a vCPU may need to wait for multiple time slices before being rescheduled. The I/O throughput of a VM drops significantly with a consolidation rate of 8 as recommended by VMware [47], based on our evaluation in Section 5.

The I/O inactivity problem becomes even more pronounced when I/O requests are supposed to be processed by fast storage devices (e.g., SSDs). Usually, a vCPU remains active during I/O requests, so it can quickly process them. A similar situation is when a computation task and an I/O task run on the same vCPU. When the I/O task issues a read request and then waits for the request to be satisfied, the computation task is switched on. At this moment, the vCPU is still running; thus, when the read request is satisfied, the vCPU can quickly respond to the event and switch the I/O task back. However, if the time slice of the vCPU is used up by the computation task in one scheduling period, the I/O task cannot proceed until the next period, causing the I/O task to be slowed down significantly.

Worse, the I/O inactivity problem causes the I/O scheduler running in the host OS to work extremely ineffectively. To fully utilize the storage devices, based on the latencies of I/O devices, system designs would carefully control the factors affecting the latencies experienced by I/O workloads (e.g., wake-up latencies and priorities). Thus, I/O workloads running on bare-metal can issue the next request after the previous request is finished. I/O inactive periods make these mechanisms ineffective. Moreover, non-work-conserving I/O schedulers [40] would often hold an I/O request until the next request from the same I/O task comes in (refer to §2.2). By serving the requests from the same task continuously, which have better locality than requests from different tasks, such I/O schedulers [40] can improve I/O throughputs. However, since an I/O workload cannot continue to issue I/O requests after its vCPU becomes inactive, the I/O scheduler in the host OS must switch to serve the requests from other I/O tasks, which greatly reduces locality and I/O throughput, as we will show in our evaluation.

Last but not least, the I/O throughput of a VM can be "capped" by its amount of CPU resources. If the vCPUs in a VM (VM_a) are assigned with smaller proportions of CPU time on each pCPU than the vCPUs on another VM (VM_b), the I/O workloads on VM_a will get less time to issue I/O requests and may only be able to occupy a smaller proportion of the available I/O bandwidth. Since the actual I/O throughputs of the VMs are affected by both I/O scheduling and vCPU scheduling, it is difficult for the I/O scheduler to ensure fairness between the VMs.

All the above problems share the same root cause, I/O inactivity, and existing works mainly try to curb vCPU inactivity but ignore this root cause. Existing works primarily follow two approaches: 1) shortening vCPU time slices (vSlicer [49]); and 2) assigning higher priority to I/O tasks running on active vCPUs (xBalloon [44]). Unfortunately, vCPUs with either approach are still descheduled frequently and cause I/O inactivity.

Since a VM often has active vCPUs, our idea to mitigate I/O inactivity is to try to efficiently migrate I/O tasks to active vCPUs. By evenly redistributing I/O tasks to active vCPUs in a VM, I/O inactivity can be greatly mitigated and I/O tasks can make progress constantly. This maintains both performance and fairness for I/O tasks as they are running on bare-metal. The fairness of I/O bandwidth among VMs on the same host is also maintained.

We implement our idea in vMIGRATER, a user level tool working in each VM. It is transparent as it does not need to modify application, OS in VM, or VMM. vMIGRATER carries simple and efficient mechanisms to predict whether a vCPU will be descheduled and to migrate the I/O tasks on this vCPU to another active vCPU.

vMIGRATER adds only small overhead to applications for two reasons. First, I/O bound tasks use little CPU time, so the I/O tasks migrated by vMIGRATER hardly affect the co-running tasks on the active vCPUs. Second, vMIGRATER migrates more I/O bound tasks to the active vCPUs with more remaining time slices, so all vCPUs' loads in the same VM are well balanced. By reducing I/O inactivity with low overhead, vMIGRATER makes applications run in a fashion similar to what they do on bare-metal, as shown in Figure 1.

vMIGRATER has to address three practical issues. First, it needs to identify I/O tasks. To address this issue, vMIGRATER uses an event-driven model to collect I/O statistics and to detect I/O bound tasks quickly. Second, vMIGRATER needs to determine when an I/O bound task should be migrated. To minimize overhead, vMIGRATER only migrates an I/O bound task when the vCPU running this task is about to be descheduled. vMIGRATER monitors each vCPU's time slice and uses the length of the previous time slice to predict the length of the current time slice. Third, vMIGRATER needs to decide where a task should be migrated to keep it active. Based on the collected time slice and I/O task information, vMIGRATER migrates I/O tasks from to-be-descheduled vCPUs to the active vCPUs with light workload.

We implemented vMIGRATER in Linux and evaluated it on KVM [30] with a collection of microbenchmarks and 7 widely used or studied programs, including small programs (sequential, random and bursty read) from SysBench [7], a distributed file system HDFS [5], a distributed database Hbase [2], a mail server benchmark PostMark [6], a database management system LevelDB [3], and a document-oriented database program MongoDB [35]. Our evaluation shows that:

1. vMIGRATER can effectively improve application throughput. Compared to vanilla KVM, vMIGRATER can improve application throughputs by up to 4.42X. With vMIGRATER, application throughput is 1.84X to 3.64X higher than vSlicer and xBalloon.
2. The effectiveness of vMIGRATER increases with consolidation rate. Compared to vanilla KVM, vMIGRATER improves application throughput from 1.72X to 4.42X when the number of consolidated VMs increases from 2 to 8.
3. vMIGRATER can maintain the fairness of the I/O Scheduler in VMM. Compared to vanilla KVM, vMIGRATER reduces unfairness between VMs by 6.22X. When VMs are assigned with the same I/O priority but different CPU time shares, the VMs can still utilize similar I/O bandwidth.

The paper makes the following contributions. First, the paper identifies I/O inactivity as a major factor degrading I/O throughputs in VMs, and quantifies the severity of the problem. Second, it designs vMIGRATER, a simple and practical user-level solution, which greatly improves the throughput of I/O applications in VMs. Third, vMIGRATER is implemented in Linux, and is evaluated extensively to demonstrate its effectiveness.

The remainder of this paper is organized as follows. §2 introduces the background and motivation of vMIGRATER. §3 presents the design principles, architecture, and other design details of vMIGRATER. §4 describes implementation details. §5 presents evaluation results. §6 introduces related work, and §7 concludes the paper.

2 Background and Motivation

This section first introduces vCPU scheduling (§2.1) and I/O request scheduling (§2.2) as the background. Then it explains three performance problems caused by I/O inactivity in virtualized systems (§2.3) to motivate our research.

2.1 vCPU Scheduling

To improve resource utilization in virtualized systems, a pCPU is usually time-shared by multiple vCPUs. A vCPU scheduler is used to periodically deschedule a vCPU and schedule another vCPU. For instance, KVM uses completely fair scheduler (CFS) [13, 44] to schedule vCPUs onto pCPUs. CFS uses virtual runtime (vruntime) to keep track of the CPU time used by each vCPU and to make scheduling decisions. With a red-black tree, it sorts vCPUs based on their vruntime values, and periodically schedules the vCPU with the smallest vruntime value. In this way, CFS distributes time slices to vCPUs in a fair way.

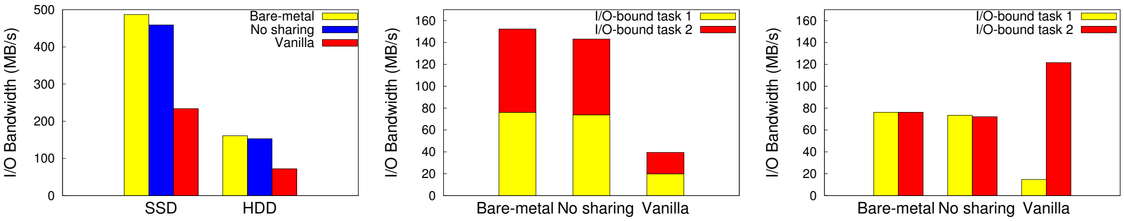
2.2 I/O Request Scheduling

I/O requests are scheduled by the I/O scheduler in the VMM. There are two types of I/O schedulers: work-conserving schedulers [19, 38] and non-work-conserving schedulers [51, 27]. A work-conserving I/O scheduler always keeps the I/O device busy by scheduling pending I/O requests as soon as possible.

Non-work-conserving I/O schedulers, such as anticipatory scheduler (AS) [27] and Completely Fair Queuing (CFQ) [12], are now widely used. A non-work-conserving scheduler waits for a short period after scheduling a request from a task, expecting that other requests from the same task may arrive. Because requests from the same task usually show good locality (i.e., requesting the data at the locations close to each other on the disk), if there are requests from the same task arriving, the scheduler may choose to schedule these requests, even when there are requests from other tasks arriving earlier. It switches to serve the requests from other tasks when the waiting period expires and there are not requests from the same task. Compared to work-conserving I/O schedulers, non-work-conserving schedulers can improve I/O throughput by exploiting locality. The length of waiting periods is selected to balance improved locality and the utilization of I/O devices. To enforce fairness between I/O tasks, an I/O request scheduler controls the distribution of disk time among the tasks.

2.3 Performance Issues Caused by I/O Inactivity

We use experiments to show that serious performance issues will be caused by I/O inactivity. Specifically, we use SysBench [7] to test I/O throughput in three settings. In the *Bare-metal* setting, we run SysBench on the host. In the *No sharing* setting, we run SysBench in a VM; the VM is the only VM in the host; In the *Vanilla* setting, we consolidate 2 VMs on the same host. In the experiments, each VM has 4 vCPUs, and the host has 4 cores. Thus, in the *No-sharing* setting, there is one vCPU on each core, and in the *Vanilla* setting, each core is time-shared by 2 vCPUs. The VMs are configured to have the same I/O bandwidth quota in KVM [30]. In each VM, the CPU workload in SysBench [7] is run as a compute-bound task, and keep the vCPUs always busy. Note that we select these



(a) I/O bandwidth of individual VM

(b) I/O bandwidth of overall vitualized systems

(c) Fairness of I/O Scheduler

Figure 2: ***Three performance issues caused by I/O inactivity*. "Bare-metal" means physical server; "No sharing" means only one VM running on the host; "Vanilla" means two VMs consolidated and managed by vanilla KVM on one host.**

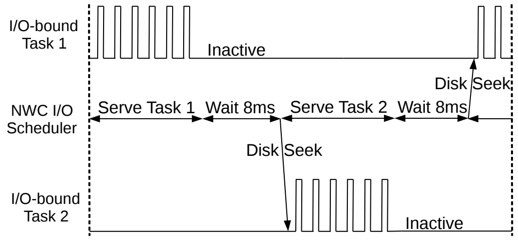


Figure 3: ***I/O inactivity makes Non-Work-Conserving (NWC) I/O scheduler used in VMM ineffective and inefficient because costly disk seeks and waiting time cannot be effectively reduced.***

workloads and settings mainly to ease the demonstration and analysis of the performance issues. Our evaluation with real workloads and normal settings (§5) show that these performance issues can actually be more severe.

Figure 2 (a) and Figure 2 (b) show that I/O inactivity significantly reduces I/O throughput in two different ways. In the experiment shown in Figure 2 (a), we run only one instance of I/O bound task (i.e., I/O workload of SysBench). Among the three settings, *No sharing* has roughly the same I/O throughput as Bare-metal; but the I/O throughput in the *vanilla* setting is about half of those of the other two settings. This is because the VM running the I/O bound task only obtains 50% of CPU time on each core. Thus, the I/O bound task is only active for 50% of the time, as illustrated in Figure 1.

In the experiment shown in Figure 2 (b), we run two instances of I/O bound task, one in each VM. For brevity, we refer to the I/O bound task in the first VM as I/O bound task 1, and refer to the task in the other VM as I/O bound task 2. The bars in the figure show the throughputs of these tasks, as well as the total I/O bandwidth. As shown in the figure, in the *Vanilla* setting, the total throughput drops by 72.1% compared to bare-metal and no sharing, which is more than 50%.

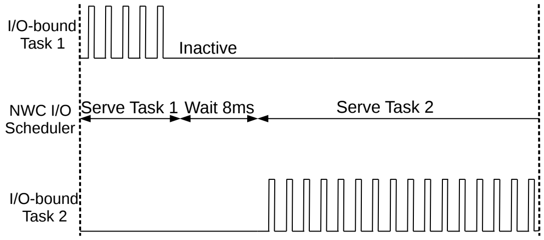

Figure 4: ***I/O inactivity causes unfairness issue.* The I/O task in a VM with more CPU time gets more I/O bandwidth.**

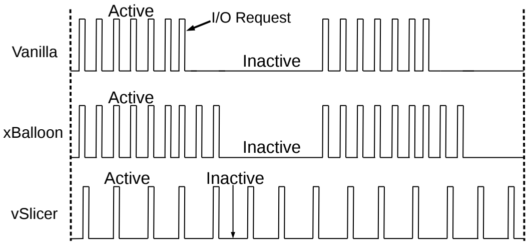

Figure 5: ***The workflow of vanilla, xBalloon and vSlicer.* xBalloon and vSlicer still experience frequent I/O inactivity periods.**

Figure 3 explains the reason. The non-work-conserving I/O scheduler in the VMM serves an I/O bound task in a VM for a short period before the vCPU running the task is descheduled. Then, it waits for 8ms without seeing any requests from I/O bound task 1. Thus, it has to switch and start to serve the I/O-bound task in the other VM (i.e., I/O-bound task 2). The changes between tasks are caused by I/O inactivity. They incur costly disk seeks. The wasted waiting time further reduces I/O throughput.

Figure 2 (c) illustrates the unfairness issue caused by I/O inactivity. It shows that two I/O bound tasks on two VMs with the same I/O priority achieve quite different I/O throughputs because the two VMs are assigned with different CPU time shares. In the experiments, for the *Vanilla* setting, we launch two VMs with the same I/O priority, and run an instance of I/O bound task on each of the VMs. We assign to the VMs with 20% and 80% of CPU time, respectively. For the *Bare-metal* setting and *No sharing* setting, we launch two instances of I/O bound task on the host and the VM, respectively. The two instances of I/O bound task are assigned with the same I/O priority but different CPU time shares (20% and 80%, respectively).

As shown in the figure, the two I/O bound tasks achieve similar I/O throughputs in the *Bare-metal* and *No sharing* settings. However, in the *Vanilla* setting, the I/O bound task in the VM with a larger CPU time share achieves a much higher (5.8x) throughput than that of the I/O bound task in the other VM. Figure 4 explains the cause of this fairness issue. Since VM1 is allocated much less CPU time than VM2, it experiences much longer I/O inactivity periods. As a result, the I/O scheduler serves VM2 for much longer time than VM1.

There are two approaches that may be used to improve I/O throughput. One approach [48, 10, 49] uses smaller time slices (e.g., vSlicer), such that vCPUs are scheduled more frequently, and thus become more responsive to I/O events. As shown in Figure 5 with the curve labeled with vSlicer, this approach reduces the length of each vCPU inactivity period. But I/O inactivity periods become more frequent, and the portion of time in which an I/O task is inactive may not be reduced. Moreover, vSlicer incurs frequent context switches between vCPUs and increases the associated overhead. The other approach [31, 44] lifts the priority of I/O tasks. For example, xBalloon controls how vCPUs consume time slices such that more CPU time can be reserved for the execution of I/O bound tasks on the vCPUs. While this actually lengthens I/O active periods, as shown in Figure 5 with the curve labeled with xBalloon, vCPUs still must be descheduled when they run out of time slices, and I/O inactivity problems are still incurred.

3 vMigrater Design

In this section, we first introduce the design principles and overall architecture of vMigrater. Then, we present the design details of each key component, focusing on how vMigrater monitors the scheduling and descheduling of vCPUs to keep track of their time slices (§3.2), quickly detects I/O-bound tasks (§3.3), and migrates I/O-bound tasks with low overhead (§3.4). Finally, we analyze the performance potential of vMigrater (§3.5).

3.1 Design Principles and Overall Architecture

The design of vMigrater follows three principles:

- Fair: the design of vMigrater must not affect vCPU scheduling (e.g., allocating more CPU time to the vCPUs running I/O tasks) or I/O scheduling in the VMM to avoid any potential unfairness between VMs.
- Non-intrusive: For the wide adoption of vMigrater, the design must be non-intrusive. It should minimize or avoid the modifications to VMM and guest OSs, and should be transparent to applications. Thus, we choose to design vMigrater in the user space of guest OSs. This also helps maintain the original vCPU scheduling and I/O scheduling decisions of the VMM. However, this poses a few challenges, since the migration of I/O bound tasks relies on some key information about vCPU scheduling (e.g., remaining time slice of a vCPU), which is not easy to obtain in the user space.
- Low overhead: vMigrater needs to migrate I/O bound tasks. Frequent migrations may incur high overhead. The design of vMigrater must effectively control the frequency of migrations.

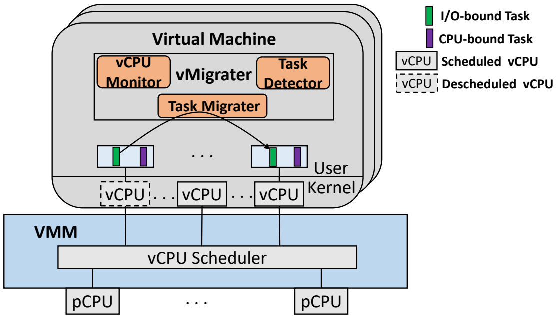

Figure 6: ***Overall Architecture of* vMigrater.**

Figure 6 shows the overall architecture of vMigrater and its position in the software stack. vMigrater resides in each VM, and runs at the user level. Following the above principles, three key components are designed as follows.

vCPU Monitor (§3.2) monitors the scheduling and descheduling of vCPUs. The objective is to measure time slice lengths for each vCPU and use the lengths to predict whether a vCPU is about to be preempted. The prediction is then used to make decisions on when an I/O bound task should be migrated and where it should be migrated.

Task Detector (§3.3) detects I/O activities to quickly determine whether a task is I/O-bound.

Task Migrater (§3.4) makes migration decisions and actually migrates I/O-bound tasks. It makes migration decisions based on the vCPU scheduling information from the Task Migrater and I/O activities of the tasks from the Task Detector. Specifically, it tries to migrate an I/O bound task detected in the Task Detector when the vCPU running the task is about to be descheduled. It migrates the task to another vCPU which may not be descheduled in near future.

3.2 vCPU Monitor Design

The vCPU Monitor uses a heartbeat-like mechanism to detect whether a vCPU is running or has been descheduled, with timer events being heartbeats. The idea is that, when a vCPU is descheduled, it cannot process timer events, and the heartbeat pauses. Specifically, vCPU Monitor runs a sleeping thread, namely vCPU Monitor thread, on each vCPU. The sleeping thread is woken up by a timer periodically. When it is woken up, it checks the current clock time, and compare the time with the time it observes last time. A time difference longer than the period for waking up the thread indicates that the vCPU was descheduled earlier, and has just been rescheduled.

This mechanism is as shown in Figure 7. The vCPU Monitor thread can detect that the vCPU is rescheduled at time t_2 and time t_6. The thread keeps track of the timestamps when the vCPU is rescheduled (e.g., t_2 and t_6) and the timestamps immediately before them (e.g., t_1 and t_5). The time slice lengths can be estimated from these timestamps (e.g., $t_5 - t_2$).

Note that, since a vCPU may be scheduled or descheduled while its vCPU Monitor thread is sleeping, the exact time of the vCPU being rescheduled/descheduled cannot be obtained, and thus accurate time slice lengths cannot be measured with this method. Waking up the vCPU Monitor thread more frequently improves the accuracy of estimation; but it increases the overhead at the same time. Considering that typical time slice lengths are tens of miliseconds, vMIGRATER sets the length of the periods for waking up vCPU Monitor threads to 300 μs to make a trade-off between accuracy and overhead.

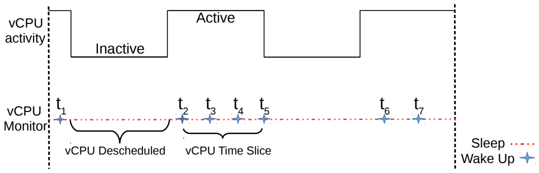

Figure 7: ***vCPU Monitor workflow*.**

3.3 Detecting I/O bound Tasks

Some applications have bursty I/O operations. Thus, vMIGRATER needs to quickly respond to workload changes in each application. vMIGRATER migrates an application when it becomes I/O bound, and stops migration when its I/O phase finishes. However, traditional methods (e.g., Linux top [45] and iotop [26]) for detecting tasks' I/O utilization usually take long time (e.g., seconds). Using these methods may miss the I/O phases in such applications. For instance, the time for an SSD to handle 100MB sequential read is only 100ms. Thus, a much faster method for detecting I/O bound tasks is needed.

vMIGRATER uses an event-driven method to detect I/O-bound tasks quickly. This method monitors the I/O events triggered by I/O requests, and collects the time spent on processing these I/O events. vMIGRATER periodically calculates the fraction of time spent on processing I/O events. (The duration of each period in our design is 5 milliseconds.) It determines that a task becomes I/O bound when the fraction exceeds a threshold.

3.4 Migrating I/O bound Tasks

Task Migrater relies the information from vCPU Monitor and Task Detector to make migration decisions. It first needs to decide which I/O tasks should be migrated. To minimize the overhead, Task Migrater only migrates I/O bound tasks when vCPUs running them are to be descheduled shortly. To find these tasks, Task Migrater estimates the remaining time slice for each vCPU[1]. If the remaining time slice is shorter than the length of two periods for waking up vCPU Monitor threads (i.e., 600 μs)[2], Task Migrater determines that the vCPU is about to be descheduled. Task Migrater then checks the tasks scheduled on the vCPU. If there is an I/O bound task reported by Task Detector, Task Migrater migrates the task.

Second, Task Migrater needs to decide which vCPU the I/O bound tasks should be migrated to. A naïve approach is to migrate I/O tasks to the vCPU with the longest remaining time slice. However, this method has two problems if Task Migrater needs to migrate multiple I/O bound tasks: (1) the I/O bound tasks are migrated to the same vCPU and cannot make progress concurrently; (2) the vCPU might be overloaded by accepting all these tasks, and the performance of its existing tasks is degraded.

Task Migrater migrates I/O tasks to vCPUs in a globally balanced way. Specifically, Task Migrater ranks active vCPUs based on the lengths of their remaining time slices, and ranks the I/O bound tasks to be migrated based on their I/O load levels. It migrates the I/O bound tasks with heavier I/O load levels to the vCPUs with longer remaining time slices. This migration mechanism can prevent the above problems because it distributes I/O bound tasks among active vCPUs. At the same time, it helps maintain high I/O throughput because the

[1] The remaining time slice of a vCPU at a moment (e.g., t_7 in Figure 7) is estimated using the length of time slice assigned to the vCPU before the most recent descheduling of the vCPU (e.g., $t_5 - t_2$) and the CPU time that has already been consumed by the vCPU after the most recent rescheduling of the vCPU (e.g., $t_7 - t_6$).

[2] This is to tolerate the inaccuracy in the estimation of time slices and remaining time slices.

tasks with the most I/O activities are scheduled on the vCPUs that are least likely to be descheduled shortly.

3.5 Performance Analysis

We use Equation (1) to show the performance potential of vMIGRATER. For simplicity, we assume each VM has at least one active vCPU at any given time. Thus, an I/O application can be kept active with vMIGRATER, except when it is being migrated.

$$Speedup_{vMigrater} = \frac{T_{ns} \times N}{T_{ns} + N_{migrate} \times C_{avg}} = \frac{N}{1 + \frac{N_{migrate} \times C_{avg}}{T_{ns}}} \quad (1)$$

Equation (1) calculates the speedup of an I/O application with vMIGRATER relative to its execution without vMIGRATER on a VM. N is the number of vCPUs consolidated on each pCPU (i.e., consolidation rate). T_{ns} is execution time of the I/O application on a VM when its execution is not affected by I/O inactivity problem. This can be achieved by running the application on a vCPU with a dedicated pCPU. It reflects the best performance that an I/O application can achieve on a VM. $N_{migrate}$ is the number of migrations conducted by vMIGRATER. C_{avg} is the average time cost incurred by each migration.

The numerator of equation (1) is the execution time of an I/O application on a VM without vMIGRATER. With N vCPUs consolidated on a pCPU, in each period of N time slices, the I/O application can be active only for a period of one time slice. Thus, its execution time is roughly $N \times T_{ns}$. The denominator is the execution time with vMIGRATER, which is determined by the time spent on application execution and the time spent on migration.

Equation (1) shows that $N_{migrate}$ must be reduced to improve the performance of vMIGRATER. Suppose vMIGRATER migrates the I/O application by a minimum number N_{min} of times in an optimal scenario. Thus, $N_{min} = T_{ns}/T_{ts}$, where T_{ts} is the length of a time slice allocated to a vCPU. In this optimal scenario, the I/O application is moved to a vCPU when the vCPU is just rescheduled; it stays there until the timeslice of the vCPU is used up; it is then moved to another vCPU which is newly rescheduled.

Replacing T_{ns} with $T_{ts} \times N_{min}$ in equation (1), we get:

$$Speedup_{vMigrater} = \frac{N}{1 + \frac{N_{migrate} \times C_{avg}}{N_{min} \times T_{ts}}} \quad (2)$$

Equation 2 shows that the speedup is determined by N and $\frac{N_{migrate} \times C_{avg}}{N_{min} \times T_{ts}}$; N, C_{arg}, and T_{ts} are constants for an application. We denote $\frac{N_{migrate}}{N_{min}}$ as $P_{vMigrater}$, which has a value greater than 1. The speedup is mainly determined by $P_{vMigrater}$. When $P_{vMigrater}$ approaches to 1, the speedup approaches to N. Our experiments show that the speedup with vMIGRATER matches the speedup calculated by Equation 1.

4 Implementation Details

We have implemented vMIGRATER on Linux. The implementation of vCPU Monitor relies on a reliable and accurate clock source to generate timer events. The traditional system time clock cannot satisfy this need when vCPUs time-share a pCPU [44]. Instead, we use the clock source CLOCK_MONOTONIC [18], which is more reliable and can provide more accurate time measurement. The implementation of Task Detector leverages BCC [11, 24] to monitor I/O requests. BCC is a toolkit supported by Linux kernel for creating efficient kernel tracing and manipulation programs.

The implementation of Task Migrater uses two mechanisms, PUSH and PULL, to migrate tasks. A PUSH operation is conducted by the source vCPU of a task to move the task to the destination vCPU, while a PULL operation is initiated by the destination vCPU to move a task to it from the source vCPU. Usually PUSH operations are used. PULL operations are only used when source vCPUs are descheduled and cannot conduct PUSH operations. vMIGRATER's source codes are available on `github.com/hku-systems/vMigrater`.

5 Evaluation

Our evaluation is done on a DELL™ PowerEdge™ R430 server with 64GB of DRAM, one 2.60GHz Intel® Xeon® E5-2690 processor with 12 cores, a 1TB HDD, and a 1TB SSD. All VMs (unless specified) have 12 vCPUs and 4GB memory. The VMM is KVM [30] in Ubuntu 16.04. The guest OS in each VM is also Ubuntu 16.04. The length of a vCPU time slice is 11ms, as recommended by Red Hat [41]. The I/O scheduler in VMM is CFQ with wait time set to 8ms, as recommended by Red Hat [42, 40].

We evaluate vMIGRATER using a collection of micro-benchmarks and 7 widely used applications. Micro- benchmarks include *SysBench [7] sequential read*, *SysBench random read*, and *bursty read implemented by us*. As summarized in Table 1, applications include *HDFS* [5], *LevelDB* [3], *MediaTomb* [9], *HBase* [2], *PostMark* [6], *Nginx* [37], and *MongoDB* [35]. To be close to real-world deployments, PostMark is run with ClamAV (antivirus program) [17] to generate the workload of a complete mail server with antivirus support; LevelDB and MongoDB are deployed as the back-end storage of a Spark [52] system.

Application	Workload
HDFS	Sequential read 16GB with HDFS TestDFSIO [25].
LevelDB	Random scan table with db_bench [4].
MediaT	Concurrent requests on transcoding a 1.1GB video.
HBase	Random read 1GB with HBase PerfEval [25].
PostMark	Concurrent requests on a mail server.
Nginx	Concurrent requests on watermarking images [1].
MongoDB	Sequential scan records with YCSB [8].

Table 1: ***7 applications and workloads.***

Most of the experiments are conducted with the SSD. Only the experiments in §5.4 (fairness of I/O scheduler) use the HDD, because they need a non-work-conserving I/O scheduler (e.g., CFQ) and CFQ is used in Linux to schedule HDD requests.

We compare vMigrater with two related solutions: xBalloon [44] and vSlicer [49]. Because they do not have open-source implementations, we implemented them based on the description in their papers.

Our evaluation aims to answer the following questions:

§5.1: Is vMigrater easy to use?

§5.2: How much performance improvement can be achieved with vMigrater, compared with vanilla KVM and two related solutions? What is the overhead incurred by vMigrater.

§5.3: What is vMigrater's performance when the workload in a VM varies over time?

§5.4: Can vMigrater help the I/O scheduler in the VMM to achieve fairness between VMs?

5.1 Ease of Use

With vMigrater, all 7 real applications we evaluated could run smoothly without any modification. When we evaluate these applications, vMigrater runs in the user-level of the guest OS. There is no need to change any parts of the VM or the VMM.

5.2 Performance Improvements

We first demonstrate that vMigrater can greatly improve the throughput of I/O intensive applications in each VM. For this purpose, we vary the number of VMs hosted on the server from 1 to 8, and run the workload with the micro-benchmarks and the workloads with the real applications summarized in Table 1. In each experiment, we run one instance of the workload in each VM. So the co-located VMs have the same workload. We measure the throughputs of the benchmarks and real applications. When only one VM is hosted on the server, the I/O inactivity problem does not happen; the benchmarks and applications achieve the highest performance. We refer to this setting as **No sharing**, and use the performance under this setting as reference performance. We normalize the performance under other settings (i.e., 2/4/8 VMs consolidated on the server) against the reference performance, and show the normalized performance. Thus, the normalized performance of 1 is the best performance that can be achieved. The closer the normalized performance is, the better the performance is.

Figure 8 shows the normalized throughputs for micro-benchmarks when the number of consolidated VMs is varied from 2 to 8. With vMigrater, the benchmarks consistently achieve better performance than they do on vanilla KVM. At the same time, the performance advantage with vMigrater becomes more prominent when more VMs are consolidated. On average, with vMigrater, the throughputs of these benchmarks are improved by 97%, 225%, and 431% than those on vanilla KVM for the settings with 2 VMs, 4 VMs, and 8VMs, respectively.

Similar performance improvements are also observed with real applications, as shown in Figure 9. On average, with vMigrater, the throughputs of these applications are improved by 72%, 192%, and 342% than those on vanilla KVM for the settings with 2 VMs, 4 VMs, and 8VMs, respectively.

Compared to vSlicer and xBalloon, the applications can also achieve better performance with vMigrater. As shown in Figure 9, On average, with vMigrater, the throughputs of these applications are improved by 88.41%, 74.86%, and 121.22% than those with vSlicer for the settings with 2 VMs, 4 VMs, and 8VMs, respectively; and the throughputs are improved by 3.29%, 83.78%, and 175.37% than those with xBalloon under these three settings.

While vMigrater can significantly improve the throughput of I/O applications when all the consolidated VMs are equipped with vMigrater. Since vMigrater is designed at the user space, it is possible that not all the VMs have vMigrater deployed. We wonder whether vMigrater can still effectively improve I/O throughput in this scenario. To answer this question, we run the workloads with HDFS and LevelDB in one VM and enables vMigrater in this VM; in other colocated VM(s), we run the IS benchmark in NPB benchmark suite [36], and disable vMigrater in the VM(s). Figure 10 shows that the effectiveness of vMigrater is not affected. On average, with

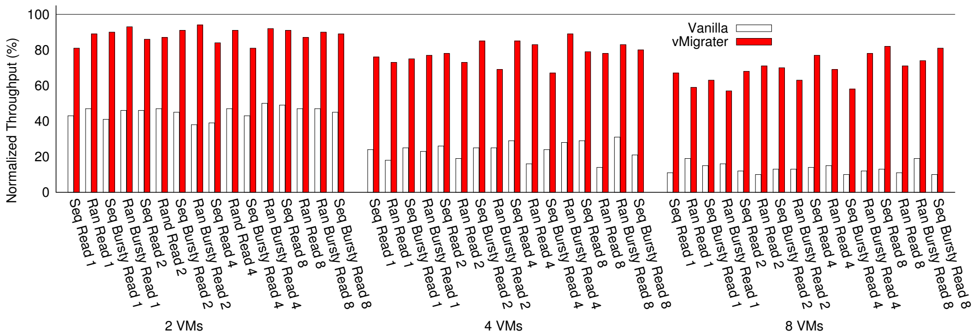

Figure 8: ***Normalized throughputs of micro-benchmarks***

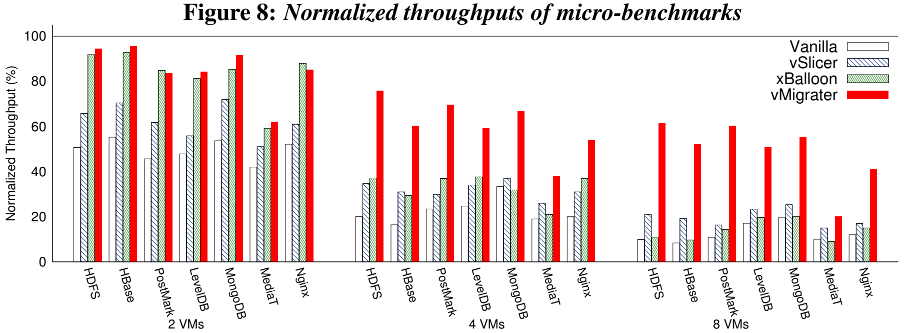

Figure 9: ***Normalized throughput of real applications***

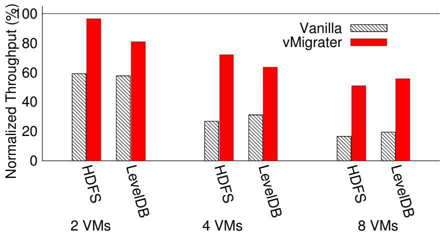

Figure 10: ***Normalized throughput of HDFS and LevelDB when* VMIGRATER *is enabled in one of the consolidated VMs.***

VMIGRATER, the throughputs of these applications are improved by 62.72%, 176.92%, and 218.75% than those on vanilla KVM for the settings with 2 VMs, 4 VMs, and 8VMs, respectively.

To understand how the performance improvements are achieved with VMIGRATER, we profile the executions of the real applications. We collect the number of migrations and the time during which I/O bound tasks "run" on descheduled vCPUs (i.e., I/O inactivity time). We show the data in Table 2 and Table 3.

VMIGRATER greatly improves application performance by first dramatically reducing I/O inactivity time. As shown in Table 2, on average, for the applications, VMIGRATER reduces I/O inactivity time by 860.27%, 657.87%, 562.92%, respectively, relative to vanilla KVM, vSlicer, and xBalloon.

When I/O inactivity time has been dramatically reduced, as we have analyzed in Section 3.5, VMIGRATER maintains high throughputs by minimizing the time spent on migrating tasks, which is determined by the number of migrations and the time to finish each migration. As shown in Table 3, for most applications, the $P_{vMigrater}$ values are very close to 1. This confirms that the migration mechanisms in VMIGRATER are well designed. On one hand, they have effectively migrated I/O bound tasks to keep them active and minimize I/O inactivity. On the other hand, they only migrate the tasks for close-to-minimal times, so as to keep the time spent on migration low. We notice that the $P_{vMigrater}$ value is the highest (1.34) for `MediaTomb` among these applications, and its Speedup is the lowest (1.41). This confirms our performance analysis in Section 3.5.

We also notice that the effectiveness of VMIGRATER slightly reduces when the consolidation rate increases. This is caused by the special design with the vCPU scheduler in KVM (i.e., CFS in Linux), which allocate smaller time slices with higher consolidation rates. This reduces the opportunity to migrate I/O bound tasks. This problem can be mitigated by waking up Task Detector threads more frequently.

Figure 11 shows the response time of the three systems normalized to no sharing. For 7 applications, the response times of VMIGRATER and xBalloon are almost the same. Since each VM has 50% CPU resource, xBalloon has good performance (mentioned above). For `MediaTomb`, all three systems incur high response time because `MediaTomb` combines I/O and compute in one task.

Figure 12 shows three systems' overhead to co-

Application	Vanilla	vSlicer	xBalloon	vMigrater	Ratio
HDFS	121.82s	92.91s	75.27s	6.62s	18.39
LevelDB	129.45s	101.55s	79.84s	17.86s	7.25
HBase	98.13s	69.37s	75.71s	18.93	5.19
MongoDB	39.49s	30.34s	40.57s	3.49s	11.31
PostMark	225.32s	168.01s	113.01s	12.92s	17.44
MediaTomb	108.61s	89.46s	116.96s	34.95s	3.11
Nginx	59.15s	61.72s	42.37s	8.03s	7.37

Table 2: *I/O inactivity time (seconds) of 7 applications.* Four VMs are used. The last column is the ratio between the I/O inactive time with vanilla KVM and that with VMIGRATER.

Application	$N_{migrate}$	N_{min}	$P_{vMigrater}$	Speedup
HDFS	3363	3181	1.05	1.86
LevelDB	2154	2003	1.07	1.75
HBase	3454	3181	1.08	1.76
MongoDB	1545	1363	1.13	1.70
PostMark	5181	4818	1.07	1.82
MediaTomb	2454	1818	1.34	1.41
Nginx	4181	4090	1.02	1.73

Table 3: VMIGRATER *only migrates I/O bound tasks for close-to-minimal times.* Two VMs are used.

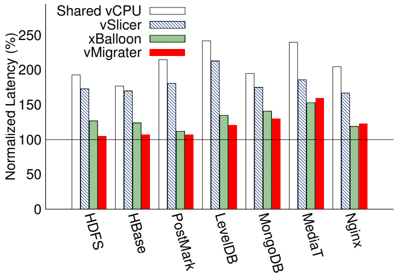

Figure 11: *Response time normalized to "no vCPU sharing".* Two 12-vCPU VMs share 12 pCPUs.

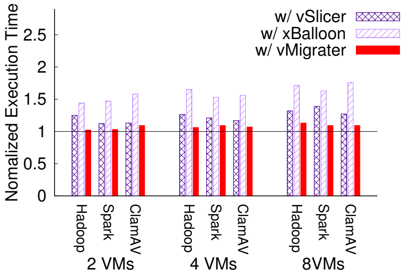

Figure 12: *Execution time normalized to "Vanilla".* "Hadoop" means each VM is running Hadoop standard TeraSort workload; "Spark" means each VM is running standard WordCount workload; "ClamAV" means each VM is scanning virus for the whole OS. Each VM has 12 vCPUs.

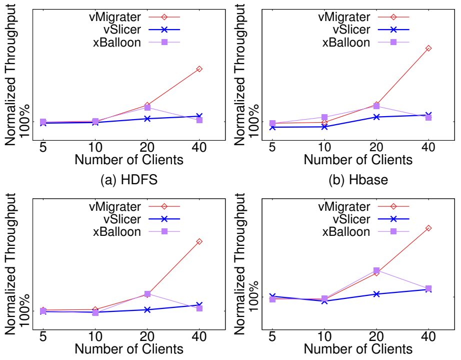
running compute-bound applications in the same VM. xBalloon's overhead is much higher than VMIGRATER and vSlicer because xBalloon prioritizes I/O-bound tasks and delays compute-bound tasks. vSlicer's overhead is higher than VMIGRATER because it incurs much more context switching overhead for compute-bound tasks. Unlike xBalloon and vSlicer, VMIGRATER almost would not delay co-running applications (§3).

5.3 Robustness to Varing Workloads



(a) HDFS

(b) Hbase

(c) PostMark

(d) MongoDB

Figure 13: *Throughput scalability on the loads of VMs, normalized to vanilla.* Each client consumes around 20% CPU resources; two 2-vCPU VMs share two pCPUs; the more concurrent clients, the more faster VMIGRATER than vSlicer and xBalloon.

Figure 13 shows the three systems' throughput under varing workloads. When the number of clients is lower than 10, the throughput of VMIGRATER is almost the same as vSlicer and xBalloon because VMs are not shared. VMIGRATER is not started when there is no sharing. As the number of clients increased to 40, VMIGRATER outperforms the other two systems significantly because VMIGRATER can efficiently avoid I/O inactivity periods by migrating I/O tasks to scheduled vCPUs. vSlicer and xBalloon do not work when vCPU is inactive. xBalloon has almost the same performance as VMIGRATER for around 20 clients (each VM has 50% CPU resource). However, VMIGRATER is much more scalable than vSlicer and xBalloon when workloads increase.

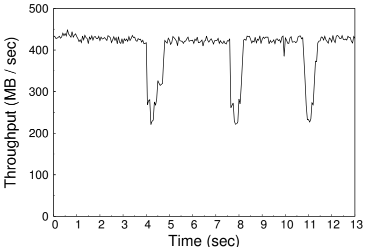


Figure 14: VMIGRATER*'s performance on handling the load change of vCPUs by adding clients dynamically.* 8 clients at the time 0; each client exhausts 20% CPU resource; two 2-vCPU VMs share two pCPUs.

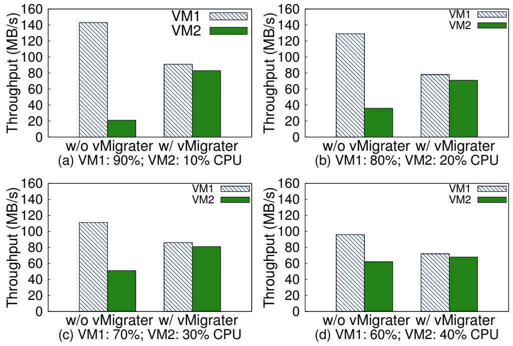
Figure 14 shows the robustness of VMIGRATER in the face of suddenly changing workloads. There are 8 clients at 0s, and the VMs are not overloaded. At around 4s, 8s and 11s , 4, 8 and 16 more clients are added, VMIGRATER's throughput decreases to around 240MB/s, but it becomes stable (peak, around 430MB/s) again after a short period because VMIGRATER needs some time to precisely re-estimate the time slices of vCPUs and then migrate the I/O bound tasks (§7).

5.4 Fairness for I/O Scheduler



(a) VM1: 90%; VM2: 10% CPU

(b) VM1: 80%; VM2: 20% CPU

(c) VM1: 70%; VM2: 30% CPU

(d) VM1: 60%; VM2: 40% CPU

Figure 15: vMigrater *improves the fairness of I/O Scheduler.* Two 12-vCPU VMs share 12 pCPUs; each VM is allocated different CPU resources but the same I/O bandwidth.

Figure 15 shows the fairness of the VMM I/O scheduler among VMs. In Figure 15 (a), (b), (c) and (d), VM1's CPU resource decreases from 90% to 60%, and VM2's CPU resource increases from 10% to 40%. Each VM runs `TestDFSIO` (I/O-bound task) and `TeraSort` (compute-bound task) concurrently, and each VM is allocated with the same I/O bandwidth. Without vMigrater, `TestDFSIO` throughput is related to the CPU resource allocated to the VM, which shows that vanilla hurts the fairness of the I/O scheduler in the host OS. With vMigrater, two VMs in each figure achieve roughly the same `TestDFSIO` throughput, which implies vMigrater maintains fairness (roughly the same I/O bandwidth) for the two VMs.

6 Related Work

Shortening time slices. Many efforts have focused on shortening the time slices of vCPUs [10, 49, 48] for vCPUs to process I/O requests more frequently. This solution has two drawbacks: (1) the I/O inactivity period still exits and could degrade I/O performance; (2) it suffers from performance degradation because of frequent context switches [21, 46, 32]. [48] uses the same idea to reduce the delay of IRQ processing. These solutions require intensive modifications to both the VMM and guest OS kernel.

Dedicating CPUs. Dedicating CPUs [43, 14] aims to solve the resource contention problem. This solution makes fewer vCPUs share one pCPU in order to reduce contention. These systems are complementary to vMigrater because they focus on reducing the vCPU sharing, while vMigrater focuses on improving performance in the shared setting.

Task-aware Priority Boosting. Existing systems [21, 31, 15, 44, 39, 20, 29, 50, 23, 34, 22, 33, 16, 28] focus on prioritizing latency-sensitive tasks to improve overall performance. Task aware VM scheduling [31] improves the performance of workloads by prioritizing I/O bound VMs. [31] works in the VMM layer and may require changing the source codes of the host OS. xBalloon preserves the priority of I/O tasks by preserving CPU resource for I/O tasks. However, the vCPUs are still descheduled so the I/O inactivity periods still exist. xBalloon works best for VMs with single vCPUs, while vMigrater is designed for multi-vCPU VMs.

7 Conclusion and Future Work

This paper identifies I/O inactivity problem in VMs which has not been adequately studied before. It presents vMigrater, a simple, fast and transparent system that can greatly mitigate I/O inactivity.

vMigrater has two limitations, and we leave them as future work. First, when vMigrater runs in a VM, the performance of an application in the VM may drop temporarily when the application's workload changes suddenly. Our evaluation (see §5.3) shows that, when the number of clients for HDFS increased from 16 to 32, HDFS's throughput dropped by 45.6% for 1.3 seconds and then went back to the peak throughput immediately. The reason is that the sudden changing workload makes time slices of some vCPUs not stable, and vMigrater needs some time to precisely re-estimate the time slices of vCPUs and then migrate the I/O bound tasks. Second, vMigrater mainly aims to mitigate the performance degradation caused by disk (HDD or SSD) I/O inactivity periods in VMs, and it is not designed to handle network I/O. Comparing to disk I/O, network I/O is much more sparse, and we have not come across any situation where vMigrater affects the performance of network I/O in our evaluation.

Abstract

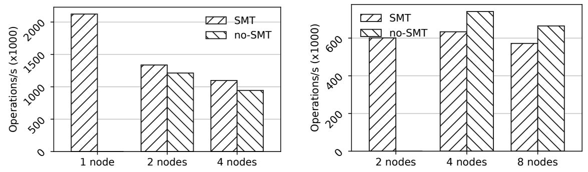
Our work addresses the problem of placement of threads, or virtual cores, onto physical cores in a multicore NUMA system. Different placements result in varying degrees of contention for shared resources, so choosing the right placement can have a large effect on performance. Prior work has studied this problem, but either addressed hardware with specific properties, leaving us unable to generalize the models to other systems, or modeled much simpler effects than the actual performance in different placements.

Our contribution is a general framework for reasoning about workload placement on machines with shared resources. It enables us to build an accurate performance model for any machine with a hierarchy of known shared resources *automatically*, with only minimal input from the user. Using our methodology, data center operators can minimize the number of NUMA (CPU+memory) nodes allocated for an application or a service, while ensuring that it meets performance objectives.

1 Introduction

We address the problem of placing a virtual container on a multicore NUMA system. Hardware resources allocated to a container determine how well it performs and how much energy it consumes. Roughly speaking, there are two decisions affecting which hardware resources are allocated to a container. First, the user decides how many cores, memory and perhaps other resources the container requires. Second, the system software decides, when launching the container, how to map the container's virtual cores onto physical cores. Our work proposes a solution for automatically making this second decision.

The placement of virtual cores onto physical cores can have a large and unpredictable effect on performance. Consider the following experiment, where we use MongoDB's WiredTiger key-value store [3] running a B-tree search using 16 threads. We run this application in a `lxc` container on an Intel NUMA system and on an AMD NUMA system (Fig. 2 provides their overview). Suppose our goal is to maximize the throughput. How should we place this container? Assuming that each virtual core gets its own physical core, how do we place virtual cores onto NUMA nodes? Do we squeeze them onto as few nodes as possible?, do we spread them evenly across all nodes?, or do we use a middle ground?



(a) WiredTiger, Intel

(b) WiredTiger, AMD

Figure 1: Throughput of the WiredTiger key-value store on two NUMA systems.

As Fig. 1 shows the right answer can vary greatly from one system to the next. On the Intel system, the application performs significantly better when all of its threads run on a single node. On the AMD system, four nodes are better than two, only if we do not use SMT, but using eight nodes does not buy you better performance[1].

There is a number of factors responsible for this dissimilar behaviour. When all threads are squeezed into a single NUMA node, they experience more resource sharing: on the Intel system they have no choice but to share the SMT pipeline and the L3 cache. Resource sharing can be contentious (where threads compete for cache space and hardware queues [34]) or cooperative (where threads pre-fetch data for each other [27]). Furthermore, with all the threads running on a single NUMA node,

[1] A single-node configuration for AMD is not shown: we used 16 virtual cores, so we could not fit them onto a single node (with 8 cores) while ensuring that each virtual core gets its own physical core.

cross-thread communication has a lower latency, because it occurs via the L3 cache, as opposed to a slower cross-chip interconnect. Apparently, the benefits of faster communication and cooperative resource sharing outweigh the cost of resource contention on the Intel system, but not on the AMD system.

The best-performing placement for a container, therefore, is difficult to predict. The problem becomes even harder if the goal is to not only pick the best-performing placement, but to achieve a trade-off between the number of used nodes and performance. Our work proposes a solution that works as follows:

Step 1: The user provides a simple abstract specification of the shared resources present on the target hardware. Identifying the right level of abstraction was key to being able to automatically construct models for different target systems. The abstraction we propose in this work is called *scheduling concerns* (§4).

Step 2: Using shared resource specification, our algorithm generates, for a given container size, a list of *important placements* – placements that will likely yield different performance on the target hardware[2]. This step is crucial for automatically training a model: while the total number of potential placements is measured in billions (making training infeasible), the number of important placements is only a couple dozen. We introduce the concept of important placements and propose the algorithms for automatically generating them (§4).

Step 3: Using our script, the user trains a machine learning model for the target hardware and the target number of vCPUs (§5). Unlike prior work, we do not rely on hardware performance events (HPE) as model features. Manual selection of the right HPEs puts too much burden on the user. Automatic selection turned out to be impractical on modern machines with 1000s of HPEs. Instead, our model uses as inputs actual performance measurements obtained in two different placements. This approach makes our model-building methodology easier to port across hardware, reduces the training time and achieves higher accuracy, compared to using HPEs.

Step 4: The scheduler runs the virtual container in two different placements, for a couple of seconds in each, feeds their performance into the model and obtains a vector of predicted performance values in each important placement. Using this vector, the system decides what placement to use and remaps the virtual cores. Since the container needs to run in two placements, its memory may need to be migrated if these placements do not use the same NUMA nodes. We improve on memory migration in Linux and evaluate its overhead in §7.

Our solution enables determining the best placement for a *specific virtual container*, but not how to interleave different containers on the same NUMA node. Some data center operators we spoke to do not interleave containers, others do, so we leave that decision up to the operator. Going back to the scenario in Fig.1, using our tools the scheduling system can quickly decide that on the Intel host it is sufficient to provide a single NUMA node for the key-value store in order to maximize its throughput. Then the remaining nodes can be used to host other containers. We believe that our techniques can be used to build scheduling systems that pack virtual containers onto physical hardware more efficiently.

Our main contribution is ***abstractions and methodology for constructing accurate and portable models for predicting performance of a container in various placements on NUMA systems, regardless of what shared resources are present***. We evaluate it by automatically generating performance models for two different hardware systems and measuring their accuracy using cross-validation (§6). We also present a use case demonstrating how the model could be used in practice (§7).

2 Background and Related Work

Workload placement on multicore systems has been explored for over a decade. Early studies examined contention between single-threaded applications for a specific resource, such as the SMT instruction pipeline [25, 14], or shared caches and memory controllers [34, 12, 21, 31]. Later work extended the techniques to multithreaded workloads and to additional resource combinations, such as SMT and shared caches [33], memory controllers and the shared interconnect [9, 18]. While laying a crucial foundation for our work, these prior techniques did not provide a general solution for reasoning about such systems. For instance, while the work of Zhuravlev et al. [34] showed us how to avoid interference for shared memory controllers and the work of Lepers et al. [18] showed us how to place applications on machines with asymmetric interconnects, we still do not know how to build a model that combines both concerns.

Techniques used in prior work did not allow for automatic combination of several models. Every model required manual design: careful selection of hardware performance events [34, 17, 18, 9, 12] or even manual crafting of artificial "probe" workloads or "Rulers" [31, 33] that must be run side-by-side with the target workloads to determine their sensitivity to contention.

Dwyer used an automated model-building methodology, where automatically selected features (from all HPEs available on the machine) were fed into a variety of machine-learning models [11]. However, the model predicted a rather simple outcome: a performance degradation when a target workload was co-scheduled with an interfering one, and not the performance in different place-

[2] §4 defines the *important placement*.

ments. Consistent with our finding that HPEs observed in a single placement are poor model features, Dwyer's study reported rather poor prediction accuracy.

A recent system, Pandia [15] not only accurately predicts performance of different workload placements on a multicore NUMA machine, but also predicts how an application would perform with different numbers of threads. Unforunately, to make predictions, Pandia requires performance observations of six runs with different thread counts, which is difficult to do online because most real applications cannot easily reconfigure their thread count on demand. Despite addressing many limitations of previous work, fundamentally Pandia still relies on the machine-specific modelling methodology that prevents easily transferring results to other systems. Pandia's authors capture factors that contribute to performance, such as cache contention, latency of communication, and load balancing, in a set of machine-specific equations. If the model had to be adapted to another machine, the equations would have to be manually reformulated.

We believe that investing that much effort into designing new models for every new type of hardware puts an unreasonable burden on system engineers. Instead, we sought a future-proof methodology that uses easily available information about a machine's shared resources and automatically builds an accurate performance model.

There are two recent studies that address a different problem, but use techniques that could be adopted in our work. CherryPick [4] handles cloud configuration options, like CPU count, amount of RAM, disk speed, and network speed, but not multicore resources. CherryPick uses Bayesian optimization to minimize the number of search configurations needed and achieves high accuracy despite the non-linearity of performance. The Bayesian optimization approach could potentially work well with our goal and resources, and is a possible avenue of future work. PARIS [30] is similar to CherryPick in that it handles the same type of resources and its goal is to help cloud customers choose the correct cloud configuration. It does not abstract or handle multi-core resources.

3 Assumptions and Limitations

Identically scored placements yield identical performance. As we explain in §4, a placement is identified by the degree of sharing for each hardware resource, to which we refer as the *score*. A vector of scores identifies a placement. Placements with identical score vectors are deemed to yield identical performance for a given workload. This assumes that our machine model must be informed about all shared resources that might affect performance. Most solutions in this space also assume awareness of all shared resources. A radically different approach would be a statistical technique that searches for an optimally performing placement by trying a sufficient number of random placements [23]. Unfortunately, the best known techniques require trying *thousands* of placements and assume that performance in all placements fits a Generalized Pareto distribution — an assumption that does not hold in our case.

A workload is encapsulated in a virtual container. Data centers use virtualization for a variety of reasons, so this assumption dovetails with our target environment. Managed cloud environments present their offerings as a menu of virtual instances with a fixed number of vCPUs per instance (see [1], for example). As a result, we can feasibly train a separate model for each type of hardware and each vCPU count; we do not have to incorporate the effects of varying number of threads into the model, which would make it more complicated. We are not addressing the problem of finding the optimal number of threads or vCPUs for the workload; for that, users can resort to other tools [15, 26].

A NUMA node is a unit of resource allocation. Our solution predicts the performance of a container in all important placements, provided that the target container does not share NUMA nodes with other containers. Unused NUMA nodes can be safely used to run other containers without interference as long as those nodes do not share the interconnect – a condition that can be automatically checked using the machine specification[3]. Suppose that the "best" number of NUMA nodes chosen for a container gives us more physical cores than the container needs. Then the remaining cores would be left idle if no other containers used them. Some data center operators find this acceptable, reasoning that the cost of leaving cores idle is negligible relative to missing performance targets; others contend that maximizing the utilization of physical cores is very important. Our solution does not dictate the decision. If the operator chose to interleave containers on NUMA nodes, our modeling techniques would need to be extended to provide performance predictions under interleaving. Another alternative would be to only interleave with "safe" containers, e.g., those with low CPU utilization or otherwise known to cause negligible interference. We leave the exploration of these scenarios to future work.

We consider only balanced placements. A balanced placement is one where the number of vCPUs is evenly divisible by any number of shared resource units considered for placement. For instance, if we have shared L3 caches on the system, we will only consider placements where the number of vCPUs sharing each L3 cache is equal. Uneven sharing can cause unpredictable performance effects on the workload, for example by creating

[3] Experimental results confirming this statement are available [13].

stragglers, so we choose to not model these effects.

4 Abstract machine model

A major obstacle to a solution to the placement problem is the sheer number of possible placements. For 16 virtual cores on a 64 core system, the number of possible placements is the combinations of 16 objects chosen from a set of 64, which is on the order of 10^{14}. It is essential to exploit the symmetry in the system to reduce the number of placements to a manageable number. By this we mean that for most types of shared resources it does not matter *which* shared resources are being used but *how much* of the shared resources is available to the workload. For instance, for the workload in Fig. 1 on the AMD system, it does not matter which L3 cache it uses, all that matters is whether it has two, four or eight L3 caches at its disposal.[4]

We tackle this with the concept of ***scheduling concerns***. A single scheduling concern is responsible for a single hardware resource, or an inseparable set of hardware resources that affect the performance of vCPU placements. The primary purpose of a scheduling concern is to provide a numerical ***score*** when given a vCPU placement. The score represents the *static* utilization of the particular resource, meaning that it only depends on the vCPU placement, not the dynamic behavior of a workload. A simple example is an "L2 cache" resource. If in a given placement all the virtual cores share a single L2 cache, the score for the L2 cache scheduling concern will be equal to one. If in another placement the cores are spread over two L2 caches, the score will be equal to two, and so on. So, two placements might use completely different NUMA nodes and physical cores, but if they use the same number of L2 caches then they will both have the same L2 cache score. From the vantage point of the L2 cache, these placements will be *identical* in terms of performance. For non-symmetrical resources, such as the cross-chip interconnect on some systems, instead of counting how many links are used by a placement in order to obtain the score, we would add up the total available bandwidth of all links used by a placement. A vector of numeric scores for all scheduling concerns uniquely identifies each placement that is distinct with respect to sharing of resources. Placements with identical vectors are deemed identical with respect to resource sharing, so we can discard the duplicates when training our model. ***By considering only the placements with distinct score vectors, we substantially reduce the space of relevant placements and make the problem tractable.***

There are two additional pieces of information a scheduling concern needs in order to identify the important placements. The first is whether the concern's score is proportional to the user's cost, which is the case for resources like NUMA nodes because fewer nodes (lower score) means more containers can be packed onto a system. If a lower score for a resource only meant worse performance, we could simply discard placements with a lower score for that resource (all other scores being equal) from our list of important placements. But since we want users to be able to make cost-performance trade-offs, placements with lower scores but potentially lower cost could still be relevant. The second piece of information needed by a scheduling concern is whether the resource encompassed by a concern can ever have an inverse relationship with performance. For some resources, like the L2 cache, a higher score is usually better, but for some workloads such as those showing cooperative cache sharing, a smaller score (using fewer L2 caches) may actually improve performance. For other resources, like the shared interconnect described below, a lower score will never improve performance and would not result in a lower cost for the user, so we can safely ignore placements with lower scores when all else is equal.

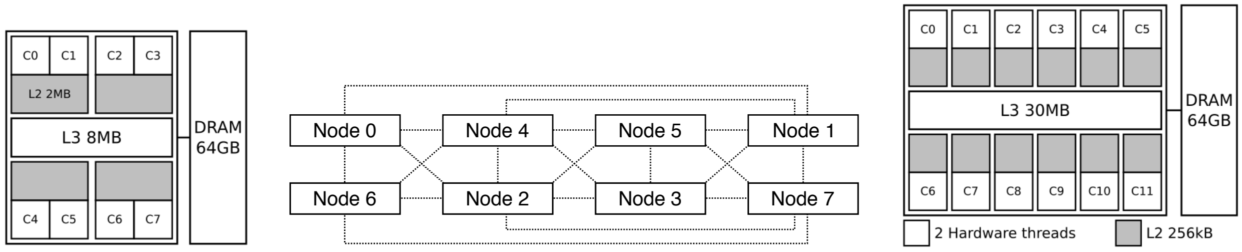
In practice, a single scheduling concern may cover multiple shared resources because some resources are inseparable with respect to thread placement. Threads sharing a physical core via SMT typically share a cache, the instruction front-end, and functional units. In cases like this, a single scheduling concern is still sufficient.

Our AMD system (Fig. 2) has multiple NUMA nodes, an asymmetric interconnect, and a form of SMT. For this system we developed the scheduling concerns shown in Table 1. For the L2/SMT and L3 concerns, the score for a particular placement can be calculated directly from information provided by the operating system. The OS also provides information on the interconnect topology, but it is simpler and more accurate to measure the aggregate bandwidth with a benchmark (e.g. *stream* [20]) for each possible combination of nodes.

For example, for a 16-vCPU container in an eight-node placement without SMT the score vector for the AMD system is [16, 8, 35000], because this placement uses 16 L2 caches (16 hardware threads, one per cache), eight L3 caches (8 nodes) and has an IC bandwidth of 35GB/s. For the same placement, but with SMT, the score vector would be [8, 8, 35000], because on each node two hardware threads would be collocated on the same L2 cache, so we would use half the L2 caches than in the case without SMT.

Each concern is relatively easy to implement, and can be developed independently. Since it does not require a performance expert, we envision the specification of concerns being provided as part of system BIOS. ***Over-***

[4] The exception is asymmetric resources, for instance if one NUMA node is positioned closer to the system NIC than others; our model allows caputring this asymmetry.



(a) AMD Opteron 6272 node

(b) AMD interconnect

(c) Intel Xeon E7-4830 v3 node

Figure 2: The two systems used in our study. The first is a quad AMD Opteron 6272. It has eight NUMA nodes (schematically shown in Figure 2a) connected with an asymmetric interconnect (Figure 2b) and a total of 64 cores. Pairs of cores share the instruction front-end, L2 cache, and floating point units. The second system is a quad Intel Xeon E7-4830 v3 with four NUMA nodes (Figure 2c) and 96 hardware threads (12 physical cores per node with SMT). The interconnect (not shown) is symmetric.

Concern	Score	Resources	Cost?	Inverse Perf Possible?
L2/SMT	Number of L2 caches in use	L2 cache, instruction fetch and decode, and floating point units	Y	Y
L3	Number of L3 caches in use	L3 cache, memory controller, and bandwidth to DRAM	Y	Y
Interconnect	Aggregate bandwidth between nodes in use	Interconnect bandwidth	N	N

Table 1: Scheduling concerns used on our AMD test system (shown in Figure 2).

all, we found scheduling concerns to be a powerful abstraction that enables encoding shared resources on a variety of hardware and makes the model easy to port to new hardware.

Next, from the concerns and hardware topology we need to derive the *important placements*. An important placement must have a score that ensures it satisfies three properties: **(1)** conform to our balanced assumption, **(2)** be feasible: i.e., not assign more than one vCPU to a single hardware thread, and **(3)** not be superseded by a strictly better placement.

Given a score s and the number of vCPUs v, the balance property is encoded as $v \bmod s = 0$, and the feasibility property is encoded as $v/s \leq Capacity$, where capacity is the number of hardware threads available in a single instance of the resource if applicable: e.g. there are eight hardware threads per L3 cache on our AMD test system. We also define the *Count* of a concern as the total number of that resource on the system, so our AMD test system has an *L2Count* of 32 for example. The first step in generating important placements is generating the possible scores that satisfy the balance and feasibility requirements individually. This is done for each scheduling concern that can affect cost or have an inverse relationship with performance. For our AMD test system this step is shown in Algorithm 1.

Now that we have all balanced and feasible placements, and before filtering the duplicates, we need to enumerate all possible placements whose performance the scheduler might want to predict if more than one container were running on the system. For example, suppose that after placing one container onto two nodes on the system, the scheduler might want to place other containers on the remaining nodes, so it should be able to predict the performance on any combination of those nodes. Therefore, we must keep track of possible placements on those remaining nodes in order to properly train the model. The packings are generated with a recursive method shown in Algorithm 2. On our AMD system, we use the L3 scores because the L3 scheduling concern corresponds to NUMA nodes, and NUMA nodes are our unit of resource allocation (see §3).

Next, as shown in Algorithm 3, packings that are duplicates and packings that are not Pareto-efficient with respect to the interconnect score are filtered out (since the interconnect concern does not affect cost and cannot have an inverse relationship with performance). Because the L2 and L3 scores can affect cost or have an inverse relationship with performance, placements are not filtered based on them.

As an example of a Pareto-efficient packing, on our AMD system we need to keep the 4-node placement that

Algorithm 1 Generating possible L2 and L3 scores

```
L3Scores = List()
for $i \leftarrow 1, L3Count$ do
    if $v/i \leq L3Capacity \wedge v$ mod $i = 0$ then
        L3Scores.append(i)
    end if
end for
L2Scores = List()
for $i \leftarrow 1, L2Count$ do
    if $v/i \leq L2Capacity \wedge v$ mod $i = 0$ then
        L2Scores.append(i)
    end if
end for
return L3Scores, L2Scores
```

Algorithm 2 Generating packings of placements

```
Packings = List()
procedure GENPACK(L3Scores, NodesLeft, Current)
    for all $L3S$ in L3Scores do
        if $L3S >$ len(NodesLeft) then
            continue
        end if
        for all $n$ in Combinations(NodesLeft, L3S) do
            Remaining = NodesLeft - $n$
            NewPacking = Current.append($n$)
            if len(Remaining) $> 0$ then
                GenPack(L3Scores, Remaining,
                            NewPacking)
            else
                Packings.append(NewPacking)
            end if
        end for
    end for
end procedure
return Packings
```

uses nodes $\{2,3,4,5\}$ because it is the 4-node placement with the highest interconnect score. Therefore the placement using nodes $\{0,1,6,7\}$ is also an important placement and will be kept because it is the placement that can be packed with the best 4-node placement. Continuing, suppose that we consider a 4-node placement that uses nodes $\{0,1,4,5\}$. If we were to use this placement at runtime, the remaining set of four nodes, potentially used for another workload, is $\{2,3,6,7\}$. Both of these placements have poor interconnect scores, in part because there is a two-hop distance between nodes $\{0,5\}$ and nodes $\{3,6\}$. Instead, we can pack the machine with a better combination of 4-node placements: $\{0,2,4,6\}$ and $\{1,3,5,7\}$. Using this observation, the vectors for placements $\{0,2,4,6\}$ and $\{1,3,5,7\}$ will be kept over the worse pair of 4-node placements.

Algorithm 3 Generating important placements

```
Nodes = range(0, L3Count)
Packings = GenPack(L3Scores, Nodes, List())
Remove duplicates from Packings
for all ($a$,$b$) in Permutations(Packings, 2) do
    if L3 Scores in $a \neq$ L3 Scores in $b$ then
        continue
    end if
    $aIC$ = Sorted interconnect scores of $a$ placements
    $bIC$ = Sorted interconnect scores of $b$ placements
    ToRemove = True
    for $i$ in range(0, len($aIC$)) do
        if $aIC[i] > bIC[i]$ then
            ToRemove = False
        end if
    end for
    if ToRemove then
        Remove $a$ from Packings
    end if
end for
ImportantPlacements = List()
for all Placements $p$ in Packings do
    $n \leftarrow L2Count/L3Count$
    $L3S$ = L3 Score of $p$
    for all L2S in L2Scores do
        if $n \cdot L3S \geq L2S$ then
            ImportantPlacements.append($p$)
        end if
    end for
end for
return ImportantPlacements
```

After this process is complete, we are left with the important placements. For our AMD system we have 13 of them: two 8-node placements (one sharing L2 caches and one not), three 2-node placements (with the best and second-best interconnect score, and one placement used to pack when specific 4-node placements are used), and eight 4-node placements (half sharing L2 caches, half not, and various interconnect scores relevant for packing). Our Intel test system (Fig. 2), on the other hand, only uses an L2/SMT concern and an L3 concern. With 24 virtual cores per container, it has seven important placements which are all of the placements that satisfy the balance and feasibility constraints: a one node placement sharing L2 caches, two 2-node placements, two 3-node placements, and two 4-node placements.

5 Performance Predictions

Automatic model-building techniques learn how to map a set of features describing data to a predicted outcome.

The outcome we would like to model is a vector of performance values in all important placements, relative to a baseline placement. For example, if there are three important placements, and the performance in the second and third is 20% and 30% better than that in the first baseline placement, the performance vector will be: $[1.0, 0.8, 0.7]$. Our data elements are executions of workloads in different placements, and the features are some metrics describing the execution.

Model-building methodology and feature selection. To build a model, we use a multi-output *Random Forest* regressor (RF). RF is a machine learning technique known for its ability to learn non-linear functions with very little or no tuning. More complex techniques, like deep neural networks, can yield slightly higher accuracy, but require substantial tuning and are prone to overfitting, especially if not given the "right" features.

Any modelling technique requires predictive input features. Feature selection turned out to be a challenge. In the past, to model performance on multicore systems, researchers used hardware performance events as inputs to the model. In most cases, the HPEs were selected manually[5], which required substantial insight into the intricacies of hardware architecture and its effects on software. Our goal was to make model training automatic, so manual HPE selection was not an option. Automatic selection, on the other hand, turned out to be impractical.

Modern machines have many hundreds of HPEs, some more than 1000 [32]. Automatic feature selection would measure *all* HPEs during training and use feature selection to identify the best predictors. Only four HPEs can be measured at a time, because there is usually only four hardware counter registers, so measuring all the HPEs for the entire training set can take weeks (66 days on our Intel machine), even if we use sampling.

In an effort to find an acceptable compromise, we first used a combination of the manual and automatic approaches. We started with a set of plausible features (41 HPEs on the Intel test system and 25 the AMD) covering cache, memory, TLB, interconnect, and pipeline behaviour, which are metrics commonly used in similar work. We then used *Sequential Forward Selection* [10, 16] (SFS) to pick the best ones. The final RF model would take a vector of selected HPEs observed in a single baseline placement as the input and produce the performance vector as the output. Even after this rigorous feature selection process, we were not happy with the accuracy (see §6).

Finally, we designed a solution that is more robust, requires little training time, and is largely automatic. Instead of relying on HPEs describing various architectural events, we rely on *observations of actual performance in two different configurations from the set of important placements*. Performance can be measured using instructions per cycle (IPC), transactions per second, or any other application-specific metric – the only requirement is that it must be possible to obtain this metric online. Specifying the performance metric for a container is the only manual part of the process. Beyond that, the training process automatically finds the two of the important placements that give the highest accuracy when used as inputs to the model. The final model takes as inputs the performance observations in these two placements and outputs the predicted performance vector. A separate model is trained for each number of vCPUs used in virtual containers.

The downside of this approach is that at runtime we have to run the container in two placements instead of one before obtaining the predictions, but the advantage is that the predictions are more accurate and we do not have to use the time-consuming feature selection process for each new target hardware.

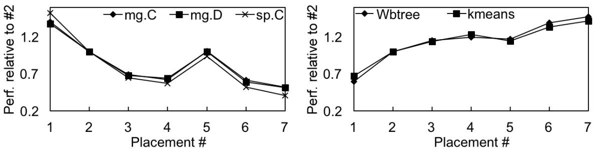


Figure 3: Performance relative to the baseline placement (#2) for workloads in two example clusters on Intel.

Why do performance observations have good predictive ability? Empirical evidence suggests that workloads naturally fall into several categories, according to the shapes of their performance vectors. Figure 3 shows two example categories on the Intel system. As we can see, the vectors within the category are almost identical, but the vectors in different categories are very distinct.

To generate these categories we used k-means clustering. To automatically determine the best value for *k*, we select the *k* that maximizes the average Silhouette coefficient [24, 2] over all data points, which is the standard practice in the field. This clustering method produced six categories on our systems (full results are reported in [13]). This suggests that workloads may naturally form distinct categories depending on their performance trends. For example, workloads that are not memory intensive and are not adversely affected by sharing SMT contexts could belong to the same category (where thread placement does not matter). Another category could be one where using fewer NUMA nodes and fewer physical cores greatly hurts performance, and so on. Then there is no surprise that a ML model could quickly narrow down the category, and hence the shape of the per-

[5] Dwyer's [11] and Zellweger's [32] works are the only exceptions known to us.

formance vector, from two observations of performance.

6 Evaluation

In this section we focus on evaluating the accuracy of predictions. Since our training method does not require automatic feature selection, training the model takes seconds. The algorithms used to determine important placements also run in a matter of seconds. The inference time is negligible (milliseconds).

We had three model variants to compare: the first one used as inputs the actual performance measurements observed in two important placements, the second used only the HPEs observed in a single placement, the third used both. The third variant did not improve accuracy over the first one, so we do not include the data for it.

The set of applications we experimented with are drawn from the NAS Parallel Benchmark suite [6], Parsec suite [7], the Metis map-reduce benchmarks [19], and BLAST [5]. Also included are the Linux kernel compile gcc benchmark, two Spark graph workloads, TPC-C [28] and TPC-H [29] on Postgres and a WiredTiger [3] BTree benchmark. Workloads were run using `lxc` containers and configured to use 16 vCPUs on the AMD system and 24 vCPUs on the Intel system (Fig. 2). Within containers, the number of application threads is set so as to achieve $>$70% CPU utilization on each core, typical of what is done in practice.

Figure 4 show the actual and predicted performance for each workload for important placements on the AMD and Intel systems. The x-axis shows the IDs of the important placements, numbered 1–13 on the AMD system and 1–7 on the Intel system. The y-axis shows the performance in the placements relative to the baseline. Placement #1 was used as the baseline for the AMD system, and placement #2 for the Intel system – the baseline placement can be any of the two placements whose performance is required as the input to the model.

The results are per-application cross-validated. For example, when training the model that will be used for predicting a Spark workload neither the data from *spark-cc* (a Spark connected components algorithm run on the LiveJournal database) nor *spark-pr-lj* (a PageRank algorithm run on the LiveJournal database) is included in the training. We cross-validated every workload, but for space constraints we omit the results for most of the NAS and Parsec benchmarks. They are qualitatively similar to others and we are happy to provide them upon request.

Overall the accuracy when using only the actual performance measurements as model features is high. The predicted performance is within 4.4% of actual on average on the AMD system, and within 6.6% on Intel. A couple of exceptions are the cases where the training set did not include any workloads that behaved similarly to the predicted benchmark, for example *kmeans* on the AMD system, which was the only benchmark in our training set that preferred SMT, or *canneal* on Intel.

Prediction accuracy when using only the HPEs from a single placement was a lot less reliable. On the AMD system it produced good results overall, but the accuracy was still noticeably worse compared to the model variant that relied only on actual performance measurement. On Intel the model relying only on HPEs produced many poor predictions. It completely missed the performance trend for *ft.C* and *freqmine*, produced errors of over 40% for *kmeans* and *WTbtree*, and is noticeably worse for several other workloads.

An example of why HPEs observed in a single placement could have poor predictive power, and one of the reasons why the Intel system produced worse predictions, is predicting the effect of inter-thread communication latency. There is a huge latency difference for communication between a single-node placement and placements including more than one node. For some applications, reduced inter-thread communication latency when all threads are running on a single node has a major performance impact, as is the case for *WTbtree*. Separating the sensitivity to latency from overall memory intensiveness (which can be measured by the cache miss rate) is difficult to do with HPEs. Similarly, it is also very difficult to determine if a workload's working set will fit in a given number of L3 caches by only measuring HPEs on a single placement. ***We conclude that using actual performance observations as model features is likely to produce higher accuracy, in addition to being a more practical method of training the model, than using selected architectural events.***

7 Using the model in practice

There are many ways in which data center operators can use our model. To illustrate one potential use case we set up a scenario, where the user would like to pack as many instances of a given virtual container into a physical server while respecting a performance target. For demonstration of the complete solution we implemented its prototype (covering steps 1-4 in §1). To assess the overheads, we measure the costs of container migration.

We use virtual containers of three types: WiredTiger running a B-tree search workload, Postgres running TPC-H, and Spark running PageRank on a LiveJournal database. For clarity, we present the results of homogeneous configurations, where many containers of the same type are packed into each system. Performance results with our model in heterogeneous configurations can be inferred from these figures, because different containers collocated on the same system do not interfere with our approach. Actual data can be provided upon request.

Figure 5: Instances per machine (left y-axis, higher is better) and % performance goal violation (right y-axis, lower is better).

The performance goal can be specified in terms of an application-level metric such as transactions per second or a generic metric such as instructions-per-cycle. The placement policy is agnostic to the metric used and only requires that the application make this metric available at runtime. For simplicity, we set the performance goals to correspond to 90%, 100% and 110% of the performance observed in the baseline placement.

We compare four hypothetical container placement policies. The first policy, referred to as **ML**, is based on our techniques. It decides how many nodes to allocate to the container based on performance observations in two placements and the model presented in the previous section. It runs the workload in two placements during the first few seconds of the execution without interrupting the workload, and then migrates it into the best predicted placement. To separate various aspects of performance, the results shown here do not include the migration overhead; it is studied separately in the next section. The second policy, **Conservative**, is a naïve policy that allocates the entire machine to each instance, allowing only one instance per machine. The third policy, **Aggressive**, is another simple policy that fills the system with as many instances as possible, maximizing machine utilization at the risk of performance violations. For example, our AMD system allows up to four 16-core instances and our Intel system up to four 24-core instances. Neither Conservative nor Aggressive pin vCPUs to cores, allowing Linux to perform the mapping in the way it wishes, and possibly creating unneeded contention. We also evaluate a more sophisticated fourth policy, **Smart-Aggressive**. This policy is similar to Aggressive, except each instance is pinned to the best minimum set of nodes, which we define as having the highest interconnect bandwidth. This policy requires an analysis of the interconnect topology in order to find the correct set of nodes.

We could not make a fair comparison to any other method presented in earlier work. As we explained in §2, most earlier models targeted very different systems and most did not predict performance vectors, so we could not apply them directly.

We evaluate the policies by measuring how many instances of the same workload they were able to pack per machine (higher is better) and the degree of violation of the performance goal as the percent of the target (lower is better). All workloads were run using `lxc` containers and configured to use 16 vCPUs on the AMD system and 24 vCPUs on the Intel system. Figure 5 show the results for the three container types. The bars show the number of instances packed (left y-axis), while the "stars" shows the deviation from the target performance goal, expressed as percentage (right y-axis).

The ML policy always meets the performance goal while in most cases packing more instances per machine than the conservative scheduler. The conservative policy almost always packs fewer instances per machine than ML, but also, surprisingly, may cause performance target violations, because Linux may map vCPUs unevenly to shared resources, causing unnecessary contention.

The aggressive policy packs a maximum possible number of containers per machine, at the cost of performance target violations, up to 46% with WiredTiger on AMD, and 43% with Spark on Intel. It is surprising that even when the aggressive policy packs the same number of containers per machine as the model-based policy, it still often reports a higher violation percent. That is because this policy allows virtual containers to share NUMA nodes. Smart-aggressive addresses this shortcoming, but even that policy can cause performance violations (e.g., 20% for WiredTiger on AMD), because it does not take into account all ways in which workload placement might affect performance.

Memory migration overhead. Memory migration in Linux is known to be inefficient [18]. Since we need to measure the performance of workloads in two or three configurations, fast memory migration is needed in that phase to reduce overheads. Lepers et al. [18] propose a method that freezes the application and migrates pages with concurrent worker threads. We improve on this by migrating the page cache and reducing locking overhead. Table 2 shows migration times for the workloads of §5. We observed similar results on the Intel system. Note that page cache migration time is counted with our method only since Default Linux doesn't support it – and yet, it can be a large part of migration overhead (93% with BLAST, 75% with TPC-C and 62% on TPC-H). We are able to migrate a large amount of memory in a few seconds, usually one order of magnitude faster than Default Linux (38× faster for Spark). Linux is especially inefficient for workloads with many processes such as TPC-C, since it has per-task overhead linked to updating the `cpuset` at each migration.

A drawback of our method is that it requires freezing the container during migration in order to reduce contention on some critical kernel locks. It is therefore suitable for non-latency-sensitive workloads. For latency-sensitive workloads, we have the option of not freezing the container and to instead throttle the bandwidth given to the migration process so as to reduce the impact on the running application. Thus, the migration takes more time but with a smaller impact on the running container. Using this method, the overhead of migration for the WiredTiger workload[6] is between 3% and 6%, and the migration takes 60 seconds. In comparison, Linux takes 43.8 seconds, has a overhead of 20% at best and completely freezes the applications for several seconds. It also does not migrate the page cache.

Overall, we observe that the migration overhead is proportional to the amount of memory used by the container, except in cases with extremely high thread counts. Using the container's memory footprint, the user can estimate whether the migration cost warrants an online deployment of the placement algorithm, or if it is preferable to use it offline for placement of recurring jobs.

Benchmark	Memory (GB)	Fast Migration (s)	Default Linux (s)
BLAST	18.5	3.0	5.9
canneal	1.1	0.3	3.9
fluidanimate	0.7	0.3	2.3
freqmine	1.3	0.3	4.2
gcc	1.4	0.3	2.8
kmeans	7.2	1.5	6.5
pca	12.0	2.8	10.0
postgres-tpch	26.8	5.8	117.1
postgres-tpcc	37.7	14.9	431.0
spark-cc	17.0	3.7	139.9
spark-pr-lj	17.1	3.8	137.0
streamcluster	0.1	0.1	0.4
swaptions	0.01	0.1	0.0
ft.C	5.0	1.3	19.4
dc.B	27.3	5.4	51.7
wc	15.4	3.4	19.5
wr	17.1	3.6	18.9
WTbtree	36.3	6.3	43.8

Table 2: Migration performance on the AMD system, compared to the default Linux migration method. The amount of memory includes processes' memory and the page cache associated with the container.

8 Conclusion

Modern multicore systems have a complex hierarchy of shared resources and performance can vary wildly depending on how virtual CPUs are mapped to hardware contexts. Operators waste resources and money by using conservative and sub-optimal placement policies. We have shown a solution to this problem using a methodology to abstract a system's shared resources, identify important placements, and predict their performance. Our method can lead to very significant advantages in machine utilization while keeping performance guarantees.

CPU architecture is continually changing, often by sharing resources between cores in new ways, in order to continue scaling the core count. AMD's newly introduced Zen architecture [8] has L3 cache sharing separate from sharing the memory controller. Intel's Haswell-E architecture has asymmetric links between NUMA nodes through its cluster-on-die feature [22], which has unique performance implications different from other asymmetric architectures. The flexibility of our methods means that they can be used on systems like these or future architectures without significant retooling by an expert.

Getting to the Root of Concurrent Binary Search Tree Performance

Maya Arbel-Raviv

Tel Aviv University

Abstract

Many systems rely on optimistic concurrent search trees for multi-core scalability. In principle, optimistic trees have a simple performance story: searches are read-only and so run in parallel, with writes to shared memory occurring only when modifying the data structure. However, this paper shows that in practice, obtaining the full performance benefits of optimistic search trees is not so simple.

We focus on optimistic binary search trees (BSTs) and perform a detailed performance analysis of 10 state-of-the-art BSTs on large scale x86-64 hardware, using both microbenchmarks and an in-memory database system. We find and explain significant unexpected performance differences between BSTs with similar tree structure and search implementations, which we trace to subtle performance-degrading interactions of BSTs with systems software and hardware subsystems. We further derive a prescriptive approach to avoid this performance degradation, as well as algorithmic insights on optimistic BST design. Our work underlines the gap between the theory and practice of multi-core performance, and calls for further research to help bridge this gap.

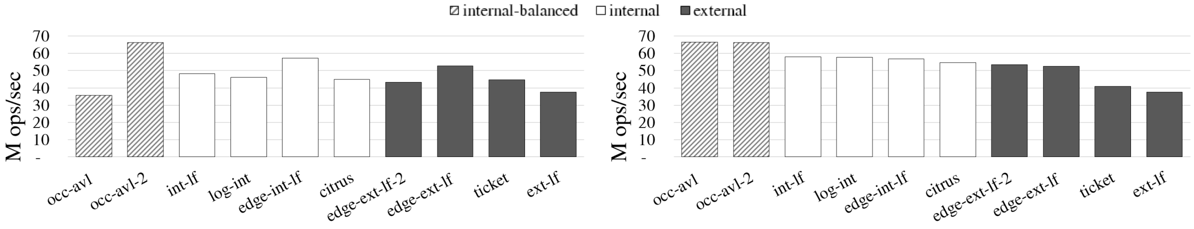
1 Introduction

Many systems rely on optimistic concurrent search trees for multi-core scalability. (For example, in-memory databases [35], key/value stores [29], and OS virtual memory subsystems [10].) Optimistic search trees seem to have a simple performance story, based on the observation that to scale well a workload must contain sufficient high-level parallelism (e.g., operations should not all modify the same key [21]). Optimistic search trees therefore strive to avoid synchronization contention between operations that do not conflict semantically, such as updates to different keys. In particular, optimistic trees use *read-only* searches, which do not lock or otherwise write to traversed nodes, with writes to shared memory occurring only to modify the data structure [7, 29]. This design is considered key to search tree performance [12, 18].

We show, however, that realizing the full performance benefits of optimistic tree designs is far from simple, because their performance is affected by subtle interactions with systems software and hardware subsystems that are hard to identify and solve. To demonstrate this issue, consider the problem faced by systems designers who need to reason about data structure performance. Given that real-life search tree workloads operate on trees with millions of items and do not suffer from high contention [3, 26, 35], it is natural to assume that search performance will be a dominating factor. (After all, most of the time will be spent searching the tree, with synchronization—if any—happening only at the end of a search.) In particular, we would expect two trees with similar structure (and thus similar-length search paths), such as balanced trees with logarithmic height, to perform similarly.

In practice, however, this expectation turns out to be false. We test the above reasoning on optimistic *binary* search trees (BSTs), since there are BST designs with various tree structures [2, 7, 14, 15, 22, 23, 32, 33]. We find significant performance differences between BSTs with similar structure and traversal techniques. Figure 1a depicts examples of such anomalies. (We show a *read-only* workload, consisting only of lookups, to rule out synchronization as a cause. We detail the studied BSTs and experimental setup in § 2.) For instance, one unbalanced internal BST (*edge-int-lf*) outperforms other BSTs with the same tree structure (*log-int* and *citrus*). There is even a significant difference between two implementations of the same BST algorithm (*occ-avl* and *occ-avl-2*).

The goal of this work is to explain and solve such unexpected performance results. We perform a detailed performance analysis of 10 state-of-the-art optimistic BST implementations on large scale x86-64 hardware, in which we uncover the root causes of the observed anomalies. Using microbenchmarks, we find that performance anomalies are caused by multiple performance-degrading interactions of BSTs with systems software and hardware subsystems, mostly related to cache effects. These cache effects are due either to cache-unfriendly implementation oversights or, more interestingly, to memory layout pathologies that are caused by interactions between the BST and the memory allocator. To determine whether our observations are only artifacts of micro benchmarking, or whether similar issues appear in more complex software, we deploy the BSTs as the index structure in DBx1000, an in-memory database [4, 27, 39, 40]. We find that similar anomalies exist in DBx1000 as well. Most importantly, we find that a simple approach of *segregating* BST-related allocations, so that BST data is not mixed with application data, improves performance of the BSTs by up to 20%



a. Current state: Multiple anomalies.

b. Following our analysis and fixes.

and of the overall application by up to 10%. Figure 1b demonstrates part of our results.

Our work underlines the gap between the theory and practice of multi-core performance. As we show, it is non-trivial to understand a search tree's performance, and specifically, whether performance is due to fundamental algorithmic factors or to implementation issues. While we focus on BSTs, the effects we uncover are relevant to other optimistic concurrent data structures, as they stem from general principles of memory allocator and systems design. (But we leave such analysis for future work.) Our results therefore call for further research to help bridge the gap between the principles and practice of multi-core performance, to simplify the task of deploying a concurrent data structure and reasoning about its performance.

2 Scope

2.1 BSTs

We analyze C implementations of 8 BST algorithms, two of which have independent implementations, for a total of 10 implementations. The algorithms implement the standard key/value-map operations, `lookup`, `insert` and `remove`. [1] Table 1 lists the implementations studied. These BSTs span the known points in the design space, covering combinations of synchronization techniques, tree types (internal vs. external), and balancing choices (unbalanced vs. self-balancing algorithms).

All BSTs but *int-lf* feature read-only traversals; in *int-lf*, a traversal might synchronize with a concurrent update. In the *lock-free* BSTs, updates manipulate the data structure using atomic instructions, such as `compare-and-swap` (CAS), instead of synchronizing with locks. Both *int-lf* and *ext-lf* use *operation descriptor* objects to implement *helping* between their operations. A descriptor details the memory modifications that an update operation needs to perform. Before performing its modifications, the update operation CASes a pointer to its descriptor in each of the nodes it needs to update. Other operations that encounter the descriptor use the information therein to help the update complete. *edge-int-lf* and *edge-ext-lf* avoid descriptors by "stealing" some bits from node left/right pointers to encode helping-related information.

Table 1: BST implementations studied (ordered by the expected performance of searches).

An *internal* BST stores an item in every node, whereas an *external* BST stores items only in leaves. Internal BSTs have different solutions for removing a node with two children while maintaining consistency of concurrent searches. *edge-int-lf* and *int-lf* searches use *validation* to detect such a concurrent removal and restart the search. *log-int* avoids restarts by having an unsuccessful search (i.e., that fails to find its target key) traverse an ordered list which links all nodes, to verify that the key is indeed not present. Finally, *occ-avl* marks a node with two children as logically removed instead of physically removing it from the data structure, resulting in a *partially external* tree. *occ-avl* uses validation to restart a search that could take the wrong path due to a concurrent tree rotation.

The BSTs appear in Table 1 according to their expected relative performance in workloads where search time dominates performance: all else being equal, one expects self-balancing BSTs, which maintain logarithmic height, to outperform unbalanced BSTs; and internal BSTs to outperform external BSTs.

The original implementation of two of the BSTs [7, 14] is in Java. We choose, however, to evaluate 3rd-party C implementations of these BSTs, to obtain an apples-to-apples comparison and to simplify the analysis.

We fixed incorrect use of the C `volatile` keyword in some of the evaluated implementations. In general, to

avoid such problems, one should either use C `atomics`, or place the `volatile` keyword correctly: a volatile pointer to a node is written `node * volatile ptr`, not `volatile node * ptr`.

2.2 Experimental setup

We perform experiments on two multi-socket x86 platforms, by AMD and Intel. Table 2 details the hardware characteristics of these platforms. Both machines are NUMA platforms, configured so that DRAM is equally divided between the NUMA nodes. When running experiments, we use the standard practice of interleaving the benchmark's memory pages across the system's NUMA nodes (using the `numactl` command) to prevent any NUMA node from becoming a bottleneck. We compile the benchmarks with `gcc` v4.8. As in prior work, we use a scalable memory allocator (`jemalloc` [16]) to prevent memory allocation from becoming a bottleneck.

3 BST performance in isolation

We begin by analyzing BST performance on the standard microbenchmark used in the concurrency literature [2, 7, 11, 14, 22, 23, 32, 33], which models an application using a BST. The benchmark consists of a loop in which each thread repeatedly performs a random BST operation on a random integer key, and its performance metric is the obtained aggregate throughput of BST operations. We find that several implementations make simple oversights that lead to inefficient BST searches, but that fixing these problems still leaves many unexpected results (§ 3.1). These remaining anomalies occur due to cache behaviour differences due to BST memory layout (§ 3.2) and due to subtle interactions with the prefetching units (§ 3.3).

3.1 BST implementation issues

Most of the BST implementations contain one or more of three implementation oversights that negatively impact the performance of BST searches. Table 3 summarizes our findings, which we discuss next:

Bloated nodes Most implementations unnecessarily bloat the tree nodes, reducing the amount of the tree that can fit in each level of the cache hierarchy. Some lock-based implementations use `pthread` mutex locks, which occupy 40 bytes, instead of `pthread` spin locks, which occupy 4 bytes. Several implementations pad BST nodes to cache line size, presumably to avoid false sharing.

Scattered fields Fields commonly read by traversals (key/left/right, as well as fields related to detecting concurrent tree modifications) should be located first in the node structure, to minimizes the chance that a search accesses two cache lines when traversing a node.

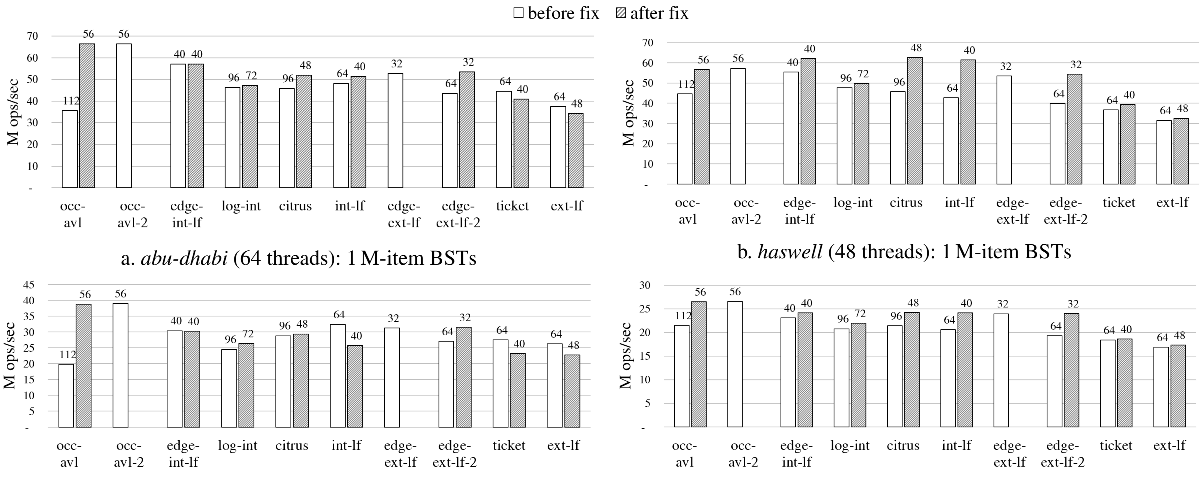
Heavy traversals *edge-int-lf* and *ext-lf* base all operations on one shared traversal method, and so end up burdening `lookup` operations with the book-keeping required only for updates, such as maintaining pointers to the parent/grandparent of the current node.

3.1.1 Evaluating impact of implementation issues

We fix the above implementation issues by replacing `pthread` mutex locks with spin locks, removing padding and reordering node fields in the affected implementations, and evaluate the impact of these fixes.

Methodology Our benchmark is parameterized by the distributions that the operation types and keys are chosen from, the size of the key space, and the number of items (key/value pairs) initially present in the tree. Following the practice in the concurrency research literature, we (1) choose operation keys uniformly at random; (2) perform `insert` and `remove` with equal probability throughout the benchmark; and (3) initialize the BSTs (using concurrent `insert()`s) with $U/2$ random items, where U is the size of the key space. We report averages of five 3-second runs on an otherwise idle system.

Results Figure 2 shows the performance impact of our changes on trees that initially contain 1 M and 10 M items, to model realistic working sets. We show results from read-only (100% `lookup`) workloads so that we can reason about search performance and remove synchronization effects as a confounding factor. We have, however, verified that read-only workloads are a good proxy for read-dominated workloads on this benchmark: e.g., in workloads with 90% `lookups`, the relative performance order of the BSTs matches that of the read-only case almost perfectly and most comparison points remain similar



a. *abu-dhabi* (64 threads): 1 M-item BSTs

b. *haswell* (48 threads): 1 M-item BSTs

c. *abu-dhabi* (64 threads): 10 M-item BSTs

d. *haswell* (48 threads): 10 M-item BSTs

Figure 2: Impact of fixing BST implementation issues. Numbers on top of the bars show the BST node size.

even at a 70% lookup rate.

We show results from executions with the maximum number of threads on each platform, as all BSTs scale with the amount of concurrency. On the 1 M-item tree, our fixes improve the throughput of the BSTs by up to 86% on *abu-dhabi* and by up to 43% on *haswell*, with a geo mean improvement of 11% on *abu-dhabi* and 23% on *haswell*. Moreover, reducing *occ-avl*'s node size brings its performance to the level of *occ-avl-2*.

Unexpected results Several unexpected results remain even after fixing the BST implementation issues, and we uncover their cause in the remainder of this section:

- Why does decreasing node size *hurt* throughput for 10 M-item *int-lf*, *ticket* and *ext-lf* on *abu-dhabi*? (§ 3.2.2)
- Why does *int-lf* benefit from a reduction of 64-byte nodes to 48-byte nodes much more than *ticket* on *haswell*? Why does *log-int* perform worse than the other unbalanced internal BSTs? (§ 3.2.3)
- Why does *edge-ext-lf* outperform other external BSTs, when they all have the same tree structure? (§ 3.2.4)
- Why do *occ-avl* and *occ-avl-2*, self-balancing BSTs, behave differently on *abu-dhabi* and *haswell*? On *abu-dhabi* they significantly outperform unbalanced trees (as expected), whereas on *haswell* they do not. (§ 3.3)

3.2 Memory layout issues

We trace most of the anomalies to memory layout issues that lead to different cache behaviours between the BSTs. These memory layout issues result from subtle interactions between the BST's allocation pattern and the policies of the memory allocator, particularly the use of *segregated free lists* [24] for satisfying allocations.

3.2.1 Segregated free list allocation

At a high level, scalable memory allocators [5, 16, 17] avoid contention by providing each thread with its own heap. These heaps are implemented as a set of free lists [24], one for each possible *size class*. Free lists are generally implemented as *superblocks*, which contain an array of blocks. To satisfy an *n*-byte allocation request, the allocator rounds *n* up to the nearest size class, *s*, and returns an *s*-byte block obtained from the relevant free list. In the jemalloc memory allocator we used for our experiments, the size classes used for allocations of up to 1 KiB are $8, 16, 32, 48, 64, 80, 96, 112, 128, 192, 256, 320, 384, 448,$ 512, and 1024. In addition to size classes, allocators differ in the structure and size of superblocks, the algorithm for mapping a block to its superblock, policies for allocating and releasing superblocks, and synchronization schemes. The important point in our context is that we can model the behaviour of the memory allocator as satisfying allocations of size *s* from an array of blocks of size *s*.

3.2.2 Crossing cache lines

In the BSTs we study, visiting a node should in principle incur at most one cache miss: the size of the searched fields (key, child pointer, and any fields used to synchronize with concurrent updates) fit in one cache line. We find, however, that the memory allocator might place a node in memory so that these search fields straddle a cache line boundary, causing a visit to the node to incur 2 cache misses.

Consider, for example, a BST whose searches access the first 24 bytes of a node (8-byte key and 8-byte left or right child pointer). If its node size is 48 bytes and the memory allocator's block array is cache line-aligned, then nodes will start at offsets 0, 16, 32, and 48 within cache lines. For the nodes at offset 48, the last 8 bytes of these searched fields extend into the next line, possibly leading to a cache miss. Such a miss occurs with probability $1/8$, as one in 4 nodes straddles a cache line boundary, and a search reads each next pointer with probability $1/2$.

Originally, *int-lf*, *ticket* and *ext-lf* do not experience such cache line crosses, as they have padded 64-byte nodes that the memory allocator allocates from a size class of 64-byte blocks. Decreasing their node size introduces this issue, whose performance impact is a trade-off that depends on the workload. At one end of the spectrum, if a smaller node size allows the entire tree to fit into the LLC, then one can eliminate cache misses altogether. At the other end, if the workload is such that almost every node traversed incurs a cache miss, then it is better to increase the node size to avoid crossing cache lines, as otherwise the expected number of cache misses per search increases by the expected number of nodes whose search incurs an extra miss (e.g., by $1\frac{1}{8}\times$ for 48-byte nodes).

In our workloads, we observe a 17% (geo mean) throughput degradation on the 10 M-item tree on *abudhabi*, but negligible overhead on the 1 M-item tree. We do not observe this anomaly on *haswell* because it has an adjacent-line prefetcher [36] that effectively doubles the cache line size and hides the effect of misses caused by cache line crossings.

3.2.3 Underutilized caches due to allocation pattern

We find that BST allocation patterns can lead to *cache set underutilization*,[2] in which the workload uses some cache sets more than others, thereby leading to increased associativity misses on the overused cache sets. We identify two causes for underutilized cache sets. First, the memory allocator might place allocated nodes in memory so that they map to just a subset of the cache sets. More insidiously, even if the nodes cover all cache sets but are allocated next to cache lines containing useless data, then prefetching this data evicts useful nodes from the cache.

We demonstrate cache set underutilization that occurs in *int-lf*; *log-int* has a similar issue, whose description we omit due to space constraints.

***int-lf* analysis** We observe an anomaly on *haswell*, in which *int-lf* benefits from a reduction of 64-byte nodes to 48-byte nodes much more than *ticket*. We focus on the 1 M-item tree experiment. While performance counter data shows that *int-lf*'s throughput improvement with smaller nodes is correlated with reduced LLC miss rates, the 1 M-item tree should almost fit into *haswell*'s 30 MiB LLC even with bloated nodes. This points to a cache set underutilization problem, in which *int-lf* effectively runs as if with a smaller cache. We verify this hypothesis by computing the cache set indexes of each node,[3] finding that the original *int-lf* implementation uses only 50% of the L2 and LLC sets. Next, we analyze *int-lf*'s allocation pattern to find the cause for this problem.

int-lf variant	ops/sec	unused L1 sets	unused L2 sets	unused L3 sets
64 b node	42.5M	1.6%	50.8%	50.8%
64 b node, w/ allocs	42.5M	1.6%	1.6%	1.6%
64 b node, w/ allocs, no prefetching	60.0M	1.6%	1.6%	1.6%
40 b node	60.0M	1.6%	1.6%	1.6%

Table 4: *int-lf* on *haswell* cache set usage (1 M-item BST).

Like many lock-free algorithms, *int-lf* uses *operation descriptors* so that threads can help each other to complete their operations (see § 2.1). Each thread's allocation pattern during the BST initialization is thus *NDNDND*..., as each `insert` operation allocates a new node of size N and a descriptor of size D. The size of both descriptors and *int-lf*'s original padded nodes is 64 bytes, the cache line size. Both allocation types are thus satisfied from the same allocator size class, and consequently, nodes occupy only even (or only odd) cache set indexes, utilizing only 50% of the available cache sets. (We note that *int-lf* intentionally does not free descriptors, to avoid an ABA problem[4] on the descriptor-pointer field in the nodes. The idea is that if the content of this field only changes from one descriptor to another, an ABA problem cannot occur.)

Fixing cache set underutilization Shrinking *int-lf*'s node size as part of fixing its implementation oversights has the serendipitous effect of *segregating* node and descriptor allocations. As nodes and descriptor allocations become satisfied from different size classes, nodes occupy all cache sets. Moreover, only nodes are allocated from their size class, and so no prefetching of useless data occurs. To prevent cache set underutilization in a principled way, we explicitly segregate BST nodes by allocating them from a dedicated memory pool; see § 4 for details.

It remains to show that cache set underutilization is not only caused by mapping nodes to a strict subset of the cache. To this end, we modify the microbenchmark to add allocation calls of random sizes between BST operations. These random allocations break the benchmark's regular allocation pattern, causing *int-lf* nodes to map to all cache sets. Nevertheless, unless we additionally disable prefetching,[5] *int-lf* performs poorly. Table 4 shows the result of our experiments. Fixing cache set underutilization improves throughput by 40% on the 1 M-item tree.

3.2.4 Collocated children

We find that the high throughput obtained by *edge-ext-lf* compared to the other external BSTs is due to a fortunate allocation pattern, which causes many leaves to be

[2] An 2^n-way associative cache of size 2^C bytes with 2^l cache lines groups its slots into *sets* of size 2^{C-l-n}. Bits $l+1,\ldots,C-n+1$ of an address determine its set index.

[3] We compute LLC set indexes using the physical addresses of the nodes. Specifically, we use the techniques of [30, 38] to reverse engineer the mapping from physical address to *haswell* LLC cache slices.

[4] An ABA problem occurs when a thread reads the same value (A) from a location twice, interpreting this to mean that the location has contained (A) at all times between the two reads, whereas between the two reads, the location was actually changed to (B) and back to (A).

[5] Specifically, the L1 data cache prefetcher.

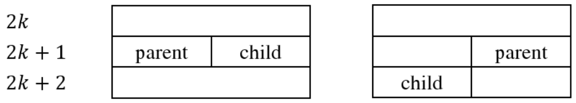


Figure 3: Collocated and shifted nodes in *edge-ext-lf*.

collocated on the same cache line with their parent.

edge-ext-lf is an external BST with immutable 32-byte nodes: an `insert` whose search completes at leaf u allocates a new internal (routing) node v and a new leaf node (with the inserted item) w, which is a child of v. It then replaces u with v. The memory allocator satisfies node allocations from a superblock of 32-byte blocks. Therefore, v and w might be collocated on the same cache line.

We analyze the node addresses in the evaluated trees and find that 75% of the internal nodes which have a leaf child are also collocated in the same cache line with one of their children. (This collocation can only occur for leaves. Whenever *edge-ext-lf* extends a path, it breaks the previous parent/child collocation.)

To evaluate the performance impact of the collocation property, we implement *shifted* versions of *edge-ext-lf*, where we add one 32-byte allocation before the initialization of the tree. This shifts the cache line offsets of all later allocations, moving the child nodes to a different cache line (Figure 3). As expected, we find that in the shifted implementations, 75% of internal nodes which have a leaf child have a child located on the adjacent cache line. On a 1 M-item BST, we observe throughput slowdowns of 14% and 11% on *abu-dhabi* and *haswell*, respectively.

The reason that prefetching does not hide this problem is again due to the allocation pattern. We examine the node addresses and find that 100% of the nodes which have a leaf child in the next cache line are themselves located on an odd cache line (Figure 3). The adjacent-line prefetcher on *haswell* "fetches the cache line that comprises a cache line pair" [36]. This appears to imply that it is only triggered on accesses to an even cache line, and thus is ineffective in this case.

3.3 Prefetching issues

Bronson et al.'s relaxed balance AVL BST [7] (*occ-avl* and *occ-avl-2*) is considered as one the fastest BSTs. While on *abu-dhabi* the AVL tree indeed outperforms the other BSTs by a geo mean of 40% in both tree sizes, on *haswell* it is not the best performer on the 1 M-item tree experiment. We trace this anomaly to a novel interaction of the BST's optimistic concurrency control (OCC) and the L2 prefetcher, which is exposed after removing a different bottleneck in the OCC implementation.

The algorithm uses *versioning*—an OCC implementation technique—to detect concurrent tree modifications during searches. Glossing over some details, each child pointer has an associated version number that increases when the pointer is updated. Observing that this version has not changed between time t_0 and t_1 allows a search to verify that the associated pointer has not changed as well. Searches use this property to verify that they traverse through a node only if both the inbound pointer to u and the outbound pointer to the next node on the path were valid together at the same point in time.

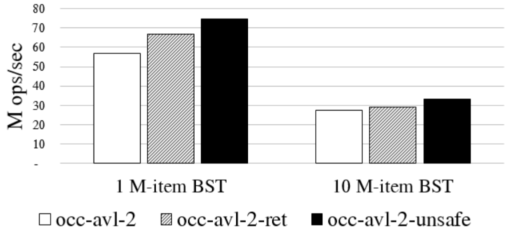

Figure 4: Impact of OCC changes in *occ-avl-2* (*haswell*).

When the validation at some node u fails, the search starts ascending along the traversed path, revalidating at each node, until it returns to a consistent state from which it resumes the search. Both *occ-avl* and *occ-avl-2* use recursive calls to visit nodes, thereby recording this bookkeeping data on the stack. This information, however, is used only if a search encounters a concurrent update, which is expected to be a rare event. We therefore change *occ-avl-2* to restart the search from the root when validation fails, yielding the *occ-avl-2-ret* implementation.

In the 1 M-item tree experiment, *occ-avl-2-ret* outperforms *occ-avl* and *occ-avl-2* by 17% on *haswell*. We observe, however, that it generates many L2 prefetch misses. Our workload does not benefit from hardware prefetching, since the next cache line a BST search visits is random. Prefetching thus hurts BST throughput, as it evicts potentially useful tree nodes (e.g., nodes at the top of the tree) from the cache.

We find that reading the version stored in the nodes triggers an L2 prefetch. While reading twice from the cache line (key and next pointer) does not trigger prefetching, *any* additional read from the node does. To evaluate the impact of prefetching, we implement a variant of the algorithm without the version reads, *occ-avl-2-unsafe*. This variant is safe to run only in a read-only workload; we use it just to estimate the performance lost due to prefetching. Figure 4 shows the results: On a 1 M-item tree, *occ-avl-2-unsafe* improves a further 12% over *occ-avl-2-ret*, for an overall 31% improvement over *occ-avl-2*; its total improvement over *occ-avl-2* on a 10 M-item BST is 21%.

4 BST performance in an application

The next logical step is to ask whether these performance issues are simply artifacts of micro benchmarking, or whether similar issues appear in more complex software. To this end, we study an *in-memory database management system* called DBx1000 [39] (henceforth, simply DBx), which is used in multi-core database research [4, 27, 39, 40]. In this section, we focus on the *haswell* machine.

DBx DBx implements a single relational database, which contains one or more *tables*, each of which consists of a sequence of *rows*. It offers a variety of different concurrency control mechanisms for allowing processes to access tables and rows. We use its 2-phased locking option, which locks individual rows of tables, and has been shown to scale on simulated systems containing up to one thousand cores [39].

Each table can have one or more *key fields* and associated *indexes*. Each index allows processes to query a specific key field, quickly locating any rows in which the key field contains a desired value. Any thread-safe data structure can serve as an index in DBx, as long as it implements a *multimap*. A multimap represents a set of keys, each of which maps to one or more *values* (pointers to rows of a table), and offers three operations: `search`(key), `insert`$(key, value)$ and `remove`$(key, value)$. `search`(key) returns all of the values to which *key* maps in the multimap. `insert`$(key, value)$ adds a mapping from *key* to *value*. If *key* maps to *value*, then `remove`$(key, value)$ removes the mapping from *key* to *value*, and returns true. Otherwise, it simply returns false.

Methodology We replace the default index implementation in DBx with each of the BSTs that we study. To do so, we had to overcome a minor complication: each of these BSTs implements a *map*, not a *multimap*. That is, each *key* maps only to a single value. We transformed these maps into multimaps as follows. Instead of storing keys and pointers to rows in the map, each key maps to the head of a linked list that is protected by a lock. (The locks are stored in a separate lock table.) Then, to perform `insert`$(key, value)$ on the multimap, where *value* is a pointer to a *row*, we simply insert *row* into the appropriate linked list in the underlying map.

Workloads To analyze the performance of the various BST implementations in DBx, we use the well known Yahoo! Cloud Serving Benchmark (YCSB), and the Transaction Processing Performance Council's TPC-C benchmark. The relatively simple transactions in YCSB comprise a read-mostly workload on a large table with a single index. TPC-C has more complex transactions, many indexes, and many writes.

In all of our experiments, we measure the number of committed transactions, the number of index operations performed, the time needed to perform all transactions (*total time*), and the time spent accessing the index(es) (*index time*). Timing measurements were performed using x86-64 RDTSC instructions. The overall performance of a benchmark is measured in terms of *transaction throughput*, the total number of committed transactions divided by *total time*. We define *dbx time* as the time in an execution that is not spent accessing the index(es) (i.e., *total time*−*index time*).

4.1 YCSB

Following the approach in [39], we run a subset of the YCSB core with a single table containing ten million rows. Each thread performs a fixed number of transactions (100,000 in our runs), and the execution terminates when the first thread finishes performing its transactions. Each transaction accesses 16 different rows in the table, which are determined by index lookups on randomly generated keys. Each row is read with probability 0.9 and updated with probability 0.1. The keys are generated according to a Zipfian distribution following the approach in [19].

Segregating tree data When we use a BST implementation as the index in YCSB, we are effectively merging the memory address space of YCSB with the address space of the BST. In doing so, we may change the memory layout of objects in YCSB (for example, by interleaving nodes with table rows in YCSB), which can have a significant impact on performance. We can isolate and study these memory layout changes, and selectively eliminate them, by using *segregation* to effectively separate parts of the address spaces for the BST and YCSB.

In a real application, it can be difficult to segregate simply by changing object sizes, so we implement segregation by using *several separate instances* of the memory allocator: one for YCSB, and one for each type of objects we would like to segregate from other object types. In our case, this means one for BST nodes, one for BST descriptors, and one for other implementation specific tree data. Consequently, when we segregate tree data, nodes are allocated consecutively in each page, descriptors are *not* interleaved with nodes (avoiding the performance problem with *int-lf* in § 3.2.3), and tree data is *not* interleaved with YCSB data.

4.2 Comparison with the microbenchmark

We first address the question: to what degree do the results of YCSB match our microbenchmark results? We compare with microbenchmark results for trees containing 10 million keys, since this is approximately the size of the index in YCSB. The left side of Figure 5 contains the results of running the microbenchmark for all of the BSTs we studied, after fixing all of the performance issues described. To make the results easier to understand, we sort the BSTs by performance and group them into the following equivalence classes: (*occ-avl*, *occ-avl-2*), (*log-int*, *edge-int-lf*, *citrus*, *int-lf*, *edge-ext-lf-2*, *edge-ext-lf*), (*ticket*), (*ext-lf*). Within each of these equivalence classes, the performance differences are not significant.

The results of our YCSB experiments appear in Figure 5. The BSTs are listed in the same order as they appear in the microbenchmarks. Without segregation (middle

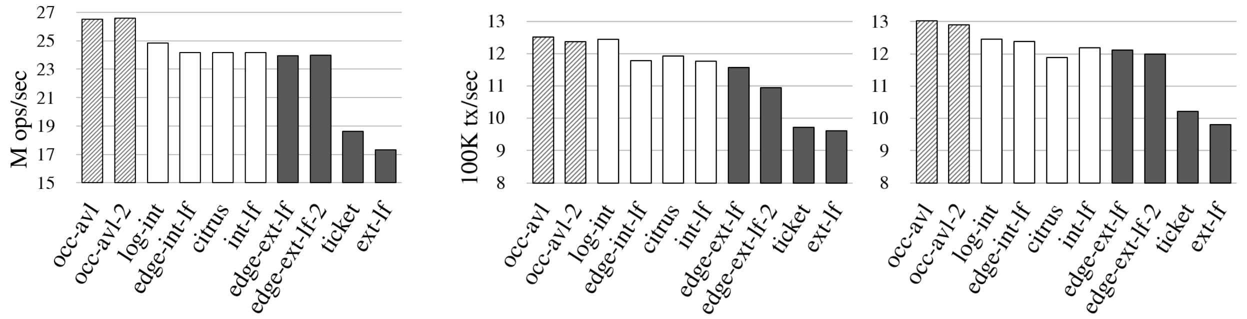

Figure 5: Microbenchmark compared to YCSB results: (left) Microbenchmark for 10M item BSTs (middle) YCSB *without* segregation, (right) YCSB *with* segregation.

graph) there are several differences between the YCSB results and the microbenchmark results. First, *log-int* performs about as well as *occ-avl* and *occ-avl-2*, which were significantly faster than *log-int* in the microbenchmarks. Here, it appears that *log-int* belongs in the same equivalence class as *occ-avl* and *occ-avl-2*. Second, *edge-ext-lf-2* is significantly slower than *edge-ext-lf*, whereas they have the same performance in the microbenchmark. Third, *ticket* and *ext-lf* have the same performance, whereas *ticket* is significantly faster in the microbenchmark. As the graph on the right shows, segregating the tree data bring the results closer to the original behaviour observed in the microbenchmark.

4.3 Memory layout issues

In our analysis of YCSB, we found several memory layout issues that were similar to the issues we found in our microbenchmarks. We describe a few key examples.

4.3.1 Underutilized caches due to allocation pattern

When we add all of our BST implementations to YCSB, several of them exhibit very poor cache set utilization. We find that their nodes map to only 1/3rd of the L3 cache sets, rendering 2/3rds of the L3 cache unusable for the storing nodes. These implementations include *occ-avl* and *occ-avl-2*, which have 64-byte nodes. Only implementations with 64-byte nodes were affected.

Since we did not observe this behaviour in the microbenchmarks, we hypothesize it is the result of adding these trees to YCSB (more specifically, merging each tree's memory space with the memory space of YCSB). We analyze the allocations performed by YCSB, and find that it allocates a large number (millions) of objects in size classes: 8, 32, 48, 64, 128, 192 and 384. In the 64-byte size class, it allocates only *row* and *row wrapper* objects. In particular, it always allocates a row, followed by a row wrapper, and then inserts the row into the index (BST). In the BSTs that exhibit this memory layout problem, index insertion allocates one 64-byte node. Thus, the allocation pattern in memory is RWNRWNRWN... where R is a row, W is a row wrapper, and N is a node. Consequently, rows have addresses satisfying $addr = 0 \ (mod\ 192)$, row wrappers have addresses satisfying $addr = 64 \ (mod\ 192)$ and nodes have addresses satisfying $addr = 128 \ (mod\ 192)$. That is, each object type has a 192-byte stride.

This pattern turns out to have a pathological interaction with the processor's internal hash function that maps physical addresses to L3 cache sets, resulting in an execution where rows, row wrappers and nodes each map to only 1/3rd of the L3 cache sets. (This is similar to how we saw a memory layout anomaly with a 128-byte stride in § 3.2.3.) In contrast, if a particular object type appears with a 256-byte stride, the L3 hash function will map objects approximately uniformly over all cache sets.

We break up this deleterious allocation pattern by segregating the tree data. This segregation results in a significant speedup for these data structures, since it allows nodes to occupy the entire cache. For example, in *occ-avl*, it reduces *index time* from 121 to 108 seconds (a 13 second difference), and *total time* from 188 to 178 seconds (a 10 second difference). Note, however, that it increases *dbx time* by 3 seconds. Further timing measurements demonstrate that the increase in *dbx time* is due to added contention on *row locks*. In fact, we can show that *whenever* segregation increased *dbx time* in YCSB, the increase is due to added contention on row locks.

Perhaps surprisingly, the deleterious allocation pattern we saw above did *not* affect *ticket*, which has 64-byte nodes, or a variant of *ext-lf* with 64-byte nodes. (These were the only other implementations with 64-byte nodes.) The explanation turns out to be fairly simple. Although their nodes are 64 bytes, these trees are external, so they allocate *two* nodes per insertion operation, producing the allocation pattern RWNNRWNNRWNN. The second node allocation breaks up the (pathological) 192-byte strides that we saw above.

4.3.2 Accidentally fixing a memory layout problem

In the previous section, we saw how merging two address spaces can cause a memory layout issue. In this section, we see how merging two address spaces can fix a preexisting memory layout issue.

When adding BSTs with 48-byte nodes to YCSB, and experimenting to see how much segregation helps, we find that segregating tree data for these BSTs caused significant *increases* in *dbx time*. For example, segregation increases *dbx time* for *edge-int-lf* by 9 seconds, from 58 to 67. Analyzing executions of YCSB, we find that approximately ten million *row locks* (implemented with `pthread` mutexes) and 4,000 other miscellaneous objects are allocated in the 48-byte size class (in addition to any 48-byte nodes).

If there are no 48-byte node allocations, then these 48-byte row locks experience false sharing. Since the locks are smaller than a cache line, and they are allocated consecutively, a single cache line contains parts of two different locks. Thus, write contention on one lock additionally creates write contention on another lock. This is exacerbated by the adjacent line prefetcher, which effectively causes accesses to a lock to contend with the (three to four) locks stored in *two* cache lines. By merging the address space of a BST with 48-byte nodes with the address space of YCSB, we accidentally mitigated this false sharing by interleaving row locks with nodes. Of course, this unfairly favours the BSTs with 48-byte nodes over the other BSTs. Thus, we fix this problem in a more principled way by padding the row locks to eliminate false sharing. (The same effect was seen, and fixed, in TPC-C.)

4.3.3 Unnecessary page scattering

So far, we have seen that segregation can improve performance by breaking up deleterious memory layouts, and generally improving cache behaviour. Our results have thus far suggested that we can reasonably expect to see some change in performance due to segregation whenever nodes are allocated from the same size class as some other objects. However, it turns out that segregation can improve performance, even when nodes are the only allocations performed from a given size class.

Once the row locks in YCSB are padded, YCSB only performs about 4,000 miscellaneous allocations from the 48-byte size class. Thus, in BSTs with 48-byte nodes, nodes are the only significant source of allocations in their size class. We were quite surprised to find that segregation significantly improved performance for these trees.

One interesting difference caused by segregation is a substantial reduction in the TLB miss rate for algorithms with 48-byte nodes. This improvement comes from an interaction between *huge pages* and the allocator. When huge pages are enabled in Linux, pages occupy 2MB instead of 4096 bytes. This generally improves TLB miss rates, since a program's working set can be represented using fewer pages.

However, we found that the allocator `jemalloc` divides each huge page into 512 chunks of 4096 bytes each, and distributes these into different size classes. More specifically, during its initialization, `jemalloc` allocates a bank of chunks for each thread. Each thread distributes these chunks *on-demand* to its individual size classes. Whenever a thread runs out of space in the current chunk for one of its size classes, it fetches one (or more) chunks from its bank, and assigns them to this size class. In our experiments, we observed that threads fetch one chunk at a time for the 32-, 48- and 64-byte size classes.

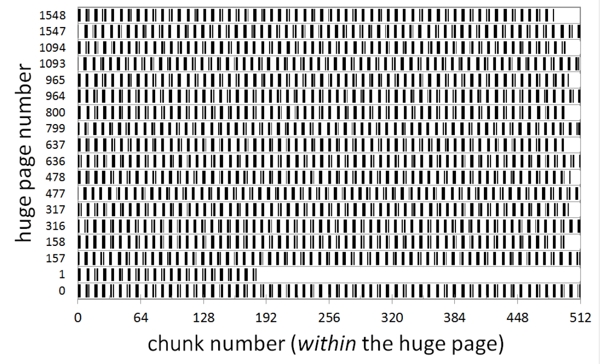

Figure 6: Layout of pages *without* segregation: all *chunks* used to store nodes by *occ-avl-2* in YCSB (*haswell*).

In YCSB, this has the following effect. Before performing insertion on a BST, a transaction allocates a 64-byte row, followed by 128 bytes of data, a 64-byte row wrapper, a 192-byte (padded) `pthread` mutex, and a 32-byte value. Thus, for each node allocated by an insertion operation, several objects are allocated in several different size classes. Consequently, each thread regularly takes chunks from its bank and assigns them to these size classes, almost in round-robin fashion, but with more chunks going to the size classes that exhaust them more quickly.

As a result, in the small size classes used for nodes, the chunks often do *not* have consecutive addresses. For example, in a variant of *edge-int-lf* with 48-byte nodes, we found that threads would allocate full 4096-byte chunks of nodes, but would only store nodes in approximately one out of every 10 chunks that it allocated. As another example, in *occ-avl-2*, which has 64-byte nodes, threads would use up to three consecutive chunks to store nodes, and then the next chunk used to store nodes would typically appear five or six chunks later in the address space. Figure 6 visualizes the actual layout of chunks used to store nodes in an execution of YCSB with *occ-avl-2*.

We now consider what happens when the tree data for *occ-avl-2* is segregated. Figure 7 shows the resulting layout of chunks used to store nodes. The difference is striking. Since the nodes are allocated by a separate instance of `jemalloc`, each thread uses its entire bank of chunks to store nodes. Consequently, the chunks allocated for nodes almost always have consecutive addresses. This

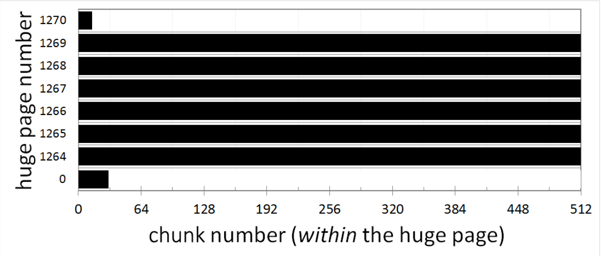

Figure 7: Layout of pages *with* segregation: all *chunks* used to store nodes by *occ-avl-2* in YCSB (*haswell*).

significantly reduces the number of pages needed to store the tree, and results in far fewer TLB misses. In YCSB with *occ-avl-2*, the average number of TLB misses per YCSB transaction decreases from 412 to 161 (a 61% reduction). Segregation reduces TLB misses in all of the BSTs we studied.

4.4 TPC-C

TPC-C simulates a large scale online transaction processing application for the order-entry environment of a wholesale supplier. According to the Transaction Processing Performance Council, it represents the business activity of "any industry that must manage, sell, or distribute a product or service." At a high level, TPC-C assumes that business operations are organized around a fixed number of warehouses, which each service a number of districts. For each warehouse and district, the database stores information about customers, orders, payments, items for sale, and warehouse stock. TPC-C features complex transactions over nine tables with widely varying row types and population sizes, and with varying degrees of non-uniformity in the data. These tables are indexed by up to three different indexes on different key fields.

Our implementation of TPC-C executes a representative subset of the TPC-C transactions. In particular, we include the *new-order* and *payment* transactions, which comprise 88% of all transactions executed in the full TPC-C benchmark. This same approach was taken in [39].

Note that payment transactions update data in the *warehouse* table, and thus contend with all transactions operating on the same warehouse. Consequently, concurrency in TPC-C is limited by the number of warehouses. Thus, it is common to run with at least as many warehouses as there are concurrent threads in the experimental system. We run with 48 warehouses.

Segregating tree data As in YCSB, we segregate the tree data by using several allocator instances: one for TPC-C, one for BST nodes, one for descriptors, and one for other implementation specific tree data. All indexes share the same allocators. So, for example, all indexes use the same allocator for nodes. Thus, nodes for all indexes are interleaved with one another, but not with TPC-C data.

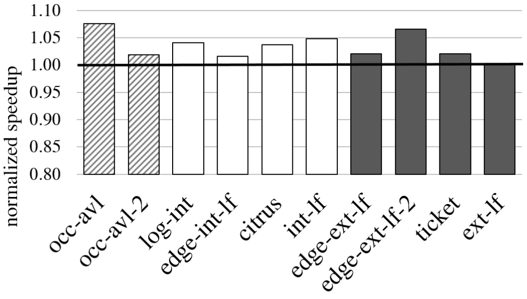

Figure 8: TPC-C: baseline vs. improved implementations.

4.5 Impact of improved BSTs on TPC-C

We now present an experiment that demonstrates the impact of our improvements to the BSTs on the performance of TPC-C. The results appear in Figure 8. We obtain each data point by dividing the throughput of TPC-C when the final BST implementation is used for indexes (with segregation) by the throughput when the baseline BST implementation (without segregation) is used for indexes.

By improving the BST implementations, we obtain an overall improvement of up to 7.6%. Initially, this improvement might seem somewhat small, but TPC-C is a large, complex workload that takes over 200 seconds to run, and allocates over 30 GiB of memory. Accesses to the indexes comprise a relatively small part of the work, and Amdahl's law limits the improvement we can see, so a 7.6% overall improvement is actually fairly substantial.

Source of the improvement Let us drill down into the details of where this improvement comes from. As an example, we consider *occ-avl* (which obtains the full 7.6% improvement). With the baseline implementation of *occ-avl*, the *total time* to run TPC-C is 249 seconds. This breaks down into 108 seconds of *index time* and 141 seconds of *dbx time*. If we follow the recommendations in § 3, then *total time* decreases by 9 seconds to 240. This breaks down into 105 seconds of *index time* and 135 seconds of *dbx time*. If we additionally segregate tree data, then *total time* further decreases by 8 seconds to 232. This breaks down into 95 seconds of *index time* and 137 seconds of *dbx time*.

Interestingly, segregation causes a slight increase in *dbx time*. It turns out that, when the indexes in DBx speed up significantly, a new bottleneck appears. This manifests as increased contention on row locks. However, this is not the only component of the increase in *dbx time*. DBx and TPC-C are quite complex, and there is an additional component that we are unable to identify. We leave it as future work to perform additional profiling of DBx.

4.6 Impact of segregation on TPC-C

We now study the effect of segregation on the other BSTs. Figure 9 shows the breakdown of TPC-C *total time* into *index time* and *dbx time* both with and without segregation

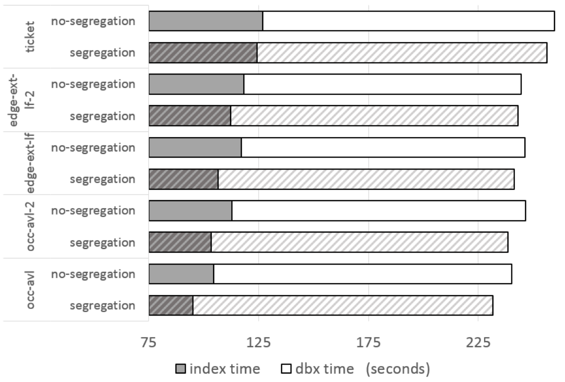

Figure 9: Impact of segregation on TPC-C.

of tree data. Note that the x-axis starts at 75 seconds. The BSTs that are not shown in the graph do not experience significant changes in either *index time* or *dbx time*.

As we saw above, segregation improves the *index time* of *occ-avl* by 10 seconds, and *hurts* its *dbx time* by 2 seconds. That is, it helps *index time* much more than it hurts *dbx time*. In contrast, consider *edge-ext-lf*, for which segregation improves *index time* by 10 seconds, but *hurts dbx time* by 6 seconds, negating most of the benefit. In this case, approximately 2 seconds of the change in *dbx time* is due to increased contention on row locks.

Although the benefit of segregation is somewhat limited in Figure 9, it is important to remember that we are starting from optimized implementations that follow the recommendations in § 3. Different implementations will interact with TPC-C's memory layout in different ways, and may see more significant benefits. For example, we ran TPC-C with a variant of *int-lf* that has 64-byte nodes and 112-byte descriptors, instead of 48-byte nodes and 64-byte descriptors. For this BST, segregation does increase *dbx time* by 5 seconds from 135 to 140, but it greatly improves *index time* by 16 seconds from 113 to 97.

5 Related work

Memory layout issues Some of the phenomena we find are reported in other contexts [1, 28, 37], but these works do not consider the combination of all factors and their effect on BST performance. Earlier research proposed compiler and library techniques for improving cache utilization by careful placement of objects in memory [8, 9], but these techniques are not deployed and so it is not clear whether they would address the anomalies we consider.

Segregated allocations Region-based memory management [20, 34] allocates each object type from a dedicated memory pool. However, its motivation is to speed up memory allocation and freeing, not to improve cache and TLB utilization. Lattner and Adve [25] propose a compiler algorithm for segregating distinct instances of data structures into separate pools. Their approach does not segregate allocations within a data structure, which may be required to avoid underutilizing cache sets.

Understanding performance Several studies compare the performance of concurrent data structures [12, 18], but do not analyze the root causes of performance differences. Our work is complementary to research on the difficulties of understanding experimental evaluation results [6, 13, 31], which does not consider concurrent data structures.

6 Discussion

We believe that the lessons learned in this work can be applied to other concurrent data structures, as they stem from general performance principles. Here, we attempt to distill these lessons into concrete recommendations.

Data structure designers and implementers: Study the memory layout of the data structure. If cache lines adjacent to nodes often contain other objects, then the cache may be underutilized by nodes. Pad objects to separate them into different allocator size classes. Padding should also be used to avoid false sharing, particularly between frequently-accessed nodes and other program data. Such padding should take prefetching (e.g., the adjacent line prefetcher) into account. However, indiscriminately padding *all* nodes may reduce performance, since this reduces the number of nodes that fit in the LLC. Finally, watch for and avoid the implementation problems in § 3.1.

Programmers using a data structure: Importing a data structure into a program merges two memory spaces, and may create *or eliminate* false sharing or cache underutilization problems. Thus, one should either (a) inspect the combined memory layout of the data structure and the program, and fix such problems, or (b) segregate the data structure's memory by using a separate allocator.

Memory allocator designers and implementers: The above recommendations would be substantially easier to put into practice with additional support from memory allocators: First, providing an interface for *allocation segregation*. Second, providing interfaces or tools for *memory layout inspection*, to allow determining (1) the mapping of objects to size classes; (2) which object types are frequently located *close* to one another in memory (where *close* could mean in the same cache line, or in adjacent cache lines, or in the same page); and (3) the distribution of objects into cache sets in the LLC (for each object type). Such queries could also lead to high quality automated tools for identifying memory layout problems.

Abstract

This work is the first systematic investigation of stream processing with data compression: we have not only identified a set of factors that influence the benefits and overheads of compression, but have also demonstrated that compression can be effective for stream processing, both in the ability to process in larger windows and in throughput. This is done through a series of (i) optimizations on a stream engine itself to remove major sources of inefficiency, which leads to an order-of-magnitude improvement in throughput (ii) optimizations to reduce the cost of (de)compression, including hardware acceleration, and (iii) a new technique that allows direct execution on compressed data, that leads to a further 50% improvement in throughout. Our evaluation is performed on several real-world scenarios in cloud analytics and troubleshooting, with both microbenchmarks and production stream processing systems.

1 Introduction

Stream processing [7, 18, 22, 41, 1, 10, 11, 66, 48, 56, 57, 65, 21, 17] is gaining popularity for continuous near real-time monitoring and analytics. It typically involves continuous processing of huge streams of machine-generated, timestamped measurement data. Examples include latency measurements [35], performance counters, and sensor readings in a wide variety of scenarios such as cloud systems and Internet of Things (IoT) [2, 3]. In order to meet near real-time requirements, stream processing engines typically require that streaming data (coming in huge volumes) reside in the main memory to be processed, thereby putting enormous pressure on both the capacity and bandwidth of the servers' main memory systems. Having high memory bandwidth while preserving capacity is known to be difficult and costly in modern DRAM [44, 19, 63]. It is therefore important to explore ways, such as data compression, to relieve this memory pressure.

This paper presents the first systematic investigation of stream processing with data compression. The low-latency, mostly in-memory processing characteristics make data compression for stream processing distinctly different from traditional data compression. For example, in database or (archival) file systems, a sophisticated compression scheme with high compression ratio [68, 27, 37, 47] is often desirable because its overhead can be overshadowed by high disk latency. We start by observing opportunities for significant (orders of magnitude) volume reduction in production cloud measurement data streams and real-world IoT data streams, processed in real stream queries for cloud analytics and troubleshooting purposes, as well as for IoT scenarios. The high redundancy in the streaming data sets is primarily due to the synthetic and numerical nature of these data sets, including, but not limited to, timestamps, performance counters, sensor, and geolocation data. This key observation creates an opportunity to explore efficient encoding mechanisms to explore streaming data redundancy, including lossless and lossy compression (that is *harmless* with respect to specific queries output). For example, timestamps in the data streams are highly compressible even through simple lossless encoding mechanisms, such as variable-length coding [54] and base-delta encoding [53, 60]. By knowing the semantics of generic window-based streaming operators, we can further improve the benefits of compression by reducing the over-provisioning of the timestamps accuracy *without* affecting the produced results. The potential we have identified (for several representative streaming datasets) is likely to apply to other machine-generated time series as well.

Volume reduction, however, does not necessarily lead to proportional improvement in end-to-end throughput, even on a state-of-the-art stream engine such as Trill [21]. Our evaluation shows that an 8× reduction in data volume translates to less than 15% improvement in throughput on Trill, even without considering any encoding cost. This is because memory bandwidth is not yet the bottleneck thanks to significant overhead elsewhere in the system. We therefore build TerseCades[1], a lean stream processing library that optimizes away the other major bottlenecks that we have identified in the existing stream engines, using techniques such as array reshaping [67], static memory allocation and pooling [42, 26], and hashing. TerseCades provides a vastly improved and competitive baseline (by an order of magnitude in throughput over Trill), while making a strong case for compression in streaming context.

Driven by real streaming queries on production data, we have identified factors that influence the benefits and overheads due to data compression, and proposed a series of optimizations to make compression effective for stream processing. This includes the use of SIMD instructions for data compression/decompression, hardware acceleration (using GPUs and FPGAs), as well as supporting execution directly on compressed data when it is feasible. To demonstrate the end-to-end benefits of our design, we have implemented compression support with the optimizations on TerseCades. Our evaluation shows that, altogether, these optimizations can improve the throughput by another 50% in TerseCades, on top of the order of magnitude improvement over Trill, while significantly improving processing capacity diverse temporal windows due to reduced memory footprint.

In summary, our contributions are as follows. (1) We identify major bottlenecks in a state-of-art stream engine and develop TerseCades that provides an order of magnitude higher throughput. (2) We characterize representative data streams and present compression algorithms for effective in-memory stream processing. (3) We implement these compression algorithms along with a set of optimizations (e.g., direct execution on compressed data) on TerseCades, improving throughput by another 50%.

2 Is Compression Useful for Streaming?

A natural starting point to assess the usefulness of compression for streaming is to check (i) whether data streams are compressible and (ii) whether data volume reduction from compression improves the throughput of stream processing. To do so, we perform a set of analysis using the Pingmesh data streams of network reachability measurements [35] from production data centers, with respect to motivating real data set for data-center network diagnosis. We then use Trill [21], a state of the art high-performance streaming library, and the STREAM [13] benchmark suite to evaluate the effect of data volume reduction on throughput.

2.1 Streaming Data Compressibility

For compressibility, we examine the Pingmesh data records. Major fields are listed in Table 1, and here we focus on two important fields: (i) 8-byte integer `timestamp` to represent the time when the request was issued, and (ii) 4-byte integer `rtt` values to represent request round-trip-time (in microseconds).

Stream processing operates on batches of data records that form *windows*. Our analysis on those batches reveals the potential of significant volume redundancy that can be easily exploited. For example, the `timestamp` values are often within a small range: more than 99% of the values in a 128-value batch differ in only 1 lower-order byte. This potentially allows efficient compression with simple lossless compression schemes such as Base-Delta encoding [53, 60] and variable-length coding [54] to achieve a compression ratio around 8× or more. Similarly, the `rtt` values for successful requests are usually relatively small: 97% values need only two bytes. This data can be compressed by at least a factor of 2.

While lossless compression can be effective in reducing data redundancy, we observe that in many real scenarios it is profitable to explore *lossy* compression without affecting the correctness of the query results. For example, in queries where timestamps are used in a windowing operator only for assigning a record to a time window, we can replace multiple timestamps belonging to the same window with just one value that maps them to a particular window. We provide more details on lossy compression in Section 3.3.

2.2 Compressibility $\not\Rightarrow$ Performance Gain

We further study the effect of data volume reduction on stream processing using Trill, driven by a simple *Where* query that runs a filter operator on a single in-memory data field. We use two versions of the data field (8 and 1 bytes) to simulate an ideal no-overhead compression with a compression ratio of 8. This query performs minimum computation, does not incur any compression/decompression overhead, allowing Trill to focus on the actual query computation. Figure 1 shows the results.[2]

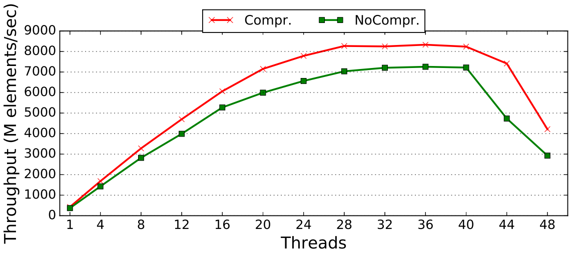

Figure 1: Throughput with data compression in Trill.

[1] TerseCades = Terse (for compression) + Cascades (for streaming). Appropriately several characters in Cascades get 'compressed'.

[2] Section 4 describes the methodology and system configurations.

As expected, the 1-byte compressed (*Comp*) version consistently outperforms the 8-byte non-compressed (*NoComp*) version. However, the amount of the improvement is relatively small (only 13-15%), compared to a factor of 8 reduction in memory traffic. This indicates that query processing in Trill is not memory-bound even when the query executes simple computation (e.g., a filter operator).

To understand the source of such inefficiency, we have run and profiled a diverse set of queries (including filter query and groupby query) using Trill. Our profiling shows that for the filter query (and similarly for other stateless queries), most of the execution time is spent in functions that generalize semantics in streaming data construction. In particular, for each incoming event, the filter query (1) performs just-in-time copy of payloads to create a streameable event (memory allocation) and (2) enables flexible column-oriented data batches (memory copying and reallocation). These operations account for more than two-thirds of the total query processing time, with limited time spent on the query operator itself. The second major overhead is inefficient bit-wise manipulation; 46% of the time is spent on identifying what bit should be set when the previous bottleneck is fully removed. For the groupby query, more than 90% of the time is spent on manipulating the hash table (e.g., key lookups), which holds the status of the identified groups. While adding concurrency mitigates such costs, they remain the largest.

In summary, we conclude that the state-of-the-art streaming engines such as Trill are not properly optimized to fully utilize the available memory bandwidth, limiting the benefit of reduced memory consumption through data compression. In our work, we will address this issue by integrating several simple optimizations that make streaming engines much more efficient and consequently memory sensitive (Section 3.1).

2.3 Compressibility ⇒ Performance Gain

To understand whether the limitations we observe with Trill are fundamental, we look at the performance of the STREAM [13] benchmark suite, which performs simple streaming operators such as copy, add, and triad on large arrays of data[3], without the overhead we observe in Trill.

Figure 2 shows the throughput of the *Add* benchmark for three different cases: (i) *Long* – 64-bit unsigned integer, (ii) *Char* – 8-bit char type (mimic 8× compression with *no* compression/decompression overhead, (iii) *CharCompr.* – compressing 64-bit values to 8-bit using Base-Delta encoding [53].

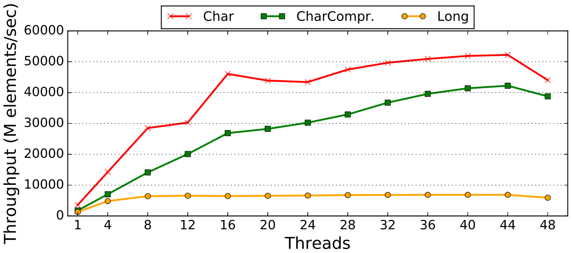

Figure 2: Add results.

We draw two major conclusions from this figure. First, when the amount of data transferred is reduced 8× (going from Long to Char), the resulting throughput also increases proportionally, from the maximum of around 7 Billion elements/sec for *Long* all the way to the maximum of 52 Billion elements/sec with *Char*). The significant throughput improvement indicates that, due to the absence of other artificial bottlenecks (e.g., memory allocation/deallocation, inefficient bit-wise manipulation, and hashmap insertions/searches), the throughput of this simple streaming engine is limited only by the main memory bandwidth, and compression reduces the bandwidth pressure proportionally to the compression ratio. Second, using a realistic simple compression mechanism, e.g., *CharCompr.* with Base-Delta encoding, still provides a lot of benefits over uncompressed baseline (the maximum increase in throughput observed is 6.1×), making simple data compression algorithms an attractive approach to improve the performance of stream processing. At the same time, it is clear that even simple compression algorithms incur noticeable overhead that reduces the benefits of compression, hence the choice of compression algorithm is important.

3 Efficient Compression with TerseCades

In this section we first describe the key optimizations (which we refer to as first-order) that are needed for a general streaming engine to be efficient. We then describe the design of a single-node streaming system that supports generic data compression. Finally, we show the reasons behind the choice of compression algorithms we deploy in TerseCades, hardware-based strategies to minimize the (de)compression overhead (using SIMD, GPU and FPGA), as well as less intuitive (but very powerful) optimizations such as direct execution on compressed data.

3.1 Prerequisites for Efficient Streaming

Our initial experiments with Trill engine (§2) show that in order to make streaming engines more efficient, several major bottlenecks should be avoided. First, dynamic memory allocation/deallocation is costly in most operating systems, and permanent memory allocation for every

[3] For our purposes, we evaluate STREAM not only on float/double data, but also for different integer types.

window (or even batch within a window) in streaming engine significantly reduces the overall throughput. This happens because the standard implementation of streaming with any window operator would require dynamic memory allocation (to store a window of data). One possible strategy to address this problem is to identify how much memory is usually needed per window (this amount tends to be stable over time as windows are normally the same size), and then use *fixed memory allocation* strategy – most of the memory allocation happens once and then reused from the internal memory pool. In TerseCades we use profiling to identify how much memory is usually needed for a particular size window, allocate all this memory at the beginning, and then only allocate more memory if needed during the execution.

Second, implementation of certain streaming operators, e.g., *GroupApply*, requires frequent operation on hashmap data structures. Similarly, many common integral data types such as strings, might require a lot of memory if stored fully (e.g., 64 bytes for the server IDs), but can be efficiently hashed to reduce space requirements. Unfortunately, the standard C++ STL library does not provide this efficiency. To address this problem, we implement our own hashmap data structure with corresponding APIs taking into the account specifics of our streaming data.

Third, efficient implementation of filtering operators (e.g., *Where*) requires efficient bit-vector manipulation. For example, when running a simple *Where* query with a single comparison condition (e.g., `Where (error Code == 0)`) with Trill streaming engine, we observe that about 46% of the total execution time is now related to simple bit-wise manipulation (1 line of the source code using standard C# data structures). Unfortunately, this huge overhead limits the benefits of any further performance optimizations. In our design, we implemented our own simple bit-wise representation (and the corresponding APIs) for filtering operators using C++ that significantly reduces the overhead of filtering. Altogether, these optimizations allows us to improve the performance our system more than 3× as we will show in Section 5.

3.2 System Overview

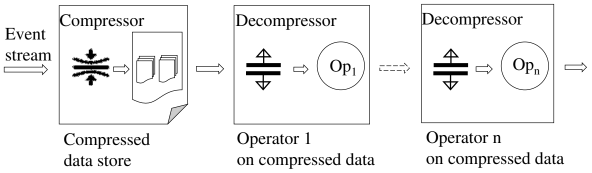

Figure 3: The streaming processing pipeline with compression and decompression.

Figure 3 shows our proposed TerseCades streaming processing pipeline in a single node. We will defer the discussion on how TerseCades is applied in the distributed system setting for monitoring and troubleshooting for a large cloud provider in Section 5.4, and in this section we focus on making this system efficient. We also note that single-node TerseCades system is generic, and both its design and optimizations behind it can be applied in other distributed streaming systems.

The major difference from traditional streaming processing, in Figure 3, is that external streaming events are first compressed before they are stored (typically in a column-oriented format that is usually more preferable for applications with high spatial locality). Note that the streaming operators also need to carry out decompression on all the compressed data before they access it (except for the cases where we use direct execution on compressed data described in Section 3.3).

The operators are chained together to form a pipeline. Different operators may work on different columns of the data, hence they may need to perform different decompression operations. Furthermore, some operators may need to produce new data sets from their input, and the newly generated data sets need to be compressed as well. This flow highlights the fact that compression/decompression operations are now on the critical path of the streaming engine execution, and have to be efficient to provide any benefits from tighter data representation .

3.3 Practical Compression for Streaming

One of the key contributions of this work is the efficient utilization of the existing memory resources (both bandwidth and capacity) by using simple yet efficient data compression algorithms. We observe that the dominant part of the data we use in stream processing is synthetic in nature, and hence it has a lot of redundancy (see Section 2 and 5) that can be exploited through data compression. In this section, we describe the key design choices and optimizations that allowed us to make data compression practical for modern streaming engines.

Lossless Compression. The key requirement of lossless compression is that the data after decompression should be exactly the same as before compression. The classical lossless compression algorithms include different flavors of Lempel-Ziv algorithm [68], and Huffman encoding [37, 27, 28, 47] and arithmetic coding [60, 36, 54, 4, 59]. These algorithms were proven to be efficient for disk/storage or virtual memory compression [62, 29, 9] and graphics workloads [60, 36, 54], but unfortunately most of these algorithms are too slow for compressing active data in memory. [4] As we will show in Section 5.1,

[4] Memory latencies are usually on the order of tens of nanoseconds [39]. Even when these algorithms were implemented as an ASIC design, e.g., IBM MXT design [8, 61], the overhead more than double the latency for main memory accesses.

software implementations of these algorithms are usually impractical.

To address this challenge, rather than using sophisticated dictionary-based algorithms, we decided to use simple arithmetic compression algorithm that was recently proposed in the area of computer architecture – Base-Delta encoding [53]. The primary benefits of this algorithm include its simplicity (e.g., only one addition is needed for decompression), and its competitive compression ratio for a wide range of data (e.g., rtts, timestamps, pixels, performance counters, geolocation data). Figure 4 shows how timestamp data can be compressed with Base-Delta encoding (8-byte base and 1-byte deltas).

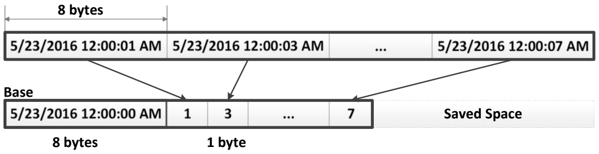

Figure 4: Base-Delta encoding applied to timestamps.

It turns out that this simple algorithm has several other benefits. First, it can be easily extended to a more aggressive lossy version that can still provide the output results that match lossless and uncompressed versions. Second, this algorithm is amenable to hardware acceleration using existing hardware accelerators such as GPUs and FPGAs, and using SIMD vector instructions available in commodity CPUs. Third, Base-Delta encoding preserves certain properties of the data (e.g., order) that can enable further optimizations such as direct execution on compressed data (Section 3.3).

Lossy Compression without Output Quality Loss. Lossy compression is a well-known approach to increase the benefits of compression at the cost of some precision loss. It is efficiently used in the areas where there is a good understanding of imprecision effect on the output quality, e.g., audio encoding, image compression. We observe that similar idea can be useful for some common data types in stream processing when the data usage and the effect of imprecision is also well understood.

For example, in troubleshooting scenario (§5.1), every record has a `timestamp` (8-byte integer) that is usually used only to check whether this timestamp belongs to a particular time window. As a result, storing the precise value of the timestamp is usually not needed and only some information to check whether the record belongs to a specific window is needed. Luckily, if the value already compressed with Base-Delta encoding, this information is usually already stored in the *base* value. Hence, we can avoid storing the *delta* values in most cases and get much higher compression ratio. For a batch of 128 `timestamp` values, the compression ratio can be as high as 128× for this data field, in contrast to about 8× compression ratio with lossless version. While this approach is not applicable in all cases, e.g., server IDs need to be precise, its impressive benefits while preserving the output quality made us consider using modified (lossy) version of Base-Delta encoding in our design.

Lossy Compression for Floating Point Data. The nature of floating point value representation makes it difficult to get high compression ratio from classical Base-Delta encoding. Moreover, getting high compression ratio with lossless compression algorithms on floating point data is generally more difficult [20, 14, 15]. Luckily, most of the scenarios using floating point values in streaming do not usually require perfect accuracy. For example, in several scenarios that we evaluated (§5), floating point values are used to represent performance counters, resource utilization percentage, geolocation coordinates, and sensor measurements (e.g., wind-speed or precipitation amount). In these cases, you usually do not need the precise values for all data fields to get the correct results, but certain level of precision is still needed.

We consider two major alternatives: (i) fixed point representation that essentially converts any floating point value into an integer value and (ii) using *lossy* floating point compression algorithms (e.g., ZFP [45]). The primary advantage of the first option is low overhead compression/decompression, because we can use Base-Delta encoding to compress the converted values. The primary benefit of the lossy floating point compression algorithms is that they usually provide higher accuracy than fixed-point representation. The lossy compression algorithm, called ZFP [45] that we use in our experiments, has the option to provide an accuracy bound for every value compressed. This option simplifies the usage of lossy compression since we only need to reason about data accuracy in simple terms (e.g., error bound per value is 10^{-6}). Moreover, this algorithm proved to have a very competitive throughput for both compression and decompression and allows to access the compressed data without decompressing it fully. Hence, in our design, we decided to use ZFP algorithm for floating point data.

Reducing the Compression/Decompression Cost. As we show in Section 2.3, even simple compression algorithms like Base-Delta encoding can add significant overhead. In this section, we will demonstrate how those overheads can be significantly reduced if we use the existing hardware to accelerate the major part of this overhead – data decompression.

Acceleration using SIMD instructions. Our original software implementation of Base-Delta encoding algorithm uses a simple add instruction to decompress a value based on its corresponding base and delta values. In streaming, usually many values are accessed at the same time, hence it is possible to reduce decompression overhead by using SIMD instructions, e.g., Intel AVX instructions (256-bit versions are available on most modern CPUs). By using SIMD instructions, we can reduce the overhead of decompression at least 4×, as four decompressions can be replaced with a single one. As we will show in Section 4.2, this optimization can significantly reduce the overhead of decompression that leads to the throughput close to the ideal compression case (with no compression/decompression overhead).

Hardware Acceleration: GPUs/FPGAs. Modern hardware accelerators such as Graphics Processing Units (GPUs) and Field-Programmable Gate Arrays (FPGAs) can be very efficient computational substrate to perform bulk compression/decompression operations [50, 31]. These accelerators are now available in commodity data centers for general-purpose use [55, 12, 16]. In our work, we also evaluate such a possibility by implementing Base-Delta encoding algorithm using CUDA 8.0 [49] on a GPU and using SystemVerilog on an FPGA. Our results (see Section 4.2) shows that by utilizing these accelerators, it is possible to perform the required data decompression (and potentially compression) without slowing down the main computation.

Direct Execution on Compressed Data. Many data compression algorithms require compressed data to be decompressed before it is used. However, performing each operation after data decompression can potentially lead to significant performance penalty. In streaming analytics, many operations are relatively simple and regular, allowing direct execution on the *compressed data itself.*[5] We find that we can run a set of stateless operators (e.g., Where) as well as aggregation operators (e.g., sum, min/-max, average, standard deviation, argmax/argmin, countif, distinct count, percentiles) on top of compressed data (assuming Base-Delta Encoding) more efficiently.

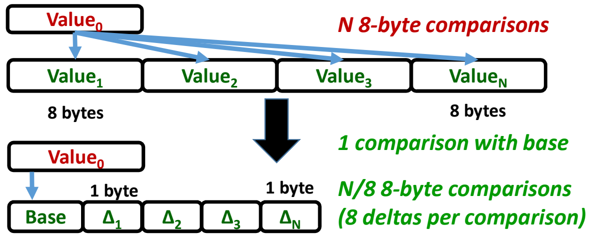

Figure 5: Direct execution on the data compressed with Base-Delta encoding.

Consider a simple *Where* query that performs a linear scan through an array on *N* values searching for a certain $value_0$ (see Figure 5). If this data is already compressed with Base-Delta encoding, then one simple strategy is to try to represent the searched value in the same base-delta format as batches of values in this array. If $value_0$ cannot be represented in this form (one comparison needed to test this), then this value is not in this batch, and there is no need to do any per-value comparisons. This avoids multiple (e.g., hundreds) comparisons per batch.

In cases where the search value can be represented similarly to the values in the batch, we still need to do value-by-value comparisons, but these values are now stored in a more narrow format (1-byte deltas in Figure 5). Instead of 8-byte comparisons, we can now group the deltas to do more efficient comparisons using SIMD instructions. This would reduce the number of comparisons by 8×. In summary, we can significantly improve the execution time for some common queries by utilizing the fact that data is stored in a compressed format to perform some operations more efficiently.

Generality of the Proposed Approach. There is a potential concern with the proposed approach due to limited generality and whether the benefits will be preserved when additional layers of indirection are added. Our current implementation supports a subset of queries from a LINQ-like proviver (e.g., *Where*, *Window*, *GroupBy*, *Aggregate* wih different operators inside of it, *Reduce*, *Process* and other operators are already supported), and is designed in a way, where it is possible to add support for new operators without significantly affecting the performance of existing ones. We currently leave it to the programmer to decide on whether they want their data being compressed using different proposed compression algo- rithms (similarly to how data compression is supported in Oracle databases). Our design favors column-oriented data allocation as it allows to get higher benefit from data locality in both DRAM and caches. It might not be al ways the best choice of each query, so we also leave the choice of memory allocation to the programmer (we pro- vide both row- and column-oriented options). Given these two inputs from the programmer, the framework then automatically allocates the memory in the form optimized for both streaming and compression, and performs execution on compressed data where applicable.

Our original intent was to perform our optimizations on top of existing state-of-the-art frameworks such as Trill, but as we show in Section 2, these frameworks are not properly tuned to exploit the full potential of existing memory subsystems. While we agree that their generality and ease of programming makes them a desirable choice in many situations, but we also envision TerseCades being further extended to be as general as these frameworks without sacrificing its performance.

4 Methodology and Microbenchmark

In this section, we will provide the detailed performance analysis of several key microbenchmarks and

[5] This idea has some similarity with the execution on encrypted data in homomorphic encryption [32], however in our case it is possible get performance even better than the uncompressed baseline.

demonstrate how different optimizations proposed in Section 3.3 affect their performance.

4.1 Methodology

In our experiments, we use two different CPU configurations. The first is a 24-core system based on Intel Xeon CPU E5-2673, 2.40GHz with SMT-enabled, and 128GB of memory, which is used in all microbenchmarks studies to have enough threads to put reasonable pressure on the memory subsystem. The second is a 4-core system based on Intel Xeon CPU E5-1620, 3.50GHz, SMT-enabled, and 16GB of memory. This system is used in all real applications experiments as it has better single-thread performance (especially higher per thread memory bandwidth). For our GPU experiments, we use NVIDIA GeForce GTX 1080 Ti with 11GB of GDDR5X memory. For FPGA prototyping, we use Altera Stratix V FPGA, 200MHz. In our evaluation, we use real applications scenarios (§5) and microbenchmarks from the STREAM suite [13]. We use *Throughput* (Millions of elements per second) and *Latency* (milliseconds) to evaluate streaming system performance; and *Compression Ratio* defined as uncompressed size divided by compressed size as the key metric for compression effectiveness.

4.2 Microbenchmark and Optimizations

SIMD-based Acceleration. To realize the full potential of data compression, it is critical to minimize the overhead due to data compression and especially decompression (that can be called multiple times on the same data). Luckily, the simplicity and inherent parallelism of the Base-Delta encoding algorithm allow to use SIMD vector instructions (e.g., Intel AVX) to perform multiple compressions/decompressions per instruction. Figure 6 shows the result of this optimization for *Add* benchmark from the STREAM benchmarks. We make two key observations from this figure.

First, when the number of threads is relatively small, this benchmark is more compute than memory limited. Hence reducing the computational overhead allows the *CharCompr.+V* version (compression plus vectorization) to almost completely match the ideal compression version (*Char*).[6] Second, when the number of threads increases (from 16 to 36), the additional overhead due to compression associated metadata becomes more important, and eventually when memory bandwidth becomes the only bottleneck, vectorization is not as useful in reducing the overhead anymore.

GPU/FPGA-based Acceleration. There are other hardware accelerators that can perform compression/decompression for Base-Delta encoding efficiently. For example, modern GPUs are suitable for massively parallel computations. We implemented the code that can perform multiple decompression operations in parallel using CUDA 8.0 [49] and tested this implementation using GeForce GTX 1080 Ti Graphics Card. Our results show that we can perform more than 32 Billion decompressions per second that is sufficient to satisfy the decompression rates required in realistic applications we will explore in Section 5. Note that this massive compute capability is frequently limited by the PCIe bandwidth that for our system was usually around 5-6 GB/sec.

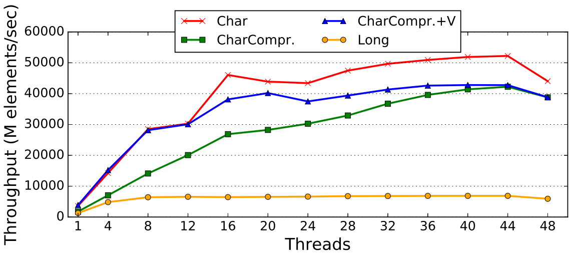

Figure 6: `Add` results with vectorization added.

Another option we explore is FPGA. We used SystemVerilog to implement the decompression logic and were able to run decompression at 200 MHz on a Stratix V FPGA board. We are able perform up to 744 Billion decompressions per second using this FPGA. Unfortunately, the bandwidth available through the PCIe again becomes the critical bottleneck limiting the number of decompressions we can perform. Nevertheless, it is clear that both GPUs and FPGAs can be efficiently used to hide some of the major data compression overheads.

Execution on Compressed Data. As we discussed in Section 3.3, the fact that the data is compressed usually comes with the burden of decompressing it, but it does not always have to be this way. There are several common scenarios when compressed data with Base-Delta encoding, can allow us to not only avoid decompression, but even execute the code faster. To demonstrate that, we take one benchmark called *Search* that essentially performs an array-wide search of a particular value (mimicking a very common *Where* operator in streaming). As we described in Section 3.3, when the data is represented in Base-Delta encoding, we take advantage of this fact and either completely avoid per value comparison within a batch (if the searched value is outside of the value range for this batch) or perform much more narrow 1-byte comparisons (8× less than in the original case).

Figure 7 presents the results of this experiment where *Compr.+Direct* is the mechanism that corresponds to compression with Base-Delta encoding and direct execution on compressed data as described in Section 3.3. Our key observation from this graph is that direct execution can not only dramatically boost the performance by

[6] Some additional overhead such as metadata and base storage overhead does not play a significant role here.

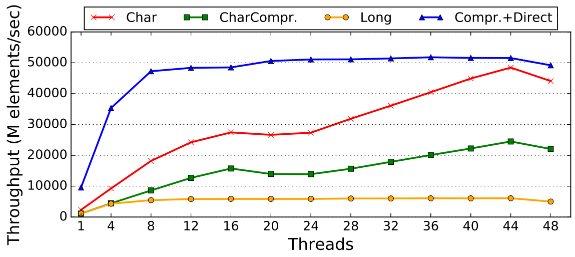

Figure 7: `Search` results with Direct Execution.

TimeStamp (8, **BD**)	ErrorCode (4, **EN+BD**)
SrcCluster (4, **HS+BD**)	DstCluster (4, **HS+BD**)
RoundTripTime(RTT) (4, **BD**)	

Table 1: Pingmesh record fields. Numbers in parenthesis are the bytes used to represent the field while letters are the compression algorithms we apply for that field. **BD**: base+delta; **HS**: string hashing; **EN**: enumeration.

avoiding the overhead of decompression (this is the performance gap between *Char*, ideal 8× compression with no overhead, and *CharCompr.*), but also significantly outperform the ideal compression case of *Char* (up to 4.1×). Moreover, it can reach almost the peak performance at just 8 threads, at which point it becomes fully memory bottlenecked, in contract to other cases where the peak performance is not reached until 44 threads are used. In summary, we conclude that direct execution on compressed data is a very powerful optimization that, when applicable, can by itself provide the relative performance benefits higher than that from data compression.

5 Applications

5.1 Monitoring and Troubleshooting

Pingmesh Data. Pingmesh [35] lets the servers ping each other to measure the latency and reachability of the data center network. Each measured record contains the following fields: timestamp, source IP address, source cluster ID, destination IP address, destination cluster ID, round trip time, and error code. Table 1 shows several of the fields that will be used in the queries in this paper. The measured records are then collected and stored. Data analysis is performed for dashboard reporting (e.g., the 50^{th} and 99^{th} latency percentiles), and anomaly detection and alerting (e.g., increased latency, increased packet drop rate, top-of-rack (ToR) switch down).

Pingmesh Queries. Here we describe implementation of several real queries on the Pingmesh data.

The query C2cProbeCount counts the number of error probes for the cluster-to-cluster pairs that take longer than certain threshold:

```
C2cProbeCount = Stream
  .HopWindow(windowSize, period)
  .Where(e => e.errorCode != 0 && e.rtt >= 100)
  .GroupApply((e.srcCluster, e.dstCluster))
  .Aggregate(c => c.Count())
```

The T2tProbeCount query is similar to the previous one, but uses Join to count the number of error probes for the ToR-to-ToR pairs:

```
T2tProbeCount = Stream
  .HopWindow(windowSize, period)
  .Where(e => e.errorCode != 0 && e.rtt >= 100)
  .Join(m, e => e.srcIp, m => m.ipAddr,
       (e,m)=> {e, srcTor=m.torId})
  .Join(m, e => e.dstIp, m => m.ipAddr,
       (e,m)=> {e, dstTor=m.torId})
  .GroupApply((srcTor, dstTor))
  .Aggregate(c => c.Count())
```

In the query, *m* is a table which maps server IP address to its ToR switch ID.

Compression Ratio, Throughput and Latency. In our experiments, we compare different designs that employ various compression strategies and optimizations: (i) *No Compression*, baseline system with all first-order optimizations described in Section 3.1, (ii) *Lossless* compression mechanism that employs Base-Delta encoding with simple mechanisms such as hashing and enumeration, (iii) *LosslessOptimized* mechanism that combines lossless compression described above with the SIMD acceleration and direct execution on compressed data, (iv) *Lossy* compression mechanism that uses lossy version of Base-Delta encoding in the cases where precise values are not needed, (v) *LossyOptimized* mechanism that combines lossy compression with the two major optimizations described in (iii). In addition, we evaluate two other designs: *Trill* streaming engine as a backend and *NonOptimized* design where we use TerseCades without any of the proposed optimizations.

The average compression ratio for these designs is as follows: *Lossless** designs have an average compression ratio on 3.1×, *Lossy** designs – 5.3×, and all other designs have no compression benefits (as compression is not used). Figure 8 compares the throughput of all the designs. First, as expected, first-order optimizations are critical in getting most of the benefits of implementing more specialized streaming engine in C++, leading to performance improvement of 9.4× over *Trill* streaming engine. As we remove most of the redundant computational overheads from the critical path, the memory bandwidth becomes a new major bottleneck. The four designs with data compression support overcome this bottleneck that limits systems' throughput – 32.3 MElems/s (Millions of elements-records per second).

Second, both *Lossless* and *Lossy* compression can provide significant throughput benefits as they have high average compression ratios (3.1× and 5.3×, correspondingly). However the full potential of these mechanisms

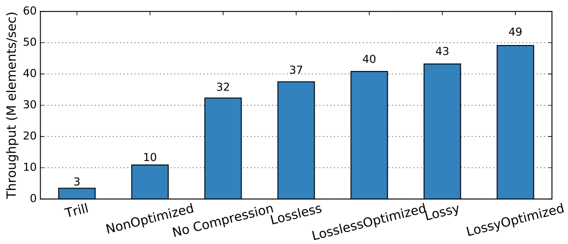

Figure 8: Throughput for the Pingmesh C2cProbeCount query. **Optimized** versions include both direct execution and SIMD optimizations.

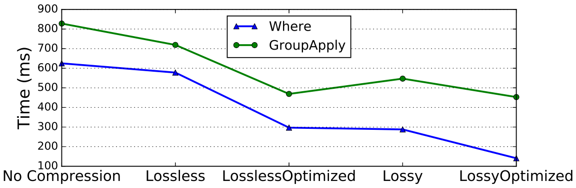

Figure 9: Execution times for Where and GroupApply operators used in the Pingmesh C2cProbeCount query. **Optimized** versions include direct execution and SIMD optimizations.

Mechanism	Throughput	Time
NoCompr.	27.7 MElems/s	2031 ms
LossyOptimized	38.3 MElems/s	1813 ms

Table 2: Throughput and Time (Join only) to perform the Pingmesh T2tProbeCount query that has Join operator.

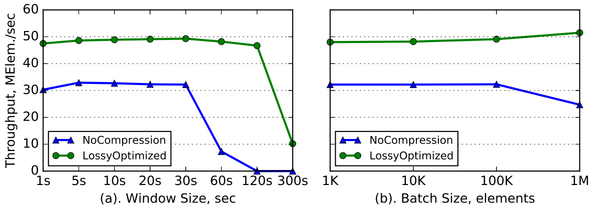

Figure 10: Throughput for the Pingmesh C2cProbeCount query with varying (a) window and (b) batch sizes.

is only uncovered when they are used in conjunction with vectorization (that reduces the overhead of compression/decompression) and direct execution on compressed data that for certain common scenarios (such as *Where* operator) can dramatically reduce the required computation (over the baseline). We conclude that efficient data compression through simple yet efficient compression algorithms **and** with proper optimizations can lead to dramatic improvement in streaming query throughput (e.g., 14.2× for troubleshooting query we analyzed).

Figure 9 shows similar results on the performance (execution time) of two major operators, *Where* and *GroupApply* for first five designs. Two observations are in order. First, both operators significantly reduce their execution time due to efficient usage of data compression, and the highest benefit is coming again from the most aggressive design, *LossyOptimized*. Second, the benefits due to compression and corresponding optimizations are more significant for *Where* operator – 4.6× improvement between *NoCompression* and *LossyOptimized* designs. This happens because *Where* operator benefits dramatically from the possibility of executing directly on compressed data (reducing the number of comparisons instructions needed to perform this operator).

Join Operator: Throughput and Execution Time. In order to demonstrate the generality of our approach, we also evaluate another scenario (T2tProbeCount query) that uses the *Join* operator. Table 2 shows the throughput and the execution time of this scenario for two designs: *NoCompression* and *LossyOptimized*. In this scenario, the throughput benefits are still significant (almost 1.4×), but the reduction in the operator's execution time is relatively small (around 12%). This is because most of the benefits are coming from the reduction in bandwidth consumption that happens mostly outside of *Join* – in *HopWindow* operator, while most of the computation performed to implement the *Join* operator is coming from hash table lookups.

Sensitivity to the Window Size. The window size used in the *HopWindow* operator can significantly affect the performance of the operators running after it. In order to understand if it is also a case for the troubleshooting scenario we consider, we study the performance of the two designs (*NoCompression* and *LossyOptimized*) on varying window size (from 1 second to 5 minutes).

Figure 10 (a) shows the results of this study. We make two observations. First, we observe that our proposed design, *LossyOptimized*, demonstrates stable throughput (around 50 MElems/sec) across different window sizes (from 1 to 120 seconds), with the variation below 5% in this range, and performance drops only at the 5-minute window. Second, in contrast to *LossyOptimized* design, the *NoCompression* design has a much shorter window of efficient operation (from 1 to 30 seconds).The primary reason for this is data compression that not only reduces the bandwidth consumed by the streaming engine, but also significantly reduces its memory footprint, allowing it to run on larger windows. Hence we conclude that compression allows to handle substantially larger windows (e.g., 4× larger) than the windows that can be efficiently handled without data compression.

Sensitivity to the Batch Size. In order to minimize the overhead of processing individual data elements, those elements are usually grouped by the streaming engines in batches. Hence the batch size becomes another knob to tune. We conduct an experiment where we vary the size

Mechanism	Throughput	Where	Group
NoCompr.	32.2 MElems/s	625 ms	828 ms
FrameRef.[33]	21.6 MElems/s	2453 ms	4078 ms
XPRESS [47]	8.5 MElems/s	7328 ms	13671 ms
LosslessOptimized	37.5 MElems/s	297 ms	469 ms
LossyOptimized	49.1 MElems/s	141 ms	453 ms

Table 3: Total throughput and time to perform Pingmesh query with optimized baseline without compression, two other compression algorithms, and our designs.

of the batch from 1K to 1M elements, and the results are shown in Figure 10 (b). We observe that in most cases the throughput of streaming engines are not very sensitive to the batch sizes in this range, except for one data point – the throughput of uncompressed design drop from 32.3 to 24.7 when going from 100K to 1M elements. Additional investigation shows that without compression for 1M elements the batch working set size exceeds the size of the available last level cache, limiting the benefits of temporal locality in the case of data reuse.

Sensitivity to the Compression Algorithms. In this work, we strongly argue that in order for compression algorithm to be applicable for streaming engine optimization, its complexity (compression/decompression overhead) should be extremely low and the algorithm itself has to be extensively optimized. We already showed that heavily optimized versions of arithmetic-based algorithm such as Base-Delta encoding can be efficient in providing significant performance benefits for streaming engines. We now compare our proposed designs with two well-known *lossless* compression algorithms used for in-memory data: FrameOfReference algorithm [33], arithmetic-based compression for low-dynamic range data, and XPRESS algorithm [47], dictionary-based algorithm that is based on LZ77 algorithm [68].

Our first comparison point is compression ratio, and as expected, both FrameOfReference and XPRESS outperform our *LosslessOptimized* algorithm in this aspect (compression ratios of 4.1× and 5.1×, respectively, vs. 3.1× for our design). However more importantly, as results in Table 3 indicate, both these algorithms prove not to be very practical for streaming engines, as their effect on throughput and execution time puts them below not only our proposed designs, but also significantly below uncompressed scenario. This happens because the cost of compression and decompression that are both on the critical path of execution outweighs the benefits of lower memory bandwidth consumption. We conclude that although it is important to have a compression algorithm with high compression ratio to provide reasonable performance improvements for streaming engines, it is even more critical to make sure those algorithms are efficient.

TimeStamp (8, **BD**)	Datacenter (3, **HS**)
Cluster (11, **HS**)	NodeId (10, **HS**)
VmId (36, **HS**)	CounterName (15, **EN**)
SampleCount (4, **BD**)	AverageValue (8, **ZFP**)
MinValue (8, **ZFP**)	MaxValue (8, **ZFP**)

Table 4: VM performance counter data fields. Numbers in parenthesis are the original sized of these fields, letters – compression algorithms used for them. **BD**: base+delta; **HS**: string hashing; **EN**: enum; **ZFP** [45].

5.2 IaaS VM Perf. Counter

Data. The cloud vendor regularly samples performance counters of an IaaS VM to determine a VM's health. If a VM is in an unhealthy state, recovery actions (e.g., relocate) will be taken to improve VM availability. Table 4 shows the fields for a performance counter record with the size to in-memory representations in the original analytics system. Each record contains the data source information (e.g., from which cluster, node and VM) and the actual values. At each regular interval, multiple such records of different types of counters will be emitted: e.g., CPU, network, disk. We use five datasets, i_1 to i_5, from different set of VMs in different timespan.

Queries. When processing these records, the data stream is grouped by timestamp and sources to get all the counters for a particular VM at each time point. We use a query to find the time and duration for a VM losing network activity: it first classifies the health of each perf counter group into different types (e.g., CPU active but network flat) and then scans the classified groups in ascending time for each unique VM to detect any type changes (e.g., from active to flat) and their durations.

Compressibility. Each performance counter record is represented with 111 bytes in memory in the original format, and a large portion of it can be compressed efficiently. For example, the `VmId` is a 36-character UUID string so that a VM can be universally uniquely identified across lifetime. But in the streaming scenario, in a given processing time window, the number of unique VMs tends not to be so large that they can be safely hashed to a 8-byte index. Note that absolute number of performance counters being emitted is large enough so that the hash table's overhead is amortized.

The compressibility can also come from batches of records rather than individual records. For example, the performance counter value is originally represented as a 8-byte double. The compressibility of a single record is not big (e.g., 2× if converted to integers). But efficient floating-point compression algorithm like ZFP can be applied across a stream of these counters to achieve high compression ratio. As Figure 11 shows, in certain runs, we can achieve near 6× compression ratio! The reason is that some VMs exhibit very regular performance patterns

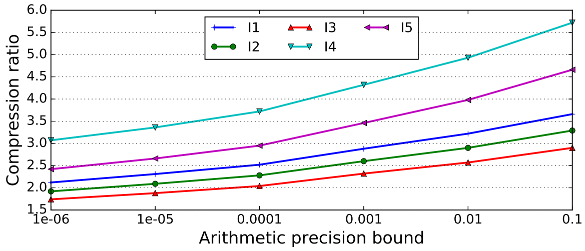

Figure 11: Compression ratio for various performance counters from VMs in a commercial cloud provider.

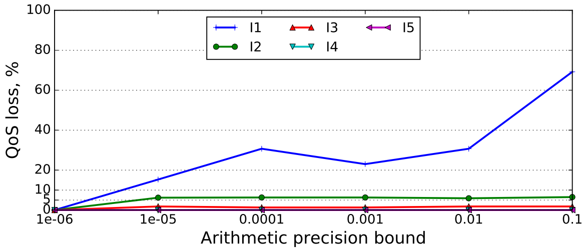

Figure 12: QoS metric loss for different compression ratios of performance counters.

(sometimes even constant) that can be exploited by ZFP. Of course, there are also some VMs that exhibit highly variable patterns, which will yield lower compression ratios (2.5× to 3× seen in our experiments).

Quality of Service. Algorithms like ZFP on floating-point values are lossy that can lose precisions when decompressed. Depending on the queries, the precision loss might sacrifice the QoS. This creates a trade-off between the compression ratio and the QoS level. We evaluated this trade-off using several queries on a set of real data coming from different regions' VMs in different timespan. The QoS loss metric is defined by the differences between the originally detected performance drop sessions with the new drop sessions: e.g., 1 additional session or missing session for a originally 100-session result is a 1% QoS loss. Figure 12 shows the result. We can see that for most datasets, the QoS loss level is low (below 5%), meaning that even aggressive lossy compression might be adopted without sacrificing QoS. For certain dataset, there is a high penalty (20% and more) because the absolute number of drop sessions are small.

5.3 IoT Data

Geolocation Data. This dataset contains GPS coordinates from the GeoLife project [2] by 182 users in a period of over three years. Figure 13 shows the average compression ratio of the dataset by using compression algorithms listed in Table 5. As we can see, these sensor data have significant redundancies because user movements tend not to have drastic changes. Even with an error bound of 10^{-6}, we can still achieve more than 4.5× compression ratio on average, creating significant opportunity for efficient real-time analytics over IoT data.

Latitude (8, **ZFP**)	Longitude (8, **ZFP**)
Altitude (4, **BD**)	TimeStamp (8, **BD**)

Table 5: Geolocation IoT data fields. Numbers and letters in parenthesis have the same meaning as Table 4.

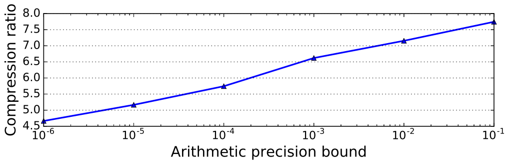

Figure 13: Compression ratio for GeoLocation IoT data.

Weather Data. We use another type of IoT data, 18,832,041 observations of weather data generated by various sensors during Hurricane Katrina in 2005 [3]. The measurements are stored as floating points in the data files but most of them are essentially integers due to the limited precisions of the sensors. Some metrics have a fixed number of digits after decimal points. They can be converted to integers as well to use integer compression algorithms like Base-Delta encoding. Across 18 metrics in the dataset, we can obtain an average of 3-4× compression ratios for each metric.

5.4 Real-World Implementation

We have built a distributed streaming system in our production data centers and implemented Pingmesh [35] usingTerseCades. In the original system, we used Trill [21] for streaming processing, which is now completely replaced with our new design. The whole system is composed of 16 servers each with two Xeon E5-2673 CPUs and 128G DRAM, running Windows Server 2016. Every server runs a frontend service and a backend service. The frontend services receive real-time Pingmesh data from a Virtual IP behind a load-balancer, and then partition the data based on the geo-region ID of the data and shuffle the data to the backend.

The whole system is designed to be fault tolerant – works well even if half services are down. The operations we perform are latency heatmap calculation at the 50^{th} and the 99^{th} percentiles, and several anomaly detections including ToR (Top of Rack) switch down detection. The aggregated Pingmesh input streaming is 2+ Gb/s, making it bandwidth-sensitive when properly optimized. The busiest server needs to process 0.5 millions events per second and uses 50% CPU cycles and 35GB memory. Using TerseCades to replace Trill, we reduce the sixteen servers to only one.

6 Related Work

Streaming System. Numerous streaming systems have been developed in both industry and literature [7, 18, 22, 41, 1, 10, 11, 66, 48, 56, 57, 65] to address the various needs for streaming processing: to name a few, Spark Streaming [66] applies stateless short-task batch computation to improve fault tolerance, MillWheel [10] supports user-defined directed graph of computation, Naiad [48] provides the timely dataflow abstraction to enable efficient coordination. One common requirement for these systems is to handle massive amount of unbounded data with redundancies. This motivates us to look into efficient data compression support in stream processing. Complimentary to these work, which focuses on high-level programming models in distributed environment, we focus on data compression in lower level core streaming engines that can potentially benefit these systems regardless of their high-level abstractions.

Memory Compression: Software and Hardware Approaches. Several mechanisms were proposed to perform memory compression in software (e.g., in the compiler [43] or the operating system [62]). While these techniques can be quite efficient in reducing applications' memory footprint, their major limitation is slow (usually software-based) decompression. This limits these mechanisms to compressing only "cold" pages (e.g., swap pages). Hardware-based data compression received some attention in the past [64, 8, 24, 30, 52]. However, proposed general-purpose designs had limited practical use either due to unacceptable compression/decompression latency or high design complexity, or because they require non-trivial changes to existing operating systems and memory architecture design.

Compression in Databases and Data Stores. Compression has been widely used to improve performance of databases [34, 58, 38, 25, 69, 5, 51, 46] and recent data stores [23, 9, 40] usually by trading-off overhead due to decompression for improved I/O performance and buffer hit rate. Some recent work investigates compression in the context of column-oriented databases [5, 6]that makes a few similar observations to our work: (i) adjacent entries in a column are often similar, (which helps improving compressibility), and (ii) some operators can run directly on compressed data to mitigate decompression costs (e.g., SUM aggregate on a run-length encoded column). The key difference in our work is that we apply compression in the streaming setting, and this puts significant limitations on the compression algorithm used (compared to offline data processing where latency is way less critical) that is now on the critical execution path. The proper choice of compression algorithm for streaming, reducing the key overheads of compression by using hardware acceleration, and using direct execution on compressed data (which not only avoids decompression, but actually executes faster than the baseline) are key contributions of our work that distinguish TerseCades from prior work on database compression.

One recent work, Succinct [9], supports queries that execute directly on compressed textual data (without indexes), significantly improving both memory efficiency and latency, but at the cost of complete redesign of how the data is stored in the memory. This is complementary to our work as our primary target is machine-generated, numerical data sets that proved to be more dominant in the streaming scenarios compared to textual data.

7 Conclusion

TerseCades is the first that attempts to answer the question of "Can data compression be effective in stream processing?". The design and optimizations of TerseCades answer these questions affirmatively. Our thorough studies and extensive evaluations using real stream workloads on production data further shed light on when and why compression might not be effective, as well as what can be done to make it effective. While our current implementation supports only a subset of operators supported by mature frameworks like Trill, we hope that by demonstrating the feasibility of data compression efficiency for streaming we will open the door for incorporating data compression in the next generation of stream processing engines.

Troubleshooting Transiently-Recurring Problems in Production Systems with Blame-Proportional Logging

Abstract

Many problems in production systems are *transiently recurring* — they occur rarely, but when they do, they recur for a short period of time. Troubleshooting these problems is hard as they are rare enough to be missed by sampling techniques, and traditional postmortem analyses of runtime logs suffers either from low-fidelity of logging too little or from the overhead of logging too much.

This paper proposes AUDIT, a system specifically designed for troubleshooting transiently-recurring problems in cloud-based production systems. The key idea is to use *lightweight triggers* to identify the first occurrence of a problem and then to use its recurrences to perform *blame-proportional logging*. When a problem occurs, AUDIT automatically assigns a *blame rank* to methods in the application based on their likelihood of being relevant to the root-cause of the problem. Then AUDIT enables heavy-weight logging on highly-ranked methods for a short period of time. Over a period of time, logs generated by a method is proportional to how often it is blamed for various misbehaviors, allowing developers to quickly find the root-cause of the problem.

We have implemented AUDIT for cloud applications. We describe how to utilize system events to efficiently implement lightweight triggers and blame ranking algorithm, with negligible to $< 1\%$ common-case runtime overheads on real applications. We evaluate AUDIT with five mature open source and commercial applications, for which AUDIT identified previously unknown issues causing slow responses, inconsistent outputs, and application crashes. All the issues were reported to developers, who have acknowledged or fixed them.

1 Introduction

Modern cloud applications are complex. Despite tremendous efforts on pre-production testing, it is common for applications to misbehave in production. Such misbehaviors range from failing to meet throughput or latency SLAs, throwing unexpected exceptions, or even crashing. When such problems occur, developers and operators most commonly rely on various runtime logs to troubleshoot and diagnose the problems.

Unfortunately, runtime logging involves an inherent tradeoff between logging sufficient detail to root-cause problems and logging less for lower overhead (see for instance [1, 2, 3, 4, 5]). Our experiments show (§6) that even for web applications that are not compute intensive, logging parameters and return values of all methods can increase latency and decrease throughput by up to 7%. Moreover, determining what to log is made harder by the fact that modern cloud and web applications involve multiple software components owned by different software developer teams. As a result, most logs generated today are irrelevant when root-causing problems [6].

To solve this problem, we make an important observation that many misbehaviors in production systems are *transiently-recurring*. As many frequent problems are found and fixed during initial phases of testing and deployment, we expect many problems in production systems to be rare and transient (the rarity makes it challenging to troubleshoot using sampling techniques [1, 2]). However, when they occur, they recur for a short amount of time for a variety of reasons, e.g., the user retrying a problematic request or a load-balancer taking some time to route around a performance problem (§2.2).[1]

Contributions. In this paper, we utilize the recurrence of these misbehaviors and present the design and implementation of AUDIT (AUtomatic Drill-down with Dynamic Instrumentation and Triggers): a *blame-proportional logging* system for troubleshooting transiently-recurrent problems in production systems. The basic idea is as follows. AUDIT uses lightweight triggers to detect problems. When a problem occurs, AUDIT automatically assigns a *blame rank* to methods in the application based on their likelihood of being rel-

[1] A notable exception to transient-recurrence are *Heisenbugs* which occur due to thread-interleaving or timing issues. AUDIT is not designed to troubleshoot these problems.

evant to the root-cause of the problem. Then AUDIT drills-down—it dynamically instruments highly-ranked methods to start heavy-weight logging on them until a user-specified amount of logs are collected. Over a period of time, logs generated by a method is proportional to how often the method is blamed for various misbehaviors and the overall logging is temporally correlated with the occurrence of misbehaviors. Developers analyze the logs *offline*, and thus AUDIT is complementary to existing techniques that help in interactive settings [7, 8].

We demonstrate the feasibility and benefits of AUDIT with the following contributions. First, AUDIT introduces *lightweight triggers* that continuously look for target misbehaviors. Developers can declaratively specify new triggers, describing target misbehaviors, the set of metrics to collect, and the duration for which to collect. The design of the trigger language is motivated by recent studies on misbehaving issues in production systems and when/where developers wish to log [3, 9, 10].

To evaluate the triggers and to blame-rank methods, AUDIT uses continuous end-to-end request tracing. To this end, our second contribution is *a novel tracing technique* for modern cloud applications built using Task Asynchronous Pattern (TAP), an increasingly popular way to write asynchrnous programs with sequential control flow and found in many languages including .NET languages, Java, JS/Node.js, Python, Scala, etc. AUDIT leverages system events at thread and method boundaries provided by existing TAP frameworks for monitoring and debugging purposes. AUDIT correlates these readily available events for lightweight end-to-end tracing. As a result, AUDIT introduces acceptable (from negligible to $< 1\%$) overhead in latency and throughput during normal operations. Note that AUDIT can also support non-TAP applications using known techniques based on instrumentation and metadata propagation [8, 11, 12] that are shown to have acceptable overheads in production systems.

Our third contribution is a novel ranking *algorithm that assigns blame scores to methods*. After a trigger fires, AUDIT uses the algorithm to identify high-ranked methods to initiate heavy-logging on them. AUDIT's blame ranking algorithm uses lessons from recent studies on where and what developers like to log for successful troubleshooting [3, 13]. It prioritizes methods where misbehavior originates (e.g., at a root exception that later causes a generic exception), that slow down requests, and that are causally related to misbehaving requests. It addresses key limitations of existing bottleneck analysis techniques that ignore critical path [14] or methods not on critical paths [15, 16, 17].

Our final contribution is an *evaluation* of AUDIT. We used AUDIT on a Microsoft production service and 4 popular open source applications. AUDIT uncovered previously-unseen issues in all the applications (§6.1). Many of the issues manifest only on production, as they are triggered based on user inputs and concurrency. All the issues have been reported to and acknowledged by developers of the applications. Some of them have already been fixed by developers with insights from logs generated by AUDIT.

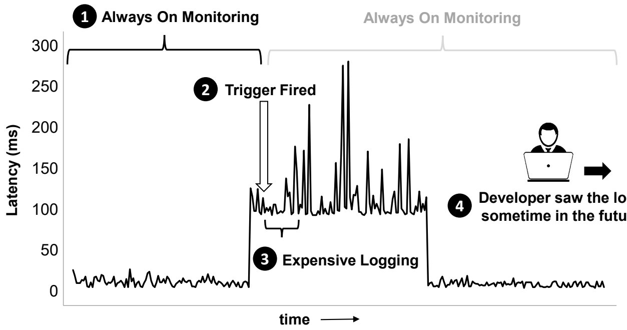

Figure 1: Timeline of AUDIT finding a performance bug in Forum.

2 Overview

2.1 A motivating case study

Microsoft Embedded Social. We start with an example demonstrating how AUDIT helped troubleshoot a problem in Microsoft Embedded Social (hereafter referred to as Social for brevity), a large-scale social service at Microsoft. Social is written in C#, deployed on Microsoft Azure, and is used by several applications and services in production. Social lets users add/like/search/delete posts, follow each other, and see feeds.[2]

Enabling AUDIT. AUDIT is easy to use. AUDIT works with unmodified application binaries and is enabled by simply setting a few environment variables. AUDIT comes with a set of triggers targeting common performance and exception-related problems. Social developers enabled AUDIT with these default triggers.

The problem. Figure 1 shows a performance problem that occurred in production: the latency of retrieving *global feeds* increased for a few hours. The developer was offline during the entire time and later relied on AUDIT logs to troubleshoot the issue.

AUDIT in operation. An AUDIT trigger fired shortly after the sudden spike in latency ((2) in Figure 1). For all misbehaving requests, AUDIT logged end-to-end *request trace* consisting of the request string, names and caller-callee relationship of executed methods. In addition, its blame ranking algorithm selected top-k (k = 5 by default) ranked methods and dynamically instrumented them to log their parameters and return values.

[2] Open source SDKs are available on GitHub, e.g., https://github.com/Microsoft/EmbeddedSocial-Java-API-Library

The *heavyweight logging* continues for a short time (5 minutes by default, stage (3) in Figure 1). This spatially- and temporally-selective logging helped the developer to root-cause of the problem, even long after the problem disappeared (stage (4) in Figure 1).

Troubleshooting with AUDIT logs. AUDIT's request traces showed that the misbehaving request was retrieving the global feed. The feed consists of a list of post-ids and contents; the latter is stored in a back-end store (Azure Table Storage) and is cached (in Redis) to achieve low-latency and high-throughput. Request tracing showed that the spike was due to post contents consistently missing the cache, albeit without revealing the cause of cache misses.

Among the methods AUDIT selected for heavyweight logging was a method that queries the backing store (Azure Table Storage). The logged arguments showed that the spike was caused by one particular post id, which according to logged return value didn't exist in the backing store. This inconsistency lead to the root-cause of the bug — a post id was present in the global feed but its contents were missing.

This inconsistency occurred when a user deleted a post. Social deleted its content from cache and backing store but failed to delete its id from the global feed due to a transient network failure. This inconsistency was not visible to users as missing posts are omitted in feeds, but it created a persistent performance spike. The inconsistency eventually disappeared when the problematic id was moved out of the global feed by other posts.

In addition to pinpointing the inconsistency, AUDIT also helped the developer root-cause the inconsistency to the failure in the delete operation through its detailed failure logging. We discuss the bug in more detail in §6.1.1. The developer chose to fix the problem by implementing negative caching, where Redis explicitly stores that a post is deleted from the backing store.

The case study demonstrates the value of AUDIT: it can capture *useful logs* for *relatively rare issues* that may appear in production or large-scale tests when the developer is absent. Moreover, logs are collected *only for a short period* after the issue occurs, reducing the log collection overhead and making it suitable even for expensive logging operations.

2.2 Transiently-recurring Problems

We argue that many problems in cloud-based production systems are transiently-recurring. First, if an error is frequent, it will most likely be detected and fixed during pre-production testing and staging of the application. Second, many problems are due to infrastructure problems such as transient network hardware issues [9, 18]; SLAs from cloud service providers ensure that such problems are rare and fixed within a short window of time. Therefore, cloud applications commonly use the "retry pattern" [19, 20] where the application transparently retries a failed operation to handle transient failures. Third, some problems are due to user inputs (e.g., malformed). Such errors are rare in well-tested production systems; however, once happened, they persist till the user gives up after several retries [21].

Note that AUDIT is also useful for troubleshooting errors that appear frequently—as long as they persist for a small window of time (e.g., not Heisenbugs).

3 AUDIT design

At a high level, AUDIT consists of four components: (1) declarative *triggers* for defining misbehaving conditions (§ 3.1), (2) a light-weight *always-on monitoring* component that continuously evaluates trigger conditions and collects request execution traces (§3.2 and § 4), (3) a *blame assignment algorithm* to rank methods based on their likelihood of being relevant to the root cause of a misbehavior (§ 3.3), and (4) a *selective logger* that uses dynamic instrumentation to enable and disable logging at top-blamed methods (§ 3.4).

3.1 AUDIT triggers

Trigger Language. AUDIT triggers are similar to *Event-Condition-Action* rules that are widely used in traditional databases [22] and in trigger-action programming such as IFTTT [23]. A key challenge in designing AUDIT's trigger language is to make it concise, yet expressive enough for a developer to specify interesting misbehaviors and useful logs. Before we elaborate on the rationale behind our choice, we first describe the four key components of an AUDIT trigger:

(1) `ON`. It specifies when (`RequestStart`, `RequestEnd`, `Exception`, or `Always`) the trigger is evaluated.

(2) `IF`. It describes a logical condition that is evaluated on the `ON` event. The condition consists of several useful properties of the request `r` or the exception `e` such as `r.Latency`, `e.Name`, `r.ResponseString`, `r.URL`, etc. It also supports several streaming aggregates: `r.AvgLatency(now,−1min)` is the average latency of request `r` in the last 1 min, `e.Count(now,−2min)` is the number of exception `e` in the last 2 mins, etc.

(3) `LOG`. It describes what to log when the `IF` condition satisfies. AUDIT supports logging `RequestActivity`[3] and `method` of a request. A key component of `LOG` is `ToLog`, which indicates target metrics to log: e.g., `args`, `retValue`, `exceptionName`, `latency`, `memoryDump`. Logs can be collected for requests matching (or not matching) the `IF` condition with a sampling probability of `MatchSamplingProb` (or `UnmatchSamplingProb`,

[3] A request activity graph (§3.3) consists of all methods invoked by the request as well as their causal relationship.

```
1 DEFINE TRIGGER T
2  ON RequestEnd R
3  IF R.URL LIKE 'http:*GetGlobalFeed*'
4     AND R.AvgLatency(-1min, now) > 2 * R.
          AvgLatency(-2min, -1min)
5  LOG RequsetActivity A, Top(5) Methods M
6     WITH M.ToLog=args, retValues
7     AND MatchSamplingProb = 1
8     AND UnmatchSamplingProb = 0.3
9  UNTIL (10 Match,10 Unmatch) OR 5 Minutes
```

Figure 2: An AUDIT trigger that fires when the latency of the global feed page in Social increases.

respectively). This enables comparing logs from "good" and "bad" requests. Finally, AUDIT supports logging all or a specified number of top performance-critical methods (with the Top() keyword). The later is useful when the request involves a large number of methods and instrumenting all of them would incur a high runtime overhead. Users can also define custom logging library that AUDIT can dynamically load and use.

(4) `UNTIL`**.** It describes how long or how many times the `LOG` action is performed.

Language Rationale. As mentioned, AUDIT's trigger language is motivated by prior works [3, 9, 10]. The general idea of enabling logging on specific misbehaving conditions (specified by `ON` and `IF`) and disabling it after some time (specified via `UNTIL`) addresses a key requirement highlighted in a recent survey of 54 experienced developers at Microsoft by Fu et. al [3]. The authors also analyzed two large production systems and identified three categories of *unexpected situation* logging. AUDIT's triggers support all of them: (1) exception logging, through `exceptionName` and `RequestActivity`, (2) return-value logging, via `retValue`, and (2) assertion-check logging, via `args`. The `ToLog` metrics are chosen to support common performance and reliability issues in production systems [9]. Logging both "good" and "bad" requests is inspired by statistical debugging techniques such as Holmes [10].

An Example Trigger. Figure 2 shows a trigger that can be used by Social for the scenario described in §2.1. The trigger fires when the average latency of the global feed page computed over a window of 1 minute increases significantly compared to the previous window. AUDIT starts logging all requests matching the `IF` condition and 30% of requests not matching the condition (for comparison) once the trigger fired. For each such request, AUDIT logs the *request activity*, consisting of all sync/async methods causally related to the request. Additionally, it assigns a blame rank to the methods and logs parameters and return values of 5 top-ranked methods. AUDIT continues logging for 10 matched and 10 unmatched requests, or for a maximum of 5 minutes.

Specifying Triggers. The trigger in Figure 2 may look overwhelming, with many predicates and parameters. We use this trigger for illustration purpose. In practice, a developer does not always need to specify all trigger parameters, letting AUDIT use their default values (all numerical values in Figure 2 are default values). Moreover, AUDIT comes with a set of predefined triggers that a developer can start with in order to catch exceptions and sudden spikes in latency and throughput. Over time, she can dynamically refine/remove existing triggers or install new triggers as she gains more operational insights. For example, the trigger in Figure 2 minus the predicate in Line 3 is a predefined trigger; Social developers modified its scope to global feed requests.

3.2 Always-on monitoring

AUDIT runtime continuously evaluates installed triggers. AUDIT instruments application binaries to get notified of triggering events such as exceptions, request start and end, etc. AUDIT automatically identifies instrumentation points for web and many cloud applications that have well-defined start and end methods for each request; AUDIT users can declaratively specify them for other types of applications. The handlers of the events track various request and exception properties supported by AUDIT trigger language. In addition, if needed by active triggers, AUDIT maintains lightweight streaming aggregates such as `Count`, `Sum`, and `AvgLatency` over a window of time.

In addition, AUDIT uses end-to-end causal tracing to continuously track identity and caller-callee relationships of methods executed by each request. For general applications, AUDIT uses existing tracing techniques based on instrumentation and metadata propagation [1, 8, 24, 25, 26, 27, 28]. For cloud applications using increasingly popular Task Asynchrnous Pattern (TAP), AUDIT uses a more lightweight and novel technique that we describe in §4.

AUDIT represents causal relationships of methods with a *request activity graph* (RAG), where nodes represent instances of executed methods and (synchronous or asynchrnous) edges represent caller-callee relationships of the nodes. A *call chain* to a node is the path from the root node to that node. (A call chain is analogous to a stack trace, except that it may contain methods from different threads and already completed methods.)

For multi-threaded applications, a RAG can contain two special types of nodes. A *fork node* invokes multiple asynchronous methods in parallel. A *join node* awaits and starts only after completion of the its nodes. A join node is an *all-join* node (or, *any-join* node), if it waits for all (or, any, respectively) of its parents node to complete. For each method in the RAG, AUDIT also tracks four timestamps: a (t_{start}, t_{end}) pair indicating when the method starts and ends, and a $(t_{pwStart}, t_{pwEnd})$ pair indicating when the method's parent method starts and ends waiting for it to complete (more details in §4).

3.3 Blame assignment and ranking

After a misbehaving request fires a trigger, AUDIT uses a novel algorithm that ranks methods based on their blames for a misbehavior – the higher the blame of a method, the more likely it is responsible for the misbehavior. Thus, investigating the methods with higher blames are more likely to be helpful in troubleshooting the misbehavior.

To assign blames, AUDIT relies on RAGs and call chains of misbehaving requests, as tracked by the always-on monitoring component of AUDIT.

3.3.1 Exception-related triggers

On an exception-related trigger, AUDIT uses the call chain ending at the exception site to rank methods (on the same or different threads). Methods on the call chain are ranked based on their distance from the exception – the method that throws the exception has the highest rank and methods nearer to the exception are likely to contain more relevant information to troubleshoot root causes of the exception (as suggested by the survey in [3]).

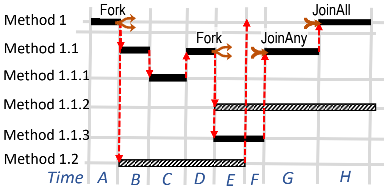
3.3.2 Performance-related triggers

On a performance-related trigger, AUDIT uses a novel bottleneck analysis technique on the RAGs of misbehaving requests. Existing critical path-based techniques (e.g., Slack [15], Logical Zeroing [16], virtual speedup [17]) fall short of our purpose because they ignore methods that should be logged but are not on a critical path or have very little exclusive run time on critical path. Techniques that ignore critical paths (e.g., NPT [14]) also miss critical methods that developers wish to log. §6 shows several real-world examples that illustrate these limitations.

Blame assignment. AUDIT addresses the above limitations with a new metric called *critical blame* that combines critical path, execution time distribution, and join-node types. Given a RAG, computation of critical blames of methods consists of two steps.

First, AUDIT identifies critical paths in the RAG. A critical path is computed recursively, starting from the last node of the RAG. Critical path to a node includes the node itself and (recursively computed) critical paths of (1) all parent non-join nodes, (2) longest parents of all-join nodes, and (3) shortest parents of any-join nodes. Each method in the critical path has the property that if its runs faster, total request latency goes down. See §5 for how these timestamps are derived.

Second, AUDIT assigns to each method on the critical path a *critical blame* score, a metric inspired by NPT[14]. Critical blame for a method consists of its exclusive and fair share of time on the critical path. Figure 3 illustrates how AUDIT computes critical blames of various methods in a RAG. Recall that each node in the RAG has four timestamps: a (t_{start}, t_{end}) pair and a $(t_{pwStart}, t_{pwEnd})$ pair. At a given time t, we consider a node to be *active* if t is within its t_{start} and t_{end} but not within any of its child method's $t_{pwStart}$ and t_{pwEnd}.



Method	Blame
1	A+H/2
1.1	(B+D+G)/2
1.1.1	C/2
1.1.2	E/3+(F+G+H)/2
1.1.3	E/3+F/2
1.2	(B+C+D)/2+E/3

Figure 3: Critical blame assignment to methods. Solid edges represent methods on the critical path.

To compute critical blames of methods, AUDIT linearly scans the above timestamps of all methods (including the ones not in the critical path) in increasing order. Conceptually, this partitions the total request lifetime into a number of discrete *segments*, where each segment is bounded by two timestamps. In Figure 3, the segments are marked as $A, B, \ldots$ at the bottom. At each segment, AUDIT distributes the total duration of the segment to all methods active in that segment. For example, in the segment A, Method 1 is the only active method, and hence it gets the entire blame A. In segment B, methods 1.1 and 1.2 are active, and hence they both get a blame of $B/2$. Total blame of a method is the sum of all blames it gets in all segments (Method 1's total blame is $A + H/2$).

Selecting top methods. Given a target number n, AUDIT first selects the set $\mathbf{B}_1$ of n highest-blamed methods on the critical path. Let α be the lowest blame of methods in $\mathbf{B}_1$. AUDIT then compute another set $\mathbf{B}_2$ of methods not in the critical path whose execution times overlap with a method in $\mathbf{B}_1$, and whose blame scores are $\geq \alpha$. Finally, AUDIT computes $\mathbf{B} = \mathbf{B}_1 \cup \mathbf{B}_2$, and outputs all unique method names in $\mathbf{B}$. Essentially, the algorithm includes all slow critical methods and some slow non-critical methods that interfere with the critical methods.

Note that size of $\mathbf{B}$ can be larger (as it takes non-critical methods in $\mathbf{B}_2$) or smaller (as it ignores method instances) than n. If needed, AUDIT can try different sizes of $\mathbf{B}_1$ to produce a $\mathbf{B}$ whose size is close to n.

The intuition behind the above algorithm is as follow: (1) we want to blame only tasks that are actually running for the time they use; (2) we want co-running tasks to share the blame for a specific time period, assuming fixed amount of resources; (3) we want to first focus on tasks that are critical path as they affect runtime directly and (4) we want to include selective non-critical path tasks as they can be on the next longest path, may interfere with tasks on the critical path, and not all critical path methods can be modified to run faster. §6.2 compares critical blame to other metrics quantitatively.

3.4 Enabling and disabling logging

AUDIT uses dynamic instrumentation to temporarily inject logging statements into blamed methods. The process works with unmodified applications and only requires setting few environment variables pointing to AUDIT library. Like Fay [7] and SystemTap [29], AUDIT supports instrumenting tracepoints at the entry, normal return, and exceptional exit of any methods running in the same address space as the application.

Specifically, AUDIT decorates each selected method with three callbacks. `OnBegin` is called as the first instruction of the method, with the current object and all arguments. It returns a local context that can be correlated at two other callbacks: `OnException`, called with the exception object, and `OnEnd`, called with the return value. These callbacks enable AUDIT to collect a variety of drilldown information. To log method parameters, global variables, or system parameters such as CPU usage, AUDIT uses `OnBegin`. To log return values, it uses `OnEnd`. Latency of a method is computed by taking timestamps at `OnBegin` and `OnEnd`. To collect memory dumps on exception, AUDIT uses `OnException`.

4 Optimizations for TAP applications

Task asynchronous pattern (TAP) is an increasingly popular programming pattern[4], especially in cloud applications that are typically async-heavy. Unlike traditional callback-based Asynchronous Programming Model (APM), TAP lets developer write non-blocking asynchronous programs using a syntax resembling synchronous programs. For example, TAP async functions can return values or throw exceptions to be used or caught by callers. This makes TAP intuitive and easier to debug, avoiding callback hell [30]. Major languages including .NET languages (C#, F#, VB), Java, Python, JavaScript, and Scala support TAP. In Microsoft Azure, for many services, TAP is provided as the *only* mechanism to do asynchronous I/O. Amazon AWS also provides TAP APIs for Java [31] and .NET [32].

One contribution of AUDIT is to show that for TAP applications, it is possible to construct RAG and call chains extremely efficiently, without extensive instrumentation or metadata propagation. Our techniques provide *intra-machine* RAG and call chains, where APIs of nodes may cross machine boundaries but edges are within the same machine. We focus only on such RAGs as we found them sufficient for our target cloud applications; if needed, inter-machine edges can be tracked by using the techniques used by Pivot Tracing [8].

4.1 Continuous tracking of RAGs

AUDIT utilizes *async lifecycle events* provided by existing TAP frameworks for constructing RAGs. For debugging and profiling purpose, all existing TAP frameworks we know provide light-weight events or mechanisms indicating various stages of execution of async methods. Examples include ETW events in .NET [33], AsyncHooks [34] in Node.js, Decorators for Python AsyncIO [35], and RxJava Plugin [36] for Java. The events provide limited information about execution times and caller-callee relationships between some async methods, based on which AUDIT can construct RAGs. Using lifecycle events for tracing is not trivial. Depending on the platform, the lifecycle events may not directly provide all the information required to construct a RAG. We describe a concrete implementation for .NET in § 5.

4.2 On-demand construction of call chains

Even though call chain is a path in the RAG, AUDIT uses a separate mechanism to trace it for TAP applications. The advantage is that it lazily constructs a call chain on-demand, only *after* an exception-related trigger fires. Thus, the mechanism has *zero cost* during normal execution, unlike existing proactive tracking techniques [11, 12, 37]. AUDIT combines several mechanisms to achieve this.

AUDIT exception handler. AUDIT registers AUDIT event handler (AEH) to system events that are raised on all application exceptions. Examples of such events are *First Chance Exception* [38] for .NET and C++ for Windows, *UncaughtExceptionHandler* [39, 40] for Java, and *RejectionHandled* [41] for JavaScript.

AUDIT's exception tracing starts whenever the application throws an exception that satisfies a trigger condition. Consider `foo` synchronously calling `bar`, which throws an exception. This will invoke AEH with `bar` as the call site and a stacktrace at AEH will contain `foo`. This enables AUDIT to infer the RAG edge from `foo` to `bar`. If, however, `bar` runs asynchronously and in a different thread than `foo`, stacktrace won't contain `foo`. To infer the async edge from `foo` to `bar`, AUDIT relies on how existing TAP frameworks handle exceptions.

Exception propagation in TAP. Recall that TAP allows an async method to throw an exception that can be caught at its caller method. When an exception `e` is thrown in the async method `bar`, the framework first handles it and then revisits or rethrows *the same* exception object `e` when the caller method `foo` retrieves the result of

[4] To quantify TAP's popularity, we statically analyzed all C# (total 18K), JavaScript (Node.js) (16K), and Java (Android) (15K) GitHub repositories created between 1/1/2017 and 6/30/2017. Our conservative analysis, which may miss applications using 3rd party TAP libraries, identified 52% of C#, 50% of JavaScript, and 15% of Java projects using TAP. The fractions are significantly higher than the previous year (e.g., 35% higher for C#), showing increasing popularity of TAP.

bar [42]. This action may trigger another first chance exception, calling the AEH with e.

AUDIT correlates on exception objects to discover async caller methods in a call chain and uses the order in which the AEHs are invoked in various methods to establish their order. In general, a call chain may contain a combination of synchronous and asynchronous edges. AUDIT uses stack traces to find small chains of consecutive synchronous edges, and correlates on exception objects to stitch the chains.

An application may catch one exception e1 and rethrow another exception e2. This pattern is dominant especially in middleware, where library developers hide low-level implementation details and expose higher level exceptions and error messages. The exception tracing technique described so far will produce two separate call chains, one for e1 and another for e2. However, since e1 has triggered e2, causally connecting the two chains can be useful for troubleshooting and root cause analysis [3].

Inheritable thread-local storage (ITS). AUDIT uses ITS to connect correlated exceptions. Inheritable thread-local storage allows storing thread-local contents that automatically propagate from a thread to its child threads. This is supported in Java (InheritableThreadLocal), .NET (LogicalCallContext), and Python (AsyncIO Task Local Storage[43]). Using ITS is expensive due to serialization and deserialization of data at thread boundaries. Existing causal tracing techniques use ITS all the time [27]; in contrast, AUDIT uses it only for exception tracing and on demand.

When e1 and e2 happens in the same thread, AUDIT can easily correlate them by storing a correlation id at the AEH of e1, and then using the id at the AEH of e2.

If e2, however, is thrown on a different thread than e1, the situation is more subtle. This is because e2 is thrown on the parent (or an ancestor) of e1's thread, and the correlation id stored in a thread's ITS is not copied *backward* to the parent thread's context (it is only copied forward to child threads).

To address this, AUDIT combines ITS with how TAP propagates exceptions across threads (described above). More specifically, AUDIT uses the first exception e1 as the correlation id and relies on TAP to propagate the id to the parent thread, which can correlate it to e1. The AEH for e2 stores e1 in ITS for further correlating it with other related exceptions on the same thread.

5 Implementation

We here describe our implementation of AUDIT for TAP applications written in .NET for Windows and cross-platform .NET Core.

Listening to exceptions. AUDIT listens to AppDomain.FirstChanceException to inspect all exceptions thrown by the application. First chance exception is a universal debugging concept (e.g., catch point in GDB, first chance exception in Visual Studio). A first chance exception notification is raised as soon as a runtime exception occurs, irrespective of whether it is later handled by the application.

Request tracing. For efficiently constructing the RAG of a request, AUDIT uses TplEtwProvider, an ETW-based [33] low overhead event logging infrastructure in .NET. TplEtwProvider generates events for the lifecycle of tasks in TAP.

Specifically, AUDIT uses TraceOperationBegin event to retrieve the name of a task. TaskWaitBegin is used for timestamp when a parent task transitions to suspended state and starts to wait on a child task. TraceOperationRelation is used to retrieve children tasks of a special join task (WhenAll, WhenAny), these join tasks are implemented in a special way such that they do not produce other life cycle events. At last, TraceOperationComplete, TaskWaitEnd, TaskCompleted, RunningContinuation, TaskWaitContinuationComplete are used to track the completion of a task. Many events are used because not all tasks generate the same event.

Constructing RAG based only on TPL ETW events is challenging for two key reasons, which AUDIT addresses by utilizing semantics of the events. First, ETW events are not timestamped by their source, but by the ETW framework after it receives the event. The timestamps are not accurate representation of the event generation times as the delivery from source to ETW framework can be delayed or out-of-order. To improve the quality of timestamps, for each method on the RAG, AUDIT aggregates multiple ETW events. For example, ideally, the t_{end} timestamp should come from the TaskCompleted ETW event. However, TPL generates other events immediately after a task completes. AUDIT takes the earliest of the timestamps of any and all of these events, to tolerate loss and delayed delivery of some events. AUDIT also uses the fact that in a method's lifetime, $t_{start} \geq t_{pwStart} \geq t_{end} \geq t_{pwEnd}$. Thus, if, e.g., all ETW events related to t_{start} are lost, it is set to $t_{pwStart}$.

Second, TPL does not produce any ETW events for join tasks, which are important parts of RAG. AUDIT uses reflection on the joining tasks (that produce ETW events) to identify join tasks, as well as their types (all-join or any-join). The t_{start} and t_{end} timestamps of a join task is assigned to the t_{start} and t_{end} timestamps of the shortest or the longest joining task, depending on whether the join task is any-join or all-join, respectively.

Dynamic instrumentation AUDIT uses .NET's profiling APIs to dynamically instrument target methods during runtime. The process is similar to dynamically instrumenting Java binaries [44].

6 Evaluation

We now present experimental results demonstrating:

1. AUDIT can effectively root-cause transiently recurring problems in production systems (§6.1).
2. AUDIT's blame ranking algorithm is more effective in root-causing than existing techniques (§6.2)
3. AUDIT has acceptably small runtime overhead for production systems, and its TAP-related optimizations further reduce the overhead (§6.3).

6.1 Effectiveness in root-causing bugs

We used AUDIT on five high-profile and mature .NET applications and identified root causes of several transiently recurring problems and bugs (Table 1). All the issues were previously unknown and are either acknowledged or fixed by developers. In all cases, AUDIT's ability to trigger heavyweight logging in a blame-proportional manner were essential to resolve problems.

6.1.1 Case study: Embedded Social

In § 2.1, we described one performance issue AUDIT found in Embedded Social (Social), a large-scale production social service in Microsoft. We now provide more details about Social and other issues AUDIT found in it. At the time of writing, Social had millions of users in production and beta deployments. We deployed Social in a deployment cluster. We enabled AUDIT with a generic exception trigger and a few performance triggers for latency-sensitive APIs (e.g. Figure 2).

Social 1: The persistent performance spike (Figure 1) arose because of an inconsistency caused by a failure (network timeout) during post deletion – the post id in the feed was left undeleted. Social swallowed the actual exception and produced only a high level exception for the entire delete operation. AUDIT logged the entire chain, pinpointed that post contents were deleted, but global feed deletion failed. AUDIT also logged the request URL, which identified the post id that was being deleted. The RAGs produced by the performance trigger showed the persistent store being consistently hit for one post. AUDIT's blame ranking algorithm top-ranked the persistent store query method, dynamically instrumented it, and logged arguments and return value for the next few requests to the global feed. The logged arguments showed the problematic post id causing the spike and the logged return value (`NULL`) indicated that it was deleted from the store and pointed to lack of negative caching as an issue. The post id matched the one logged during delete operation failure, which explained the bug.

Social 2: AUDIT revealed a few more transiently recurring issues related to lack of negative caching. For example, Social recommends a list of users with high follower count to follow. In the corner case of a popular user not following anyone, Social did not create an entity for the following count in the persistent store (and thus in the cache). In this case, the main page persistently missed the cache when reporting such users in the recommended list. AUDIT correctly assigned blame to the count-query method and logged both the user id (as part of parameters) and the return value of 0. Social's developers implemented negative caching to fix them.

Social 3: AUDIT's exception trigger in Social helped root-cause several transiently recurring request failures. We discuss a couple of them here. "Likes" for a post are aggregated and persisted to ATS using optimistic concurrency. When a specific post became hot, updates to ATS failed because of parallel requests. Through drill down, AUDIT pinpointed the post id (parameter) of the hot post and showed that like requests were failing only for that particular post id and succeeding for others.

Social 4: As posts are added, Social puts them in a queue and indexes the content of the posts in a backend worker. Typical to many systems, when a worker execution fails, the jobs are re-queued and retried a few times before being dead-lettered. This model perfectly fits AUDIT's triggered logging approach. After the first time a worker fails on a request, AUDIT triggers expensive parameter logging for subsequent retries. By logging their parameters, AUDIT root-caused many content-related bugs during indexing due to bad data formats.

We also found AUDIT useful in root-causing rare but recurrent problems in several open-source projects. Below we summarize the symptoms, AUDIT logs, and root cause of the problems.

6.1.2 Case study: MrCMS

MrCMS[45] is a content management system (CMS) based on the ASP.NET 5 MVC framework.

Symptoms. On a rare occasion, after an image is uploaded, the system crashed. Then the system became permanently unusable, even after restarting.

AUDIT logs. The AUDIT log from the first occurrence of the problem indicated an unhandled `PathTooLongException`. This was surprising because MrCMS checks for file name length. The methods on the call chain, however, indicated that the exception happened when MrCMS was creating thumbnail for the image. After AUDIT instrumented methods on the call chain, recurrence of the problem (i.e., recurrent crashing after restart) generated logs including method parameters. This included the actual file name for which a file system API was throwing the exception.

Root cause and fix. When image files are uploaded, MrCMS generates thumbnails with the image file name suffixed with dimensions. Thus, when an input file name is sufficiently long, the thumbnail file name can exceed the filesystem threshold which is unchecked and caused the crash. As most bugs in production systems, the fix for

Application	Issue	Root cause based on AUDIT log	Status from devs
Social 1	Performance spike when reading global feeds	Deleted operation failed to delete the post from global feeds	Fixed
Social 2	Poor performance reading user profiles with no following in “Popular users” feed	Lack of caching zero count value	Fixed
Social 3	Transient “Like” API failures	Concurrent likes on a hot post	Acknowledged, open
Social 4	Indexing failures	Bad data formats	Some of them fixed
MrCMS	Crash after image upload and subsequent restart of the application (Issue# 43)	Auto-generated thumbnail file name too long	Acknowledged, investigating
CMSFoundation	Failure to save edited image (Issue# 321)	Concurrent file edit and delete	Acknowledged, open
Massive	Slow request (Issue# 270)	Unoptimal use of Await	Fixed and closed
Nancy	Slow request (Issue# 2623)	Redundant Task method calls	Fixed and closed

Table 1: Summary of previously-unknown issues found by using AUDIT.

the bug once the root cause is known is simple: check file name lengths after adding the suffixes. The issue was acknowledged by the developer.

6.1.3 Case study: CMS-Foundation

CMS-Foundation[46] is a top-rated open source CMS with more than 60K installations worldwide.

Symptoms. When an admin saves after editing an image, they occasionally get a cryptic “Failed to get image properties: check that the image is not corrupt” message. The problem recurred as the admin retried the operation.

AUDIT logs. AUDIT log showed a crucial causality through two exception chains (as the application caught and rethrew exceptions) to the file being deleted while the admin was editing the image.

Root cause and fix. While the admin was editing the image, another admin deleted it, leading to a race condition. One way to fix this behavior is to use locking to prevent two admins from performing conflicting operations. The issue was acknowledged by the developers.

We now summarize two case studies demonstrating AUDIT’s value in diagnosing performance problems.

6.1.4 Case study: Massive

Massive[47] is a dynamic MicroORM and a showcasing project for ASP .NET. Massive is popular and active on GitHub, with 1.6K stars and 330 forks.

Symptoms. Slow requests for certain inputs.

AUDIT logs. AUDIT produced RAG for the slow requests, as well as input parameters and return values of 5 top-ranked methods.

Root cause and fix. The top two methods ranked by AUDIT constituted 80% of the latency for some inputs. These methods query a backend database. Input parameters (i.e., query string) of the methods indicated that the method calls are independent (we confirmed this by looking at the code), yet Massive runs them in sequence. We modified the code to call both methods in parallel. This simple change resulted in a 1.37× speedup of the query in our deployment. We filed this potential optimization on GitHub and this issue was acknowledged and fixed.

6.1.5 Case study: Nancy

Nancy[48] is “a lightweight, low-ceremony, framework for building HTTP based services on .NET Framework/-Core and Mono”. Nancy is also popular on GitHub, with 5.8K stars, 1.3K forks, and more than 250 contributors.

Symptoms. Some requests were slow.

AUDIT logs. AUDIT’s log identified RAG and top-blamed method calls for the slow requests.

Root cause and fix. The top-blamed method calls, that constitued signficant part of the latency, were expensive and redundant [42]. We therefore changed the code by simply removing the redundant code, without affecting semantics of the code. This reduced average latency of the Nancy website from 1.73ms to 1.27ms with our deployment, a 1.36× improvement. We have reported this issue to Nancy developers, who have quickly acknowledged and fixed it. This, again, shows effectiveness of AUDIT’s blame ranking algorithm.

6.2 Blame ranking algorithm

We compare AUDIT’s blame ranking algorithm with three other algorithms: (1) NPT [14] that distributes running time evenly among concurrently running methods and ranks methods based on their total time, (2) Top critical methods (TCM), which ranks methods based on their execution time on critical path, and (3) Iterative Logical Zeroing (ILZ), an extension of Logical Zeroing [16]. ILZ first selects the method that, if finished in zero time, would have the maximum reduction in end-to-end latency. It then selects the second method *after* setting the first method’s execution time to zero, and so on.

We consider four common code patterns observed in 11 different open source TAP applications and tutorials. Figure 4 shows corresponding RAGs. Two developers manually studied the applications and RAGs and identified the methods they would log to troubleshoot performance misbehaviors. Methods identified by both the developers are used as baseline.

Table 2 shows top-3 methods identified by different algorithms (and the baseline). TCM and ILZ fail to identify methods not on critical paths (e.g., Scenario 3). NPT

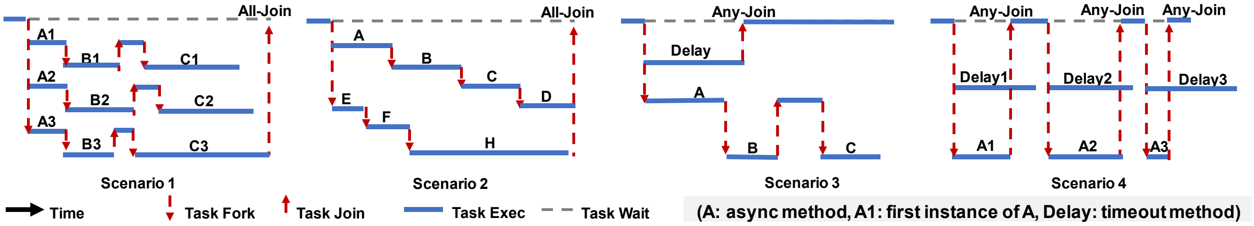


Figure 4: Common code patterns in TAP. Scenario 1 (found in Social, [49, 50]) starts parallel tasks with same code path and awaits all to finish. Scenario 2 (found in [51, 52]) starts several different tasks (which in turns fires up more children tasks) and they could finish close to each other. Scenario 3 (found in [53, 54]) starts a task and waits for a timeout. Scenario 4 (found in [20, 55, 56, 57]) retries a failed task a few times, and each trial is guarded with a timeout.

Algorithm	Scenario 1	Scenario 2	Scenario 3	Scenario 4	Total
Baseline	C_3,B_3,A_3	H,B,A	A,C,B	A_1,A_2,A_3	–
NPT	C_3,C_2,C_1	H,B,A	$A,\mathbb{D},C$	$\mathbb{D}_3,\mathbb{D}_2,\mathbb{D}_1$	6/12
TCM	C_3,B_3,A_3	B,A,C	$\mathbb{D}$	A_2,A_1,A_3	7/12
ILZ	C_3,C_2,C_1	B,H,A	$\mathbb{D}$	A_2,A_1,A_3	7/12
AUDIT	C_3,B_3,A_3	H,B,A	$\mathbb{D},A,B$	$A_1,A_2,\mathbb{D}_3$ $\mathbb{D}_1,\mathbb{D}_2,A_3$	11/12

Table 2: Top 3 blamed methods identified by various algorithms for scenarios in Figure 4. ($\mathbb{D}$ = *Delay*.)

fail to find important methods on the critical path (e.g., Scenario 4). Last column of the table shows how many of the developer-desired methods (baseline) are identified by different algorithms. Overall, AUDIT performs better – it identified 11 out of 12 methods marked by developers; while other algorithms identified 6-7 methods only. The only scenario where AUDIT failed to identify an important method C is Scenario 3, where C does neither fall on a critical path nor overlap or interfere with any method on the critical path.

6.3 Runtime overhead

We now evaluate runtime overhead of AUDIT running on a Windows 10 D8S_V3 instance, on Microsoft Azure. Web applications are hosted using ASP.NET 5 on IIS 10.0. SQL Server 2016 is used as database.

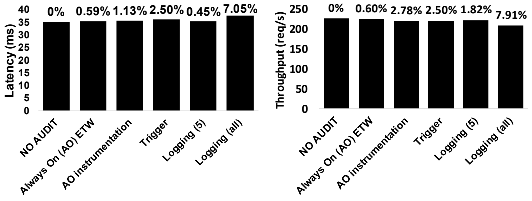
6.3.1 Micro benchmark results

Considerable design effort went in reducing the always-on overhead of AUDIT. We measure the overhead with a simple benchmark application that waits on two consecutive tasks. To measure the overhead of AUDIT's exception handling mechanism, we modified the application such that the async task throw an exception that the main task catches. Finally, to measure the *lower bound* on the cost of dynamic instrumentation, we instrumented an empty callback at the beginning and the end of each function with no parameter.

Table 3 shows AUDIT overhead numbers averaged over 100k runs. As shown, AUDIT's always-on ETW monitoring incurs small overhead – tens of μs per task.

	Without Exception	With Exception
Always-On ETW **Overhead**	15.56μs **+13.96μs/task**	112.2μs **+19.2μs/task**
Always-On INST **Overhead**	91.5μs **+89.9μs/method**	152μs **+59μs/method**
Trigger **Overhead**	29.66μs **+28.06μs/task**	283μs **+190μs/task**
Logging **Overhead**	93.5μs **+90.9μs/method**	148μs **+55μs/method**

Table 3: AUDIT overhead on benchmark application.



(a) Latency (b) Throughput

Figure 5: AUDIT overhead for Massive.

The overhead is acceptable for modern-day cloud applications that contain either compute-intensive or I/O-intensive tasks that typically run for tens of milliseconds or more. Always-on monitoring with instrumentation (Always-On INST) and metadata propagation incurs higher overhead mainly from instrumentation cost.[5] AUDIT significant lowers always-on monitoring overhead by leveraging ETW in TAP applications. The overhead is also higher immediately after a trigger fires (for constructing RAG and computing blames). This cost is acceptable as triggers are fired infrequently. Finally, logging has the highest overhead. Even an empty callback incurs hundreds of μs; serializing and logging method parameters, return values, stacktrace, etc. and writing to storage will add more overhead. This overhead clearly motivates the need for blame-proportional logging, which limits the number of logging methods and the duration of logging.

[5] Our measurement shows accessing an integer from ITS takes about 100ns and propagating an integer across thread costs 800ns, with a base cost of 700ns

6.3.2 Overheads for real applications

We measured AUDIT's overhead on Massive and Social, two TAP applications we used in our case studies. To emulate AUDIT's overhead on non-TAP applications in the always-on monitoring phase, we use AUDIT with and without its TAP optimizations (§4). We report maximum throughput and average query latency at maximum throughput over 5000 requests. We use a trigger to fire when latency is 2× the average latency (over 1 minute) and to log method parameters and return values.

Figure 5 shows the results for Massive, with a reasonably complex request that comes with Massive, involving 55 method invocations. Without TAP-optimizations, AUDIT always-on monitoring increases latency by 1.1% and reduces throughput by 2.8%. The overhead is smaller for simpler requests (with fewer methods) and is acceptable in many non-TAP applications in production. The overhead is significantly smaller with TAP-optimizations: latency and throughput are affected only by $< 0.6\%$, showing effectiveness of the optimizations.

Overhead of the trigger phase is slightly larger ($+2.5\%$ latency and -2.5% throughput). Logging all methods decreases throughput by 8% and increases latency by 7%. The high overhead is mainly due to serializing method parameters and return values of 55 dynamically invoked methods. Logging at only five top-blamed methods, however, has much smaller overhead (-0.45% latency and -1.8% throughput). This again highlights the value of logging only for a short period of time, and only a small number of top methods.

For Social, we used a complex request involving 795 method invocations. With TAP optimizations, latency and throughput overheads of always-on phase is within the measurement noise ($< 0.1\%$). Without the optimizations, the overhead of always-on is 4.3%, due to instrumentation overhead of 795 method invocations. Trigger phase incurs 4.1% overhead. Logging, again is the most expensive phase, causing 5.3% overhead.

7 Related work

In previous sections, we discussed prior work related to AUDIT's triggers (§3.1), request tracing (§4), dynamic instrumentation (§3.4), and blame ranking (§3.3). We now discuss additional related work.

AUDIT triggers are in spirit similar to datacenter network-related triggers used in Trumpet [58], but are designed for logging cloud and web applications.

Collecting effective logs and reducing logging overhead have been an important topic of research. Errlog [2] proactively adds appropriate logging statements into source code and uses adaptive sampling to reduce runtime overhead. In contrast, AUDIT dynamically instruments unmodified application binary and uses triggers rather than sampling to decide when to log. *Log*^{2} [4] enables logging within an overhead budget. Unlike AUDIT, it uses static instrumentation, continuous logging, and decides only *whether* (not *what*) to log. Several recent works investigate what should be logged for effective troubleshooting [3, 13], and AUDIT incorporates their findings in its design. Several recent proposals enhance and analyze *existing* log messages for failure diagnosis [59, 60, 61, 62], and are orthogonal to AUDIT.

Pivot Tracing [8] is closely related, but complimentary to AUDIT. It gives users, at runtime, the ability to define arbitrary metrics and aggregate them using relational operators. Unlike AUDIT, Pivot Tracing requires users to explicitly specify tracepoints to instrument and to interactively enable and disable instrumentation. Techniques from Pivot Tracing could be used to further enhance AUDIT; e.g., if implemented, happen-before join could be used as a trigger condition and baggage could be used to trace related methods across machine boundaries.

AUDIT's techniques for identifying methods related to a misbehaving request is related to end-to-end causal tracing [1, 24, 25, 26, 27, 28]. Existing solutions use instrumentation and metadata propagation; in contrast, AUDIT can also leverage cheap system events. To keep overhead acceptable in production, prior works trace coarse-grained tracepoints [1, 24], or fine-grained but a small number of carefully chosen tracepoints (which requires deep application knowledge) [26], and/or a small sample of requests [1]. In contrast, AUDIT traces all requests at method granularity, along with forks and joins of their execution.

Adaptive bug isolation [63], like AUDIT, adapts instrumentation during runtime. However, AUDIT's adaptation can be triggered by a single request (rather than statistical analysis of many requests, as in many other statistical debugging techniques [10, 64]), can work at a much finer temporal granularity (logging only for a small window of time), and has much better selectivity of logging methods due to causal tracking.

8 Conclusions

We presented AUDIT, a system for troubleshooting transiently-recurring errors in cloud-based production systems through *blame-proportional logging*, a novel mechanism with which logging information generated by a method over a period of time is proportional to how often it is blamed for various misbehaviors. AUDIT lets a developer write declarative triggers, specifying what to log and on what misbehavior, without specifying where to collect the logs. We have implemented AUDIT and evaluated it with five mature open source and commercial applications, for which AUDIT identified previously unknown issues causing slow responses and application crashes. All the issues are reported to developers, who have acknowledged or fixed them.

Abstract

NanoLog is a nanosecond scale logging system that is 1-2 orders of magnitude faster than existing logging systems such as Log4j2, spdlog, Boost log or Event Tracing for Windows. The system achieves a throughput up to 80 million log messages per second for simple messages and has a typical log invocation overhead of 8 nanoseconds in microbenchmarks and 18 nanoseconds in applications, despite exposing a traditional printf-like API. NanoLog achieves this low latency and high throughput by shifting work out of the runtime hot path and into the compilation and post-execution phases of the application. More specifically, it slims down user log messages at compile-time by extracting static log components, outputs the log in a compacted, binary format at runtime, and utilizes an offline process to re-inflate the compacted logs. Additionally, log analytic applications can directly consume the compacted log and see a performance improvement of over 8x due to I/O savings. Overall, the lower cost of NanoLog allows developers to log more often, log in more detail, and use logging in low-latency production settings where traditional logging mechanisms are too expensive.

1 Introduction

Logging plays an important role in production software systems, and it is particularly important for large-scale distributed systems running in datacenters. Log messages record interesting events during the execution of a system, which serve several purposes. After a crash, logs are often the best available tool for debugging the root cause. In addition, logs can be analyzed to provide visibility into a system's behavior, including its load and performance, the effectiveness of its policies, and rates of recoverable errors. Logs also provide a valuable source of data about user behavior and preferences, which can be mined for business purposes. The more events that are recorded in a log, the more valuable it becomes.

Unfortunately, logging today is expensive. Just formatting a simple log message takes on the order of one microsecond in typical logging systems. Additionally, each log message typically occupies 50-100 bytes, so available I/O bandwidth also limits the rate at which log messages can be recorded. As a result, developers are often forced to make painful choices about which events to log; this impacts their ability to debug problems and understand system behavior.

Slow logging is such a problem today that software development organizations find themselves removing valuable log messages to maintain performance. According to our contacts at Google[7] and VMware[28], a considerable amount of time is spent in code reviews discussing whether to keep log messages or remove them for performance. Additionally, this process culls a lot of useful debugging information, resulting in many more person hours spent later debugging. Logging itself is expensive, but lacking proper logging is *very* expensive.

The problem is exacerbated by the current trend towards low-latency applications and micro-services. Systems such as Redis [34], FaRM [4], MICA[18] and RAMCloud [29] can process requests in as little as 1-2 microseconds; with today's logging systems, these systems cannot log events at the granularity of individual requests. This mismatch makes it difficult or impossible for companies to deploy low-latency services. One industry partner informed us that their company will not deploy low latency systems until there are logging systems fast enough to be used with them [7].

NanoLog is a new, open-source [47] logging system that is 1-2 orders of magnitude faster than existing systems such as Log4j2 [43], spdlog [38], glog [11], Boost Log [2], or Event Tracing for Windows [31]. NanoLog retains the convenient printf[33]-like API of existing logging systems, but it offers a throughput of around 80 million messages per second for simple log messages, with a caller latency of only 8 nanoseconds in microbenchmarks. For reference, Log4j2 only achieves a throughput of 1.5 million messages per second with latencies in the hundreds of nanoseconds for the same microbenchmark.

NanoLog achieves this performance by shifting work out of the runtime hot path and into the compilation and post-execution phases of the application:

- It rewrites logging statements at compile time to remove static information and defers expensive message formatting until the post-execution phase. This dramatically reduces the computation and I/O bandwidth requirements at runtime.
- It compiles specialized code for each log message to handle its dynamic arguments efficiently. This avoids runtime parsing of log messages and encoding argument types.
- It uses a lightweight compaction scheme and outputs the log out-of-order to save I/O and processing at runtime.
- It uses a postprocessor to combine compacted log data with extracted static information to generate

```
NANO_LOG(NOTICE, "Creating table ’%s’ with id %d", name, tableId);

2017/3/18 21:35:16.554575617 TableManager.cc:1031 NOTICE[4]: Creating table ’orders’ with id 11
```

Figure 1: A typical logging statement (top) and the resulting output in the log file (bottom). “NOTICE” is a log severity level and “[4]” is a thread identifier.

human-readable logs. In addition, aggregation and analytics can be performed directly on the compacted log, which improves throughput by over 8x.

2 Background and Motivation

Logging systems allow developers to generate a human-readable trace of an application during its execution. Most logging systems provide facilities similar to those in Figure 1. The developer annotates system code with logging statements. Each logging statement uses a printf-like interface[33] to specify a static string indicating what just happened and also some runtime data associated with the event. The logging system then adds supplemental information such as the time when the event occurred, the source code file and line number of the logging statement, a severity level, and the identifier of the logging thread.

The simplest implementation of logging is to output each log message synchronously, inline with the execution of the application. This approach has relatively low performance, for two reasons. First, formatting a log message typically takes 0.5-1 µs (1000-2000 cycles). In a low latency server, this could represent a significant fraction of the total service time for a request. Second, the I/O is expensive. Log messages are typically 50-100 bytes long, so a flash drive with 250 Mbytes/sec bandwidth can only absorb a few million messages per second. In addition, the application will occasionally have to make kernel calls to flush the log buffer, which will introduce additional delays.

The most common solution to these problems is to move the expensive operations to a separate thread. For example, I/O can be performed in a background thread: the main application thread writes log messages to a buffer in memory, and the background thread makes the kernel calls to write the buffer to a file. This allows I/O to happen in parallel with application execution. Some systems, such as TimeTrace in PerfUtils [32], also offload the formatting to the background thread by packaging all the arguments into an executable lambda, which is evaluated by the background thread to format the message.

Unfortunately, moving operations to a background thread has limited benefit because the operations must still be carried out while the application is running. If log messages are generated at a rate faster than the background thread can process them (either because of I/O or CPU limitations), then either the application must eventually block, or it must discard log messages. Neither of these options is attractive. Blocking is particularly unappealing for low-latency systems because it can result in long tail latencies or even, in some situations, the appearance that a server has crashed.

In general, developers must ensure that an application doesn’t generate log messages faster than they can be processed. One approach is to filter log messages according to their severity level; the threshold might be higher in a production environment than when testing. Another possible approach is to sample log messages at random, but this may cause key messages (such as those identifying a crash) to be lost. The final (but not uncommon) recourse is a social process whereby developers determine which log messages are most important and remove the less critical ones to improve performance. Unfortunately, all of these approaches compromise visibility to get around the limitations of the logging system.

The design of NanoLog grew out of two observations about logging. The first observation is that fully-formatted human-readable messages don’t necessarily need to be produced inside the application. Instead, the application could log the raw components of each message and the human-readable messages could be generated later, if/when a human needs them. Many logs are never read by humans, in which case the message formatting step could be skipped. When logs are read, only a small fraction of the messages are typically examined, such as those around the time of a crash, so only a small fraction of logs needs to be formatted. And finally, many logs are processed by analytics engines. In this case, it is much faster to process the raw data than a human-readable version of the log.

The second observation is that log messages are fairly redundant and most of their content is static. For example, in the log message in Figure 1, the only dynamic parts of the message are the time, the thread identifier, and the values of the `name` and `tableId` variables. All of the other information is known at compile-time and is repeated in every invocation of that logging statement. It should be possible to catalog all the static information at compile-time and output it just once for the postprocessor. The postprocessor can reincorporate the static information when it formats the human-readable messages. This approach dramatically reduces the amount of information that the application must log, thereby allowing the application to log messages at a much higher rate.

The remainder of this paper describes how NanoLog capitalizes on these observations to improve logging performance by 1-2 orders of magnitude.

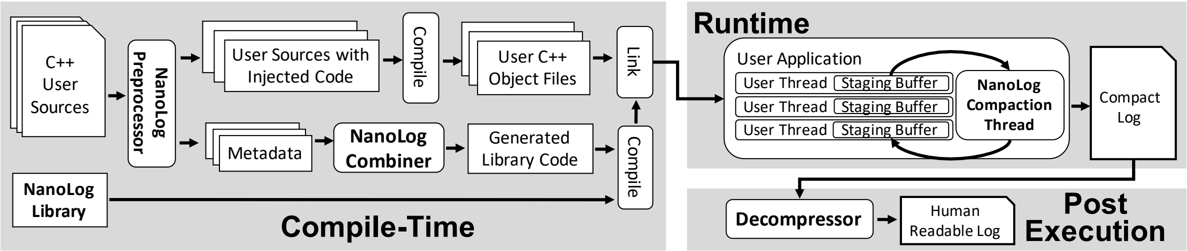

Figure 2: Overview of the NanoLog system. At compile time, the user sources are passed through the NanoLog preprocessor, which injects optimized logging code into the application and generates a metadata file for each source file. The modified user code is then compiled to produce C++ object files. The metadata files are aggregated by the NanoLog combiner to build a portion of the NanoLog Library. The NanoLog library is then compiled and linked with the user object files to create an application executable and a decompressor application. At runtime, the user application threads interact with the NanoLog staging buffers and background compaction thread to produce a compact log. At post execution, the compact log is passed into the decompressor to generate a final, human-readable log file.

3 Overview

NanoLog's low latency comes from performing work at compile-time to extract static components from log messages and deferring formating to an off-line process. As a result, the NanoLog system decomposes into three components as shown in Figure 2:

Preprocessor/Combiner: extracts and catalogs static components from log messages at compile-time, replaces original logging statements with optimized code, generates a unique compaction function for each log message, and generates a function to output the dictionary of static information.

Runtime Library: provides the infrastructure to buffer log messages from multiple logging threads and outputs the log in a compact, binary format using the generated compaction and dictionary functions.

Decompressor: recombines the compact, binary log file with the static information in the dictionary to either inflate the logs to a human-readable format or run analytics over the log contents.

Users of NanoLog interact with the system in the following fashion. First, they embed `NANO_LOG()` function calls in their C++ applications where they'd like log messages. The function has a signature similar to printf [17, 33] and supports all the features of printf with the exception of the "`%n`" specifier, which requires dynamic computation. Next, users integrate into their GNUmakefiles [40] a macro provided by NanoLog that serves as a drop-in replacement for a compiler invocation, such as g++. This macro will invoke the NanoLog preprocessor and combiner on the user's behalf and generate two executables: the user application linked against the NanoLog library, and a decompressor executable to inflate/run analytics over the compact log files. As the application runs, a compacted log is generated. Finally, the NanoLog decompressor can be invoked to read the compacted log and produce a human-readable log.

4 Detailed Design

We implemented the NanoLog system for C++ applications and this section describes the design in detail.

4.1 Preprocessor

The NanoLog preprocessor interposes in the compilation process of the user application (Figure 2). It processes the user source files and generates a *metadata file* and a modified source file for each user source file. The modified source files are then compiled into object files. Before the final link step for the application, the NanoLog combiner reads all the metadata files and generates an additional C++ source file that is compiled into the NanoLog Runtime Library. This library is then linked into the modified user application.

In order to improve the performance of logging, the NanoLog preprocessor analyzes the `NANO_LOG()` statements in the source code and replaces them with faster code. The replacement code provides three benefits. First, it reduces I/O bandwidth by logging only information that cannot be known until runtime. Second, NanoLog logs information in a compacted form. Third, the replacement code executes much more quickly than the original code. For example, it need not combine the dynamic data with the format string, or convert binary values to strings; data is logged in a binary format. The preprocessor also extracts type and order information from the format string (e.g., a `"%d %f"` format string indicates that the log function should encode an integer followed by a float). This allows the preprocessor to generate more efficient code that accepts and processes exactly the arguments provided to the log message. Type safety is ensured by leveraging the GNU `format` attribute compiler extension [10].

The NanoLog preprocessor generates two functions for each `NANO_LOG()` statement. The first function, `record()`, is invoked in lieu of the original `NANO_LOG()` statement. It records the dynamic information associated with the log message into an in-

```
inline void record(buffer, name, tableId) {
  // Unique identifier for this log statement;
  // the actual value is computed by the combiner.
  extern const int _logId_TableManager_cc_line1031;

  buffer.push<int>(_logId_TableManager_cc_line1031);
  buffer.pushTime();
  buffer.pushString(name);
  buffer.push<int>(tableId);
}

inline void compact(buffer, char *out) {
  pack<int>(buffer, out); // logId
  packTime(buffer, out); // time
  packString(buffer, out); // string name
  pack<int>(buffer, out); // tableId
}
```

Figure 3: Sample code generated by the NanoLog preprocessor and combiner for the log message in Figure 1. The `record()` function stores the dynamic log data to a buffer and `compact()` compacts the buffer's contents to an output character array.

memory buffer. The second function, `compact()`, is invoked by the NanoLog background compaction thread to compact the recorded data for more efficient I/O.

Figure 3 shows slightly simplified versions of the functions generated for the `NANO_LOG()` statement in Figure 1. The `record()` function performs the absolute minimum amount of work needed to save the log statement's dynamic data in a buffer. The invocation time is read using Intel's RDTSC instruction, which utilizes the CPU's fine grain Time Stamp Counter [30]. The only static information it records is a unique identifier for the `NANO_LOG()` statement, which is used by the NanoLog runtime background thread to invoke the appropriate `compact()` function and the decompressor to retrieve the statement's static information. The types of `name` and `tableId` were determined at compile-time by the preprocessor by analyzing the "`%s`" and "`%d`" specifiers in the format string, so `record()` can invoke type-specific methods to record them.

The purpose of the `compact()` function is to reduce the number of bytes occupied by the logged data, in order to save I/O bandwidth. The preprocessor has already determined the type of each item of data, so `compact()` simply invokes a type-specific compaction method for each value. Section 4.2.2 discusses the kinds of compaction that NanoLog performs and the trade-off between compute time and compaction efficiency.

In addition to the `record()` and `compact()` functions, the preprocessor creates a dictionary entry containing all of the static information for the log statement. This includes the file name and line number of the `NANO_LOG()` statement, the severity level and format string for the log message, the types of all the dynamic values that will be logged, and the name of a variable that will hold the unique identifier for this statement.

After generating this information, the preprocessor replaces the original `NANO_LOG()` invocation in the user source with an invocation to the `record()` function. It also stores the `compact()` function and the dictionary information in a metadata file specific to the original source file.

The NanoLog combiner executes after the preprocessor has processed all the user files (Figure 2); it reads all of the metadata files created by the preprocessor and generates additional code that will become part of the NanoLog runtime library. First, the combiner assigns unique identifier values for log statements. It generates code that defines and initializes one variable to hold the identifier for each log statement (the name of the variable was specified by the preprocessor in the metatadata file). Deferring identifier assignment to the combiner allows for a tight and contiguous packing of values while allowing multiple instances of the preprocessor to process client sources in parallel without synchronization. Second, the combiner places all of the `compact()` functions from the metadata files into a function array for the NanoLog runtime to use. Third, the combiner collects the dictionary information for all of the log statements and generates code that will run during application startup and write the dictionary into the log.

4.2 NanoLog Runtime

The NanoLog runtime is a statically linked library that runs as part of the user application and decouples the low-latency application threads executing the `record()` function from high latency operations like disk I/O. It achieves this by offering low-latency staging buffers to store the results of `record()` and a background compaction thread to compress the buffers' contents and issue disk I/O.

4.2.1 Low Latency Staging Buffers

Staging buffers store the result of `record()`, which is executed by the application logging threads, and make the data available to the background compaction thread. Staging buffers have a crucial impact on performance as they are the primary interface between the logging and background threads. Thus, they must be as low latency as possible and avoid thread interactions, which can result in lock contention and cache coherency overheads.

Locking is avoided in the staging buffers by allocating a separate staging buffer per logging thread and implementing the buffers as single producer, single consumer circular queues [24]. The allocation scheme allows multiple logging threads to store data into the staging buffers without synchronization between them and the implementation allows the logging thread and background thread to operate in parallel without locking the entire structure. This design also provides a throughput benefit as the source and drain operations on a buffer can be overlapped in time.

However, even with a lockless design, the threads' accesses to shared data can still cause cache coherency delays in the CPU. More concretely, the circular queue implementation has to maintain a head position for where the log data starts and a tail position for where the data ends. The background thread modifies the head position to consume data and the logging thread modifies the tail position to add data. However, for either thread to query how much space it can use, it needs to access both variables, resulting in expensive cache coherency traffic.

NanoLog reduces cache coherency traffic in the staging buffers by performing multiple inserts or removes for each cache miss. For example, after the logging thread reads the head pointer, which probably results in a cache coherency miss since its modified by the background thread, it saves a copy in a local variable and uses the copy until all available space has been consumed. Only then does it read the head pointer again. The compaction thread caches the tail pointer in a similar fashion, so it can process all available log messages before incurring another cache miss on the tail pointer. This mechanism is safe because there is only a single reader and a single writer for each staging buffer.

Finally, the logging and background threads store their private variables on separate cachelines to avoid false sharing [1].

4.2.2 High Throughput Background Thread

To prevent the buffers from running out of space and blocking, the background thread must consume the log messages placed in the staging staging buffer as fast as possible. It achieves this by deferring expensive log processing to the post-execution decompressor application and compacting the log messages to save I/O.

The NanoLog background thread defers log formatting and chronology sorting to the post-execution application to reduce log processing latency. For comparison, consider a traditional logging system; it outputs the log messages in a human-readable format and in chronological order. The runtime formatting incurs computation costs and bloats the log message. And maintaining chronology means the background thread must either serialize all logging or sort the log messages from concurrent logging threads at runtime. Both of these operations are expensive, so the background thread performs neither of these tasks. The NanoLog background thread simply iterates through the staging buffers in round-robin fashion and for each buffer, processes the buffer's entire contents and outputs the results to disk. The processing is also non-quiescent, meaning a logging thread can record new log messages while the background thread is processing its staging buffer's contents.

Additionally, the background thread needs to perform some sort of compression on the log messages to reduce I/O latency. However, compression only makes sense if it reduces the overall end-to-end latency. In our measurements, we found that while existing compression schemes like the LZ77 algorithm [49] used by gzip [9] were very effective at reducing file size, their computation times were too high; it was often faster to output the raw log messages than to perform any sort of compression. Thus, we developed our own lightweight compression mechanism for use in the `compact()` function.

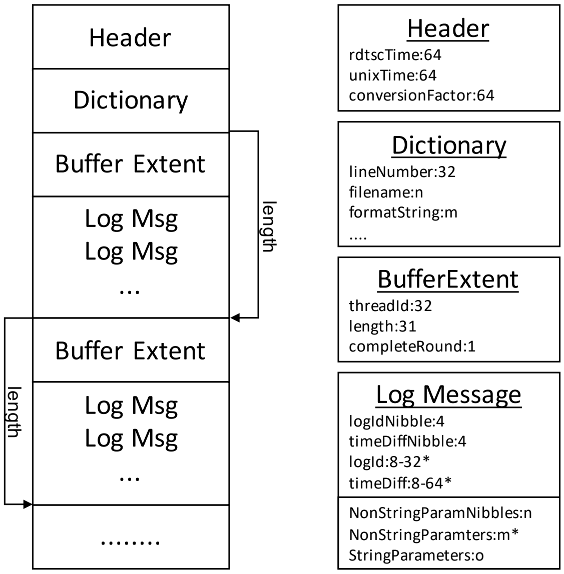

Figure 4: Layout of a compacted log file produced by the NanoLog runtime at a high level (left) and at the component level (right). As indicated by the diagram on the left, the NanoLog output file always starts with a Header and a Dictionary. The rest of the file consists of Buffer Extents. Each Buffer Extent contains log messages. On the right, the smaller text indicates field names and the digits after the colon indicate how many bits are required to represent the field. An asterisk (*) represents integer values that have been compacted and thus have a variable byte length. The lower box of "Log Message" indicates fields that are variable length (and sometimes omitted) depending on the log message's arguments.

NanoLog attempts to compact the integer types by finding the fewest number of bytes needed to represent that integer. The assumptions here are that integers are the most commonly logged type, and most integers are fairly small and do not use all the bits specified by its type. For example, a 4 byte integer of value 200 can be represented with 1 byte, so we encode it as such. To keep track of the number of bytes used for the integer, we add a *nibble* (4-bits) of metadata. Three bits of the nibble inform the algorithm how many bytes are used to encode the integer and the last bit is used to indicate a negation. The negation is useful for when small negative numbers are encoded. For example a -1 can be represented in 1 byte without ambiguity if the negation bit was set. A limitation of this scheme is that an extra half byte (nibble) is wasted in cases where the integer cannot be compacted.

Applying these techniques, the background thread produces a log file that resembles Figure 4. The first component is a header which maps the machine's Intel Time Stamp Counter [30] (TSC) value to a wall time and the conversion factor between the two. This allows the log messages to contain raw invocation TSC values and avoids wall time conversion at runtime. The header also includes the dictionary containing static information for the log messages. Following this structure are *buffer extents* which represent contiguous staging buffers that have been output at runtime and contained within them are log messages. Each buffer extent records the runtime thread id and the size of the extent (with the log messages). This allows log messages to omit the thread id and inherit it from the extent, saving bytes.

The log messages themselves are variable sized due to compaction and the number of parameters needed for the message. However, all log messages will contain at least a compacted log identifier and a compacted log invocation time relative to the last log message. This means that a simple log message with no parameters can be as small as 3 bytes (2 nibbles and 1 byte each for the log identifier and time difference). If the log message contains additional parameters, they will be encoded after the time difference in the order of all nibbles, followed by all non-string parameters (compacted and uncompacted), followed by all string parameters. The ordering of the nibbles and non-string parameters is determined by the preprocessor's generated code, but the nibbles are placed together to consolidate them. The strings are also null terminated so that we do not need to explicitly store a length for each.

4.3 Decompressor/Aggregator

The final component of the NanoLog system is the decompressor/aggregator, which takes as input the compacted log file generated by the runtime and either outputs a human-readable log file or runs aggregations over the compacted log messages. The decompressor reads the dictionary information from the log header, then it processes each of the log messages in turn. For each message, it uses the log id embedded in the file to find the corresponding dictionary entry. It then decompresses the log data as indicated in the dictionary entry and combines that data with static information from the dictionary to generate a human-readable log message. If the decompressor is being used for aggregation, it skips the message formatting step and passes the decompressed log data, along with the dictionary information, to an aggregation function.

One challenge the NanoLog decompressor has to deal with is outputting the log messages in chronological order. Recall from earlier, the NanoLog runtime outputs the log messages in staging buffer chunks called buffer extents. Each logging thread uses its own staging buffer, so log messages are ordered chronologically within an extent, but the extents for different threads can overlap in time. The decompressor must collate log entries from different extents in order to output a properly ordered log. The round-robin approach used by the compaction thread means that extents in the log are roughly ordered by time. Thus, the decompressor can process the log file sequentially. To perform the merge correctly, it must buffer two sequential extents for each logging thread at a time.

Aside from the reordering, one of the most interesting aspects of this component is the promise it holds for faster analytics. Most analytics engines have to gather the human-readable logs, parse the log messages into a binary format, and then compute on the data. Almost all the time is spent reading and parsing the log. The NanoLog aggregator speeds this up in two ways. First, the intermediate log file is extremely compact compared to its human-readable format (typically over an order of magnitude) which saves on bandwidth to read the logs. Second, the intermediate log file already stores the dynamic portions of the log in a binary format. This means that the analytics engine does not need to perform expensive string parsing. These two features mean that the aggregator component will run faster than a traditional analytics engine operating on human-readable logs.

4.4 Alternate Implementation: C++17 NanoLog

While the techniques shown in the previous section are generalizable to any programming language that exposes its source, some languages such as C++17 offer strong compile-time computation features that can be leveraged to build NanoLog without an additional preprocessor. In this section, we briefly present such an implementation for C++17. The full source for this implementation is available in our GitHub repository[47], so we will only highlight the key features here.

The primary tasks that the NanoLog preprocessor performs are (a) generating optimized functions to *record* and *compact* arguments based on types, (b) assigning unique log identifiers to each `NANO_LOG()` invocation site and (c) generating a dictionary of static log information for the postprocessor.

For the first task, we can leverage inlined variadic function templates in C++ to build optimized functions to *record* and *compact* arguments based on their types. C++11 introduced functionality to build generic functions that would specialize on the types of the arguments passed in. One variation, called "variadic templates", allows one to build functions that can accept an unbounded number of arguments and process them recursively based on type. Using these features, we can express meta `record()` and `compact()` functions which accept any number of arguments and the C++ compiler will automatically select the correct function to invoke for each argument based on type.

One problem with this mechanism is that an argument of type "`char*`" can correspond to either a "`%s`" speci-

CPU	Xeon X3470 (4x2.93 GHz cores)

OS for ETW	Windows 10 Pro 1709, Build 16299.192

Table 1: The server configuration used for benchmarking.

fier (string) or a "%p" specifier (pointer), which are handled differently. To address this issue, we leverage constant expression functions in C++17 to analyze the static format string at compile-time and build a constant expression structure that can be checked in `record()` to selectively save a pointer or string. This mechanism makes it unnecessary for NanoLog to perform the expensive format string parsing at runtime and reduces the runtime cost to a single if-check.

The second task is assignment of unique identifiers. C++17 NanoLog must discover all the `NANO_LOG()` invocation sites dynamically and associate a unique identifier with each. To do this, we leverage scoped static variables in C++; `NANO_LOG()` is defined as a macro that expands to a new scope with a static identifier variable initialized to indicate that no identifier has been assigned yet. This variable is passed by reference to the `record()` function, which checks its value and assigns a unique identifier during the first call. Future calls for this invocation site pay only for an if-check to confirm that the identifier has been assigned. The scoping of the identifier keeps it private to the invocation site and the static keyword ensures that the value persists across all invocations for the lifetime of the application.

The third task is to generate the dictionary required by the postprocessor and write it to the log. The dictionary cannot be included in the log header, since the NanoLog runtime has no knowledge of a log statement until it executes for the first time. Thus, C++17 NanoLog outputs dictionary information to the log in an incremental fashion. Whenever the runtime assigns a new unique identifier, it also collects the dictionary information for that log statement. This information is passed to the compaction thread and output in the header of the next Buffer Extent that contains the first instance of this log message. This scheme ensures that the decompressor encounters the dictionary information for a log statement before it encounters any data records for that log statement.

The benefit of this C++17 implementation is that it is easier to deploy (users no longer have to integrate the NanoLog preprocessor into their build chain), but the downsides are that it is language specific and performs slightly more work at runtime.

5 Evaluation

We implemented the NanoLog system for C++ applications. The NanoLog preprocessor and combiner comprise of 1319 lines of Python code and the NanoLog runtime library consists of 3657 lines of C++ code.

System Name	Static Chars	Integers	Floats	Strings	Others	Logs
Memcached	56.04	0.49	0.00	0.23	0.04	378
httpd	49.38	0.29	0.01	0.75	0.03	3711
linux	35.52	0.98	0.00	0.57	0.10	135119
Spark	43.32	n/a	n/a	n/a	n/a	2717
RAMCloud	46.65	1.08	0.07	0.47	0.02	1167

Table 2: Shows the average number of static characters (Static Chars) and dynamic variables in formatted log statements for five open source systems. These numbers were obtained by applying a set of heuristics to identify log statements in the source files and analyzing the embedded format strings; the numbers do not necessarily reflect runtime usage and may not include every log invocation. The "Logs" column counts the total number of log messages found. The dynamic counts are omitted for Spark since their logging system does not use format specifiers, and thus argument types could not be easily extracted. The static characters column omits format specifiers and variable references (i.e. $variables in Spark), and represents the number of characters that would be trivially saved by using NanoLog.

We evaluated the NanoLog system to answer the following questions:

- How do NanoLog's log throughput and latency compare to other modern logging systems?
- What is the throughput of the decompressor?
- How efficient is it to query the compacted log file?
- How does NanoLog perform in a real system?
- What are NanoLog's throughput bottlenecks?
- How does NanoLog's compaction scheme compare to other compression algorithms?

All experiments were conducted on quad-core machines with SATA SSDs that had a measured throughput of about 250MB/s for large writes (Table 1).

5.1 System Comparison

To compare the performance of NanoLog with other systems, we ran microbenchmarks with six log messages (shown in Table 3) selected from an open-source datacenter storage system [29].

5.1.1 Test Setup

We chose to benchmark NanoLog against Log4j2 [43], spdlog [38], glog [11], Boost log [2], and Event Tracing for Windows (ETW) [31]. We chose Log4j2 for its popularity in industry; we configured it for low latency and high throughput by using asynchronous loggers and appenders and including the LMAX Disruptor library [20]. We chose spdlog because it was the first result in an Internet search for "Fast C++ Logger"; we configured spdlog with a buffer size of 8192 entries (or 832KB). We chose glog because it is used by Google and configured it to buffer up to 30 seconds of logs. We chose Boost logging because of the popularity of Boost libraries in the C++ community; we configured Boost to use asynchronous sinks. We chose ETW because of its similarity to NanoLog; when used with Windows Software

ID	Example Output
staticString	Starting backup replica garbage collector thread
stringConcat	Opened session with coordinator at basic+udp:host=192.168.1.140,port=12246
singleInteger	Backup storage speeds (min): 181 MB/s read
twoIntegers	buffer has consumed 1032024 bytes of extra storage, current allocation: 1016544 bytes
singleDouble	Using tombstone ratio balancer with ratio = 0.4
complexFormat	Initialized InfUdDriver buffers: 50000 receive buffers (97 MB), 50 transmit buffers (0 MB), took 26.2 ms

Table 3: Log messages used to generate Figure 5 and Table 4. The underlines indicate dynamic data generated at runtime. *staticString* is a completely static log message, *stringConcat* contains a large dynamic string, and other messages are a combination of integer and floating point types. Additionally, the logging systems were configured to output each message with the context "YY-MM-DD HH:MM:SS.ns Benchmark.cc:20 DEBUG[0]:" prepended to it.

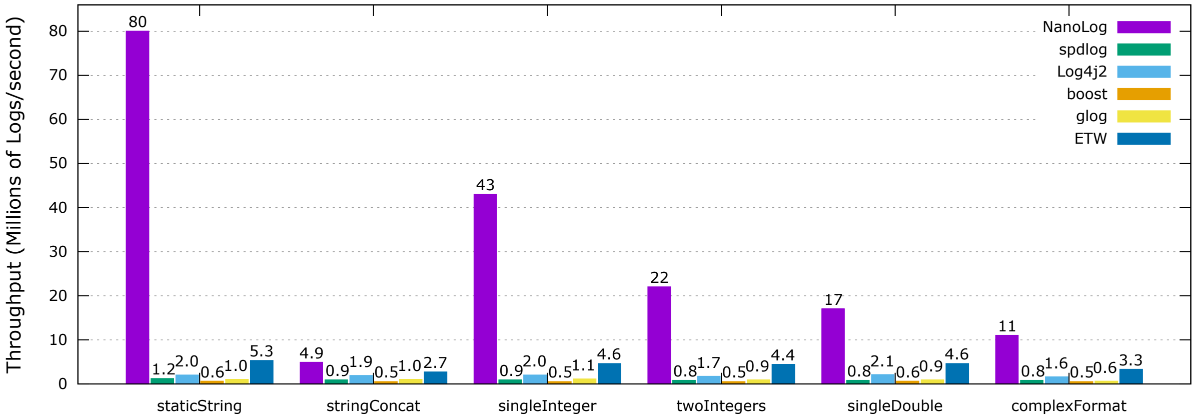

Figure 5: Shows the maximum throughput attained by various logging systems when logging a single message repeatedly. Log4j2, Boost, spdlog, and Google glog logged the message 1 million times; ETW and NanoLog logged the message 8 and 100 million times repectively to generate a log file of comparable size. The number of logging threads varied between 1-16 and the maximum throughput achieved is reported. All systems except Log4j2 include the time to flush the messages to disk in its throughput calculations (Log4j2 did not provide an API to flush the log without shutting down the logging service). The message labels on the x-axis are explained in Table 3.

Trace PreProcessor [23], the log statements are rewritten to record only variable binary data at runtime. We configured ETW with the default buffer size of 64 KB; increasing it to 1 MB did not improve its steady-state performance.

We configured each system to output similar metadata information with each log message; they prepend a date/-time, code location, log level, and thread id to each log message as shown in Figure 1. However, there are implementation differences in each system. In the time field, NanoLog and spdlog computed the fractional seconds with 9 digits of precision (nanoseconds) vs 6 for Boost-/glog and 3 for Log4j2 and ETW. In addition, Log4j2's code location information (ex. "Benchmark.cc:20") was manually encoded due to inefficiencies in its code location mechanism [45]. The other systems use the GNU C++ preprocessor macros "__LINE__" and "__FILE__" to encode the code location information.

To ensure the log messages we chose were representative of real world usage, we statically analyzed log statements from five open source systems[22, 42, 19, 44, 29]. Table 2 shows that log messages have around 45 characters of static content on average and that integers are the most common dynamic type. Strings are the second most common type, but upon closer inspection, most strings used could benefit from NanoLog's static extraction methods. They contain pretty print error messages, enumerations, object variables, and other static/formatted types. This static information could in theory be also extracted by NanoLog and replaced with an identifier. However, we leave this additional extraction of static content this to future work.

5.1.2 Throughput

Figure 5 shows the maximum throughput achieved by NanoLog, spdlog [38], Log4j2 [43], Boost [2], Google glog [11], and ETW [31]. NanoLog is faster than the other systems by 1.8x-133x. The largest performance gap between NanoLog and the other systems occurs with *staticString* and the smallest occurs with *stringConcat*.

NanoLog performs best when there is little dynamic information in the log message. This is reflected by *staticString*, a static message, in the throughput benchmark. Here, NanoLog only needs to output about 3-4 bytes per log message due to its compaction and static extraction techniques. Other systems require over an order of magnitude more bytes to represent the messages (41-90 bytes). Even ETW, which uses a preprocessor to strip messages, requires at least 41 bytes in the static string

ID	NanoLog				spdlog				Log4j2				glog				Boost				ETW			
Percentiles	*50*	*90*	*99*	*99.9*	*50*	*90*	*99*	*99.9*	*50*	*90*	*99*	*99.9*	*50*	*90*	*99*	*99.9*	*50*	*90*	*99*	*99.9*	*50*	*90*	*99*	*99.9*

singleDouble	8	9	29	34	607	637	685	1548	157	252	358	1494	2077	2135	4329	6995	2830	3479	3885	7176	187	193	248	720
complexFormat	8	8	28	33	1234	1261	1425	3360	146	233	346	1500	2570	2722	5167	8589	4175	4621	5189	9637	242	252	304	1070

Table 4: Unloaded tail latencies of NanoLog and other popular logging frameworks, measured by logging 100,000 log messages from Table 3 with a 600 nanosecond delay between log invocations to ensure that I/O is not a bottleneck. Each datum represents the 50th/90th/99th/99.9th percentile latencies measured in nanoseconds.

case. NanoLog excels with static messages, reaching a throughput of 80 million log messages per second.

NanoLog performs the worst when there's a large amount of dynamic information. This is reflected in *stringConcat*, which logs a large 39 byte dynamic string. NanoLog performs no compaction on string arguments and thus must log the entire string. This results in an output of 41-42 bytes per log message and drops throughput to about 4.9 million log messages per second.

Overall, NanoLog is faster than all other logging systems tested. This is primarily due to NanoLog consistently outputting fewer bytes per message and secondarily because NanoLog defers the formatting and sorting of log messages.

5.1.3 Latency

NanoLog lowers the logging thread's invocation latency by deferring the formatting of log messages. This effect can be seen in Table 4. NanoLog's invocation latency is 18-500x lower than other systems. In fact, NanoLog's 50/90/99th percentile latencies are all within tens of nanoseconds while the median latencies for the other systems *start* at hundreds of nanoseconds.

All of the other systems except ETW require the logging thread to either fully or partially materialize the human-readable log message before transferring control to the background thread, resulting in higher invocation latencies. NanoLog on the other hand, performs no formatting and simply pushes all arguments to the staging buffer. This means less computation and fewer bytes copied, resulting in a lower invocation latency.

Although ETW employs techniques similar to NanoLog, its latencies are much higher than those of NanoLog. We are unsure why ETW is slower than NanoLog, but one hint is that the even with the preprocessor, ETW log messages are larger than NanoLog (41 vs. 4 bytes for staticString). ETW emits extra log information such as process ids and does not use the efficient compaction mechanism of NanoLog to reduce its output.

Overall, NanoLog's unloaded invocation latency is extremely low.

5.2 Decompression

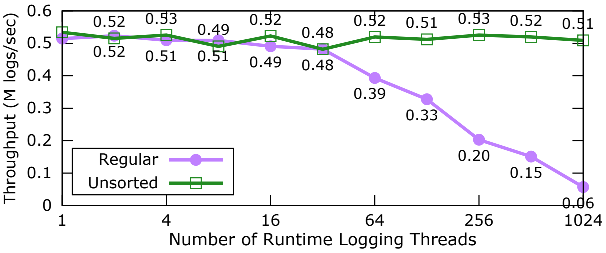

Figure 6: Impact on NanoLog's decompressor performance as the number of runtime logging threads increases. We decompressed a log file containing 2^{24} log messages (about 16M) in the format of "2017-04-06 02:03:25.000472519 Benchmark.cc:65 NOTICE[0]: Simple log message with 0 parameters". The compacted log file was 49MB and the resulting decompressed log output was 1.5GB. In the "Unsorted" measurements, the decompressor did not collate the log entries from different threads into a single chronological order.

Since the NanoLog runtime outputs the log in a binary format, it is also important to understand the performance implications of transforming it back into a human readable log format.

The decompressor currently uses a simple single-threaded implementation, which can decompress at a peak of about 0.5M log messages/sec (Figure 6). Traditional systems such as Log4j2 can achieve a higher throughput of over 2M log messages/second at runtime since they utilize all their logging threads for formatting. NanoLog's decompressor can be modified to use multiple threads to achieve higher throughput.

The throughput of the decompressor can drop if there were many runtime logging threads in the application. The reason is that the log is divided into different extents for each logging thread, and the decompressor must collate the log messages from multiple extents into a single chronological order. Figure 6 shows that decompressor can handle up to about 32 logging threads with no impact on its throughput, but throughput drops with more than 32 logging threads. This is because the decompressor uses a simple collation algorithm that compares the times for the next message from each active buffer extent (one per logging thread) in order to pick the next message to print; thus the cost per message increases linearly with the number of logging threads. Performance could be improved by using a heap for collation.

Collation is only needed if order matters during decompression. For some applications, such as analytics,

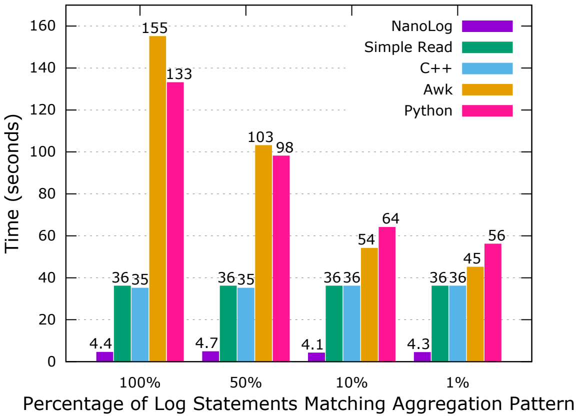

Figure 7: Execution time for a min/mean/max aggregation using various systems over 100 million log messages with a percentage of the log messages matching the target aggregation pattern "`Hello World # %d`" and the rest "`UnrelatedLog #%d`". The NanoLog system operated on a compacted file (∼747MB) and the remaining systems operated on the full, uncompressed log (∼7.6GB). The C++ application searched for the "`Hello World #`" prefix and utilized atoi() on the next word to parse the integer. The Awk and Python applications used a simple regular expression matching the prefix: "`.*Hello World # (\d+)`". "Simple Read" reads the entire log file and discards the contents. The file system cache was flushed before each run.

the order in which log messages are processed is unimportant. In these cases, collation can be skipped; Figure 6 shows that decompression throughput in this case is unaffected by the number of logging threads.

5.3 Aggregation Performance

NanoLog's compact, binary log output promises more efficient log aggregation/analytics than its full, uncompressed counterpart. To demonstrate this, we implemented a simple min/mean/max aggregation in four systems, NanoLog, C++, Awk, and Python. Conceptually, they all perform the same task; they search for the target log message "`Hello World #%d`" and perform a min/mean/max aggregation over the "`%d`" integer argument. The difference is that the latter three systems operate on the full, uncompressed version of the log while the NanoLog aggregator operates directly on the output from the NanoLog runtime.

Figure 7 shows the execution time for this aggregation over 100M log messages. NanoLog is nearly an order of magnitude faster than the other systems, taking on average 4.4 seconds to aggregate the compact log file vs. 35+ seconds for the other systems. The primary reason for NanoLog's low execution time is disk bandwidth. The compact log file only amounted to about 747MB vs. 7.6GB for the uncompressed log file. In other words, the aggregation was disk bandwidth limited and NanoLog used the least amount of disk IO. We verified this assumption with a simple C++ application that performs no aggregation and simply reads the file ("Simple Read" in the figure); its execution time lines up with the "C++" aggregator at around 36 seconds.

		No Logs	NanoLog	spdlog	RAMCloud
Throughput (kop/s)	Read	994 (100%)	809 (81%)	122 (12%)	67 (7%)
	Write	140 (100%)	137 (98%)	59 (42%)	32 (23%)
Read Latency (μs)	50%	5.19 (1.00x)	5.33 (1.03x)	8.21 (1.58x)	15.55 (3.00x)
	90%	5.56 (1.00x)	5.53 (0.99x)	8.71 (1.57x)	16.66 (3.00x)
	99%	6.15 (1.00x)	6.15 (1.00x)	9.60 (1.56x)	17.82 (2.90x)
Write Latency (μs)	50%	15.85 (1.00x)	16.33 (1.03x)	24.88 (1.57x)	45.53 (2.87x)
	90%	16.50 (1.00x)	17.08 (1.04x)	26.42 (1.60x)	47.50 (2.88x)
	99%	22.87 (1.00x)	23.74 (1.04x)	33.05 (1.45x)	59.17 (2.59x)

Table 5: Shows the impact on RAMCloud [29] performance when more intensive instrumentation is enabled. The instrumentation adds about 11-33 log statements per read/write request with 1-3 integer log arguments each. "No Logs" represents the baseline with no logging enabled. "RAMCloud" uses the internal logger while "NanoLog" and "spdlog" supplant the internal logger with their own. The percentages next to Read-/Write Latency represent percentiles and all results were measured with RAMCloud's internal benchmarks with 16 clients used in the throughput measurements. Throughput benchmarks were run for 10 seconds and latency benchmarks measured 2M operations. Each configurations was run 15 times and the best case is presented.

We also varied how often the target log message "`Hello World #%d`" occurred in the log file to see if it affects aggregation time. The compiled systems (NanoLog and C++) have a near constant cost for aggregating the log file while the interpreted systems (Awk and Python) have processing costs correlated to how often the target message occurred. More specifically, the more frequent the target message, the longer the execution time for Awk and Python. We suspect the reason is because the regular expression systems used by Awk and Python can quickly disqualify non-matching strings, but perform more expensive parsing when a match occurs. However, we did not investigate further.

Overall, the compactness of the NanoLog binary log file allows for fast aggregation.

5.4 Integration Benchmark

We integrated NanoLog and spdlog into a well instrumented open-source key value store, RAMCloud[29], and evaluated the logging systems' impact on performance using existing RAMCloud benchmarks. In keeping with the goal of increasing visibility, we enabled verbose logging and changed existing performance sampling statements in RAMCloud (normally compiled out) to always-on log statements. This added an additional 11-33 log statements per read/write request in the system. With this heavily instrumented system, we could answer the following questions: (1) how much of an improvement does NanoLog provide over other state-of-the-art systems in this scenario, (2) how does NanoLog perform in a real system compared to microbenchmarks and (3) how much does NanoLog slowdown compilation and increase binary size?

Table 5 shows that, with NanoLog, the additional instrumentation introduces only a small performance penalty. Median read-write latencies increased only by about 3-4% relative to an uninstrumented system and write throughput decreased by 2%. Read throughput sees a larger degradation (about 19%); we believe this is because read throughput is bottlenecked by RAMCloud's dispatch thread [29], which performs most of the logging. In contrast, the other logging systems incur such a high performance penalty that this level of instrumentation would probably be impractical in production: latencies increase by 1.6-3x, write throughput drops by more than half, and read throughput is reduced to roughly a tenth of the uninstrumented system (8-14x). These results show that NanoLog supports a higher level of instrumentation than other logging systems.

Using this benchmark, we can also estimate NanoLog's invocation latency when integrated in a low-latency system. For RAMCloud's read operation, the critical path emits 8 log messages out of the 11 enabled. On average, each log message increased latency by (5.33-5.19)/8 = 17.5ns. For RAMCloud's write operation, the critical path emits 27 log messages, suggesting an average latency cost of 17.7ns. These numbers are higher than the median latency of 7-8ns reported by the microbenchmarks, but they are still reasonably fast.

Lastly, we compared the compilation time and binary size of RAMCloud with and without NanoLog. Without NanoLog, building RAMCloud takes 6 minutes and results in a binary with the size of 123 MB. With NanoLog, the build time increased by 25 seconds (+7%), and the size of the binary increased to 130 MB (+6%). The dictionary of static log information amounted to 229KB for 922 log statements (∼ 248B/message). The log message count differs from Table 2 because RAMCloud compiles out log messages depending on build parameters.

5.5 Throughput Bottlenecks

NanoLog's performance is limited by I/O bandwidth in two ways. First, the I/O bandwidth itself is a bottleneck. Second, the compaction that NanoLog performs in order to reduce the I/O cost can make NanoLog compute bound as I/O speeds improve. Figure 8 explores the limits of the system by removing these bottlenecks.

Compaction plays a large role in improving NanoLog's throughput, even for our relatively fast flash devices (250MB/s). The "Full System" as described in the paper achieves a throughput of nearly 77 million operations per second while the "No Compact" system only achieves about 13 million operations per second. This is due to the 5x difference in I/O size; the full system outputs 3-4 bytes per message while the no compaction system outputs about 16 bytes per message.

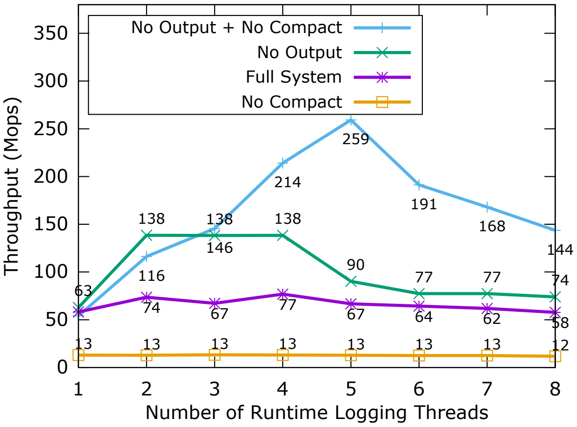

Figure 8: Runtime log message throughput acheived by the NanoLog system as the number of logging threads is increased. For each point, 2^{27} (about 134M) static messages were logged. The *Full System* is the NanoLog system as described in this paper, *No Output* pipes the log output to /dev/null, *No Compact* omits compaction in the NanoLog compression thread and directly outputs the staging buffers' contents, and *No Output + No Compact* is a combination of the the last two.

If we remove the I/O bottleneck altogether by redirecting the log file to /dev/null, NanoLog "No Output" achieves an even higher peak throughput of 138 million logs per second. At this point, the compaction becomes the bottleneck of the system. Removing both compaction and I/O allows the "No Output + No Compact" system to push upwards of 259 million operations per second.

Since the "Full System" throughput was achieved with a 250MB/s disk and the "No Output" has roughly twice the throughput, one might assume that compaction would become the bottleneck with I/O devices twice as fast as ours (500MB/s). However, that would be incorrect. To maintain the 138 million logs per second without compaction, one would need an I/O device capable of 2.24GB/s (138e6 logs/sec x 16B).

Lastly, we suspect we were unable to measure the maximum processing potential of the NanoLog compaction thread in "No Output + No Compact." Our machines only had 4 physical cores with 2 hyperthreads each; beyond 4-5, the logging threads start competing with the background thread for physical CPU resources, lowering throughput.

5.6 Compression Efficiency

NanoLog's compression mechanism is not very sophisticated in comparison to alternatives such as gzip [9] and Google snappy [37]. However, in this section we show that for logging applications, NanoLog's approach provides a better overall balance between compression efficiency and execution time.

Figure 9 compares NanoLog, gzip, and snappy using 93 test cases with varying argument types and lengths chosen to cover a range of log messages and show the

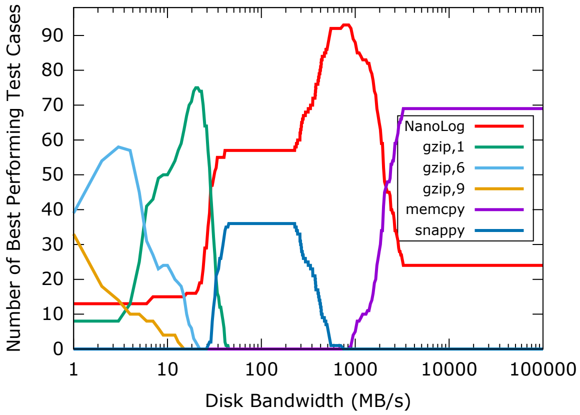

Figure 9: Shows the number of test cases (out of 93) for which a compression algorithm attained the highest throughput. Here, throughput is defined as the minimum of an algorithm's compression throughput and I/O throughput (determined by output size and bandwidth). The numbers after the "gzip" labels indicate compression level and "memcpy" represents "no compression". The input test cases were 64MB chunks of binary NanoLog logs with arguments varied in 4 dimensions: argument type (int/long/double/string), number of arguments, entropy, and value range. Strings had [10, 15, 20, 30, 45, 60, 100] characters and an entropy of "random", "zipfian" (θ=0.99), and "Top1000" (sentences generated using the top 1000 words from [26]). The numeric types had [1,2,3,4,6,10] arguments, an entropy of "random" or "sequential," and value ranges of "up to 2 bytes" and "at least half the container".

best and worst of each algorithm. For each test case and compression algorithm combination, we measured the total logging throughput at a given I/O bandwidth. Here, the throughput is determined by the lower of the compression throughput and I/O throughput (i.e. time to output the compressed data). Since the background thread overlaps the two operations, the slower operation is ultimately the bottleneck. We then counted the number of test cases where an algorithm produced highest throughput of all algorithms at a given I/O bandwidth and graphed the results in Figure 9.

From Figure 9 we see that aggressive compression only makes sense in low bandwidth situations; gzip,9 produces the best compression, but it uses so much CPU time that it only makes sense for very low bandwidth I/O devices. As I/O bandwidth increases, gzip's CPU time quickly becomes the bottleneck for throughput, and compression algorithms that don't compress as much but operate more quickly become more attractive.

NanoLog provides the highest logging throughput for most test cases in the bandwidth range for modern disks and flash drives (30–2200 MB/s). The cases where NanoLog is not the best are those involving strings and doubles, which NanoLog does not compact; snappy is better for these cases. Surprisingly, NanoLog is sometimes better than memcpy even for devices with extremely high I/O throughput. We suspect this is due to out-of-order execution[16], which can occasionally overlap NanoLog's compression with load/stores of the arguments; this makes NanoLog's compaction effectively free. Overall, NanoLog's compaction scheme is the most efficient given the capability of current I/O devices.

6 Related Work

Many frameworks and libraries have been created to increase visibility in software systems.

The system most similar to NanoLog is Event Tracing for Windows (ETW) [31] with the Windows Software Trace PreProcessor (WPP) [23], which was designed for logging inside the Windows kernel. This system was unbeknownst to us when we designed NanoLog, but WPP appears to use compilation techniques similar to NanoLog. Both use a preprocessor to rewrite log statements to record only binary data at runtime and both utilize a postprocessor to interpret logs. However, ETW with WPP does not appear to be as performant as NanoLog; in fact, it's on par with traditional logging systems with median latencies at 180ns and a throughput of 5.3Mop/s for static strings. Additionally, its postprocessor can only process messages at a rate of 10k/second while NanoLog performs at a rate of 500k/second.

There are five main differences between ETW with WPP and NanoLog: (1) ETW is a non-guaranteed logger (meaning it can drop log messages) whereas NanoLog is guaranteed. (2) ETW logs to kernel buffers and uses a separate kernel process to persist them vs. NanoLog's in-application solution. (3) The ETW postprocessor interprets a separate trace message format file to parse the logs whereas NanoLog uses dictionary information embedded in the log. (4) WPP appears to be targeted at Windows Driver Development (only available in WDK), whereas NanoLog is targeted at applications. Finally, (5) NanoLog is an open-source library [47] with public techniques that can ported to other platforms and languages while ETW is proprietary and locked to Windows only. There may be other differences (such as the use of compression) that we cannot ascertain from the documentation since ETW is closed source.

There are also general purpose, application-level loggers such as Log4j2 [43], spdlog [38], glog [11], and Boost log [2]. Like NanoLog, these systems enable applications to specify arbitrarily formatted log statements in code and provide the mechanism to persist the statements to disk. However these systems are slower than NanoLog; they materialize the human-readable log at runtime instead of deferring to post-execution (resulting in a larger log) and do not employ static analysis to generate low-latency, log specific code.

There are also implementations that attempt to provide ultra low-latency logging by restricting the data types or the number of arguments that can be logged [24, 32].

This technique reduces the amount of compute that must occur at runtime, lowering latency. However, NanoLog is able to reach the same level of performance without sacrificing flexibility by employing code generation.

Moving beyond a single machine, there are also distributed tracing tools such as Google Dapper [35], Twitter Zipkin [48], X-Trace [8], and Apache's HTrace [41]. These systems handle the additional complexity of tracking requests as they propagate across software boundaries, such as between machines or processes. In essence, these systems track causality by attaching unique request identifiers with log messages. However, these systems do not accelerate the actual runtime logging mechanism.

Once the logs are created, there are systems and machine learning services that aggregate them to provide analytics and insights [39, 3, 25, 27]. However, for compatibility, these systems typically aggregate full, human-readable logs to perform analytics. The NanoLog aggregator may be able to improve their performance by operating directly on compacted, binary logs, which saves I/O and processing time.

There are also systems that employ dynamic instrumentation [15] to gain visibility into applications at runtime such as Dtrace [14], Pivot Tracing [21], Fay [6], and Enhanced Berkley Packet Filters [13]. These systems eschew the practice of embedding static log statement at compile-time and allow for dynamic modification of the code. They allow for post-compilation insertion of instrumentation and faster iterative debugging, but the downside is that instrumentation must already be in place to enable post mortem debugging.

Lastly, it's worth mentioning that the techniques used by NanoLog and ETW are extremely similar to low-latency RPC/serialization libraries such as Thrift [36], gRPC [12], and Google Protocol Buffers [46]. These systems use a static message specification to name symbolic variables and types (not unlike NanoLog's printf format string) and generate application code to encode/decode the data into succinct I/O optimized formats (similiar to how NanoLog generates the record and compact functions). In summary, the goals and techniques used by NanoLog and RPC systems are similar in flavor, but are applied to different mediums (disk vs. network).

7 Limitations

One limitation of NanoLog is that it currently can only operate on static printf-like format strings. This means that dynamic format strings, C++ streams, and toString() methods would not benefit from NanoLog. While we don't have a performant solution for dynamic format strings, we believe that a stronger preprocessor/compiler extension may be able to extract patterns from C++ streams by looking at types and/or provide a snprintf-like function for toString() methods to generate a intermediate representation for NanoLog.

Additionally, while NanoLog is implemented in C++, we believe it can be extended to any language that exposes source code, since preprocessing and code replacement can be performed in almost any language. The only true limitation is that we would be unable to optimize any logs that are dynamically generated and evaluated (such as with JavaScript's `eval()` [5]).

NanoLog's preprocessor-based approach also creates some deployment issues, since it requires the preprocessor to be integrated in the development tool chain. C++17 NanoLog eliminates this issue using compile-time computation facilities, but not all languages can support this approach.

Lastly, NanoLog currently assumes that logs are stored in a local filesystem. However, it could easily be modified to store logs remotely (either to remotely replicated files or to a remote database). In this case, the throughput of NanoLog will be limited by the throughput of the network and/or remote storage mechanism. Most structured storage systems, such as databases or even main-memory stores, are slow enough that they would severely limit NanoLog performance.

8 Conclusion

NanoLog outperforms traditional logging systems by 1-2 orders of magnitude, both in terms of throughput and latency. It achieves this high performance by statically generating and injecting optimized, log-specific logic into the user application and deferring traditional runtime work, such as formatting and sorting of log messages, to an off-line process. This results in an optimized runtime that only needs to output a compact, binary log file, saving I/O and compute. Furthermore, this log file can be directly consumed by aggregation and log analytics applications, resulting in over an order of magnitude performance improvement due to I/O savings.

With traditional logging systems, developers often have to choose between application visibility or application performance. With the lower overhead of NanoLog, we hope developers will be able to log more often and log in more detail, making the next generation of applications more understandable.

9 Acknowledgements

We would like to thank our shepherd, Patrick Stuedi, and our anonymous reviewers for helping us improve this paper. Thanks to Collin Lee and Henry Qin for providing feedback on the design of NanoLog and Bob Felderman for refusing to use our low latency systems until we had developed better instrumentation. Lastly, thank you to the Industrial Affiliates of the Stanford Platform Lab for supporting this work. Seo Jin Park was additionally supported by Samsung Scholarship.

Model Governance: Reducing the Anarchy of Production ML

Abstract

As the influence of machine learning grows over decisions in businesses and human life, so grows the need for Model Governance. In this paper, we motivate the need for, define the problem of, and propose a solution for Model Governance in production ML. We show that through our approach one can meaningfully track and understand the who, where, what, when, and how an ML prediction came to be. To the best of our knowledge, this is the first work providing a comprehensive framework for production Model Governance, building upon previous work in developer-focused Model Management.

1 Introduction

Machine Learning (ML) and Deep Learning (DL) have recently made tremendous advances in algorithms, analytic engines, and hardware. However, production ML deployment is still nascent [17]. While production deployments are always challenging, ML generates unique difficulties [21, 7, 22]. We focus on the governance challenge: the management, diagnostic, compliance, and regulatory implications of production ML models. With recent demands for explainable/transparent ML [9, 3, 16, 5], the need to track provenance and faithfully reproduce ML predictions is even more serious. Given the strong data-dependent nature of ML/DL, even small changes in configurations can have unexpected consequences in predictions, making Governance critical to production ML.

Previous research has focused on *Model Management*: managing these models and enabling efficient reuse by developers [28, 25, 20]. Production deployment further complicates governance with i) complex topologies with retraining, ii) continuous inference programs that run in parallel with (re)training programs, iii) actions (such as model approvals) that need to be recorded for auditing, vi) model rollbacks that may occur in real time, and v) heterogeneous and distributed environments.

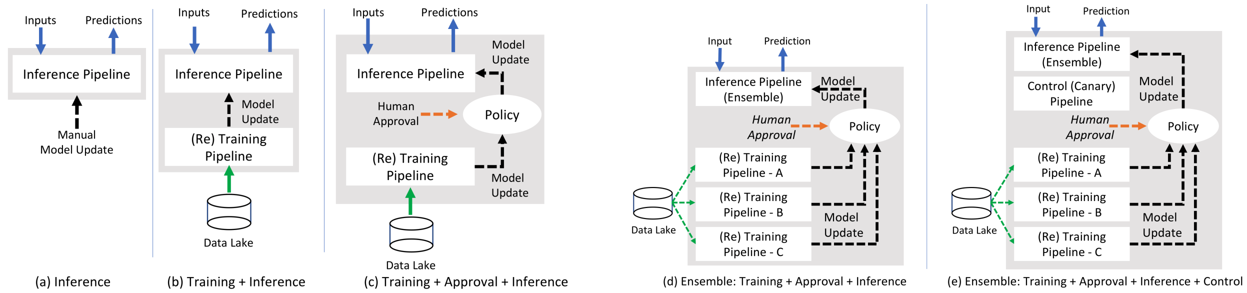
We define Production Model Governance as the ability to determine the creation path, subsequent usage, and consequent outcomes of an ML model, and the use of this information to accomplish a range of tasks including reproducing and diagnosing problems and enforcing compliance. In this paper, we propose and motivate a generic solution approach that can be adapted across different governance usage examples.

Our goal is to highlight the Model Governance problem and propose solutions. Our contributions are: i) we propose a definition for Production Model Governance and its necessary inclusive elements; ii) We propose a two-layer model for Governance. The lower layer contains each pipeline as a DAG and tracks everything (such as features, datasets, and code) similar to what is proposed by prior research. We add a second layer directed graph where each pipeline or policy invocation is a node and edges represent cross-pipeline, policy, and human action dependencies. We temporally track and correlate both of these levels to comprehensively cover Model Governance; iii) Using this model, we build a production Model Governance system that supports heterogeneous frameworks (currently, Spark, TensorFlow, Flink); iv) We propose a robust approach to a wide range of possible Governance applications via generic access to Governance metadata; and v) At the pipeline level, we expand upon prior research by illustrating a generic API-based instrumentation approach across analytic engines.

2 Motivation

Machine learning algorithms execute as ”pipelines”, which ingest data (via batch data lakes, stream brokers, etc.) and compute (feature engineering, model training, scoring, inference, etc.). Pipelines may run on engines (Spark, Flink, etc.) or as standalone programs.

To highlight the importance of Model Governance, we use an example medical application that leverages ML to recommend to a doctor which tests to run on a patient. The calling application sends user information to an ML prediction pipeline which returns a prediction. Figure 1 shows several examples of how this simple scenario can



(a) Inference (b) Training + Inference (c) Training + Approval + Inference (d) Ensemble: Training + Approval + Inference (e) Ensemble: Training + Approval + Inference + Control

Figure 1: **Evolution of ML Pipelines in production.** *(a) The prediction pipeline is executing in production and is using a model trained offline and uploaded. (b) A more dynamic scenario where the model itself is retrained on a schedule. (c) Yet another sophistication, where newly trained models undergo an approval process prior to production deployment. (d) Here an ensemble model is used for prediction (requiring each sub-model to be trained individually). Finally, (e) shows the scenario if a control pipeline (*canary*) is used in production to ensure that the primary prediction pipeline is behaving stably. The control pipeline could also be running a surrogate model to improve explainability.*

be put into production. While the basic function requires only one pipeline, once you add the need to improve accuracy via re-training, the need for human approvals, and state-of-the-art models, the complexity grows rapidly. We now illustrate sample Governance scenarios for the example in Figure 1(e).

Scenario 1: Say we needed to know why a certain patient was recommended a CT-Scan while another patient was not. For each recommendation, we would need to answer: Which model(s) were running in the ensemble? Which code was executing the models? When/How was each model trained (using which configurations and which features)? Which model provided the control pipeline and would its recommendation have differed? Which operator approved each of the models in the primary pipeline? Who approved the model in the control pipeline? Were any errors noted in this time frame? Can both predictions be reproduced in order to test for bias?

Scenario 2: Assume a data scientist wishes to leverage some of the models for a new production ML application. They would want to know under which circumstances the existing models were generated, as well as which datasets and features were used. These may also be required for production approval.

3 Model Governance

We define Production Model Governance as the ability to determine the creation path, subsequent usage, and consequent outcomes of an ML model, and the use of this information in various ways, as illustrated above. Given the wide range of usages, we believe any Model Governance solution should include:

Provenance/Lineage: For any ML prediction, the ability identify the exact sequence of events (datasets, trainings, code, pipelines, human approvals) that led to the event.

Reproducibility: The ability to replay the above sequence and replicate the prediction, thereby setting the context to investigate alternatives.

Audit and Compliance: The ability to evaluate all ML operations in an organization and determine compliance with regulations.

Leverage: The ability to reuse past ML work (such as algorithms, models, features) to determine whether the derived object is appropriate for the new usage.

Scale and Heterogeneity: The ability to work with many models, pipelines, and varied analytic engines and languages in a distributed setting such as Cloud/Edge.

Multiple Governance Metadata Usages: The ability to multi-purpose the metadata. For example, Data Scientists may analyze experiments or reuse models. Operators may diagnose issues, help address bias concerns, or ensure compliance to policies.

4 Approach and Design

Our solution must support simple to complex topologies, parallel pipelines, streaming and batch pipelines, pipelines changing state mid-run as new models arrive, policy actions and relationships between non-overlapping pipeline runs. For these we must provide: (i) Sufficient dependency information to infer provenance; (ii) Configuration including code and input parameters for reproducibility; (iii) A durable record of all metadata; (iv) Metadata from disjoint pipeline, possibly from different analytic engines and languages; (v) Metadata provenance, trends, and policy analysis and beyond.

4.1 The Intelligence Overlay Network

Core to our design is a two layer model we call the Intelligence Overlay Network (ION). An ION is a logical model that connects objects such as pipelines, policy execution modules, and messages between them. The first level of an ION is inspired by the traditional graph-based modeling of message passing parallel programs, where each node is a execution element and directed edges are messages between programs (allowing for cycles) [1]. In our case, execution nodes are ML pipelines or policy actions, and messages (such as ML models or events) are passed between them. At the second level of the ION, each execution node can itself be a DAG of components.

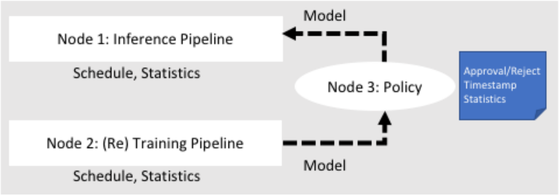


Figure 2: **ION for Flow in Figure 1(c)**

An ML pipeline is a single execution node in an ION. Figure 2 shows how Figure 1(c)'s pattern maps to an ION. The Inference and Training nodes are pipelines, the approval is a Policy node, and the edges show the path of a model. Figure 3 shows how the graph in Figure 2 is tracked by our system across time.

We apply this approach to ML workflows: (i) All execution elements are nodes. Nodes execute on a schedule (batch), continuously (streaming), or are event triggered; (ii) Nodes can pass messages and each message and send/receive events are recorded; (iii) Within each node, a DAG can be defined with its stages monitored.

The ION approach delivers important benefits. First, many ML pipelines map easily to the ION nodes as DAGs. Statistics from these pipelines are gathered as time-series variables that support Governance scenarios, for example, by providing required transparency to complex feature selection within a pipeline.

Second, the ION graph cleanly captures the dependencies and interactions between the pipelines, including their repeated executions over time, their connections to human actions, and their relationships to each other.

Finally, the combined statistics of both levels enables powerful usages, such as (a) tracking pipeline metrics like *confusion matrices* across multiple training runs, (b) comparing Models across multiple training runs, (c) tracking the approval actions of any human operator and cross-checking those against the performance of inference pipelines that ran the approved models.

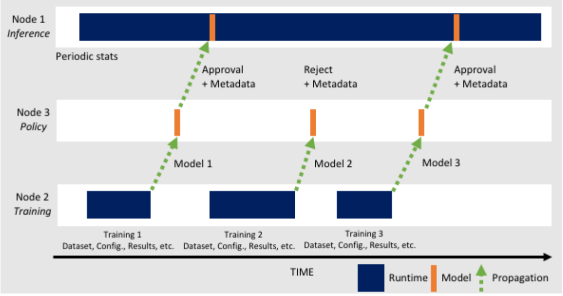

Figure 3: **ION Timeline**

4.2 System Design

We use an agent/server architecture. The agents run on each instance of an analytic engine (for example, a 15 node Spark cluster would have a single agent). Each agent communicates with its engine via standard interfaces. The server receives Governance metadata from the agents and interlinks the information via the ION. Currently our server also runs the policy execution code blocks. The server maintains a metadata database and manages garbage collection.

While recent Model Management approaches have been passive [28], we chose an active Agent based approach to enable disconnected operation (a common occurrence in Edge based ML environments [26]). During disconnections, the agent saves information locally and transmits it when connectivity is restored. If the agent is disconnected for long periods of time and runs out of local storage resources, some information can be lost. The agent/server architecture also enables scale and support of heterogeneous analytic engines.

This approach requires no changes to the analytic engines. We can also connect to existing analytic engines and can share analytic engines with other programs that we do not monitor. Any program that already works in these engines works in this environment. An Agent can also support custom standalone programs. The required changes to the programs themselves, for all the cases, are discussed in Section 4.3.

Figure 4 shows the database schema. The Level 1 schema includes tracked objects within a pipeline. The Level 2 schema captures the ION pattern as well as specific elements of each ION instance. Contextual information (such as which machines a particular pipeline ran on) is also captured. All objects are timestamped. All objects link to an ION and from the ION to each other.

4.3 Information Import and Export

ML pipelines exchange Governance metadata with our system in three ways (see Figure 5). First, a JSON-based ION definition which contains links to pipeline code is uploaded to our server. Second, each pipeline is instrumented via an API library to provide runtime metadata. Pipelines can export time series variables, digests, configuration, models, etc. Supported Model formats are PMML, SavedModel or opaque. Since our system also supports opaque model formats, other industry standard model formats (like ONNX) that we do not yet interpret can be immediately used. Third, for standard pipelines and models, we auto-extract metadata (like [25]).

The API library has import and export capabilities. On the export side, running pipelines send metadata to our Governance system. On the import side, running pipelines can query the database for stored metadata and perform additional analytics (see Section 4). The library implementation is engine-specific and to date we have implemented our API library for Spark, Flink, and Tensorflow and in Scala, Java, and Python.

Unlike prior approaches [25], we employ both a fully declarative approach (where the developer decides what to instrument) and automatic extraction wherever standardized pipelines and model formats allow. While train-

Figure 5: **Interaction of ML Pipelines with our Governance System**

ing pipelines can be quite structured (like SparkML), production inference pipelines have not standardized on any pipeline or code structure, running the gamut from auto-generated (via JPMML inference) to latency optimized hand-coded programs. This range of inference pipeline structures renders approaches that rely only on automatic extraction impractical for generalized production usage. With our approach, even custom written standalone programs can be instrumented for Governance.

4.4 Correlation and Causality

IONs are used to create a coherent time view of all metadata by (a) merging the views of multiple concurrent pipelines or policy blocks and (b) by relating different executions of the same logical node (e.g., re-training).

Causality: Within each ION node, we assume monotonically increasing timestamps. Across nodes within an ION, causality is established via messages.

Inter-Node Correlation: Across ION nodes, we assume correlation based on synchronized timestamps. Provenance is derived directly from messages and not from time correlation. Correlation is only used if a single sequence of statistics from the ION is retrieved for visualization. We have not used logical clocks to date because the governance usages we have worked with can be addressed sufficiently with the approaches above.

4.5 Governance Usages

Model Governance metadata has multiple uses. Any pipeline can use the API library to extract and compute additional analytics on governance metadata. For example, a pipeline can analyze all models approved by a user and correlate with training accuracy metrics or do additional model selection or model improvement. Compliance enforcement can be done via functions that periodically review recent metadata and confirm adherence to specific polices (such as human model approval or training accuracy thresholds for production deployed models). The metadata information can be used for advanced optimizations such as Meta-Learning. The applications of this approach are vast and to date we have only used our system to explore simple usages. Due to lack of space, we do not elaborate on this capability further in this paper but it is an area of our future work.

Total	N/A	5̃38K	452MB

Table 1: **Governance information captured from the three node ION after a day of execution.**

5 Evaluation

A governance solution should include lineage, reproducibility, audit, leverage, scale, heterogeneity, and multiple usages (see Section 3). We conduct a simple experiment to illustrate lineage, audit, scale, and heterogeneity in our solution. Additionally, we measure the overheads of Governance metadata gathering, including instrumentation and model propagation.

Our experiment consists of a three node ION: a Spark training pipeline, a Flink inference pipeline, and a policy module configured to always approve models (Figure 1c). The training pipeline is batch Logistic Regression with hyperparameter search in PySpark training a new model every hour. The selected model propagates via the Policy node to the Flink streaming inference in Scala. Governance metadata gathered includes input and prediction signatures (histograms), ML statistics, code, libraries, etc. ML statistics are any items reported via the API, including generic metrics such as accuracy, precision, recall, etc. and algorithm-specific metrics. Hyperparameter search configuration and result information is also reported via the API.

Figure 6 shows the dashboard view of a model generated in the ION. The governance dashboard provides the lineage information for every model generated (or uploaded), the training pipeline and the parameters used to generate the selected model, model approval information and the subsequent usage of the selected model in inference pipelines. Each hyperlink within the dashboard provides in-depth information on ION template, pipeline, configuration, statistics, etc. These in-depth views are not included due to lack of space.

Table 1 summarizes the list of objects that are captured in our system during the ION's execution. The overheads of our API instrumentation was less then 1% in this experiment and model propagation delay on average was around 3s for models of size 2KB. We were able to both replay and reproduce predictions using our system.

6 Related Work

The related work closest to ours includes [28, 25, 20]. We add several fundamental contributions over each. First we define and implement the ION model which links multiple pipelines and policy actions, including a full governance metadata and schema. Second, while both we and [25] integrate with multiple analytic engines, our approach adds a fully declarative instrumentation approach to the base auto-extraction approach, enabling our system to work with changing analytic engines and standalone ML programs. Finally, we have designed and built an import/export function where programs can access and compute additional analytics on Governance metadata, enabling a vast range of Governance usages which can themselves be tracked and managed. Additional model management approaches have been presented in [18]. Production ML challenges have been described in [21, 7, 22, 24, 4, 15, 8]. Meta-learning is discussed in [23, 13]. Overviews of analytic engines, libraries, and model serving systems are in [19, 10, 11, 12, 27, 2, 29, 6, 14].

7 Discussion and Future Work

Our system addresses most of the goals laid out in Section 3. We can track any prediction (or other event) to all related pipelines, datasets, execution configurations, code and human actions, and reproduce the functional steps. Via both tracking of input dataset pathnames and dataset signatures, we identify which data was used to generate which model. Using the API library, a user can write a pipeline to extract and analyze any information in the database to evaluate compliance or do audits. As another example, programs using our API can analyze data trends and correlate them with model outcomes.

For future work, we plan to explore the possibilities of meta-learning via Governance metdata and expand on how Governance relates to AI explainability. We want to couple the provenance data with explainable ML to help answer the question of not just how/where/what/when but also why ML decisions were made.

Fine-grained consistency for geo-replicated systems

Abstract

To deliver fast responses to users worldwide, major Internet providers rely on geo-replication to serve requests at data centers close to users. This deployment leads to a fundamental tension between improving system performance and reducing costly cross-site coordination for maintaining service properties such as state convergence and invariant preservation. Previous proposals for managing this trade-off resorted to coarse-grained operations labeling or coordination strategies that were oblivious to the frequency of operations. In this paper, we present a novel fine-grained consistency definition, Partial Order-Restrictions consistency (or short, PoR consistency), generalizing the trade-off between performance and the amount of coordination paid to restrict the ordering of certain operations. To offer efficient PoR consistent replication, we implement Olisipo, a coordination service assigning different coordination policies to various restrictions by taking into account the relative frequency of the confined operations. Our experimental results show that PoR consistency significantly outperforms a state-of-the-art solution (RedBlue consistency) on a 3-data center RUBiS benchmark.

1 Introduction

To cope with the demand for fast response times [36] from an increasingly large user base, many Internet service providers such as Google [8], Microsoft [9], Facebook [13] or Amazon [3] replicate data across multiple geographically dispersed data centers [38, 21, 20, 2]. However, geo-replication also leads to an inherent tension between achieving high performance and ensuring properties such as state convergence (i.e., all replicas eventually reach the same final state) and invariant preservation (i.e., the behavior of the system obeys its specification, which can be defined as a set of application-specific invariants to be preserved) [22, 40, 30, 17, 16].

Some proposals address this fundamental tension in geo-replication by weakening strong consistency to different extents: some researchers suggest to completely drop strong consistency and instead adopt some form of weaker consistency such as eventual consistency [22, 41, 19] or causal consistency [32]; other approaches allow multiple consistency levels to coexist in a single system [30, 17, 12, 4]. As an example of the latter group, our prior proposal on RedBlue consistency [30], allows some operations to execute under strong consistency (and therefore incur a high performance penalty) while other operations can execute under weaker consistency (namely causal consistency). The core of this solution is a labeling methodology for guiding the programmer to assign consistency levels to operations. The labeling process works as follows: operations that either do not commute w.r.t. all others or potentially violate invariants must be strongly consistent, while the remaining ones can be weakly consistent.

This binary classification methodology is effective for many applications, but it can also lead to unnecessary coordination in some cases. In particular, as we will later illustrate, there are cases where it is important to synchronize the execution of two specific operations, but those operations do not need to be synchronized with any other operation in the system (and this synchronization would happen across all strongly consistent operations in the previous scheme). Furthermore, while concepts such as *conflict relation* in generic broadcast [34] and *token* by Gotsman et al. [24] allow for a finer-grained coordination of operations, these either lack a precise method for identifying a set of restrictions to ensure safety or an implementation that achieves efficient coordination by adapting to the observed workload.

To overcome these limitations, in this paper, we propose a novel generic consistency definition, *Partial Order-Restrictions consistency* (or short, *PoR consistency)*, which takes a set of restrictions as input and forces these restrictions to be met in all partial orders. This creates the opportunity for defining many consistency guarantees within a single replication framework by expressing consistency levels in terms of visibility restrictions on pairs of operations. Weakening or strengthening the consistency semantics is achieved by imposing fewer or more restrictions.

Under PoR consistency, the key to making a geo-replicated deployment of a given application perform well is to identify a set of restrictions over pairs of its operations so that state convergence and invariant preservation are ensured if these restrictions are enforced throughout all executions of the system. However, this is challenging because missing required restrictions may cause applications to diverge state or violate invariants, while placing unnecessary restrictions will lead to a performance penalty due to the additional coordination. To this end, we design principles guiding programmers to identify the important restrictions while avoiding unnecessary ones.

Furthermore, from a protocol implementation perspective, given a set of restrictions over pairs of operations, there exist several coordination protocols that can be used for enforcing a given restriction, such as Paxos, distributed locking, or escrow techniques. However, depending on the frequency over time with which the system receives operations confined by a restriction, different coordination approaches lead to different performance trade-offs. Therefore, to minimize the runtime coordination overhead, we also propose an efficient coordination service called Olisipo that helps replicated services use the most efficient protocol by taking into account the system workload.

To demonstrate the power of PoR consistency, we extended RUBiS to incorporate a closing auction functionality, determined how to best run it under PoR consistency, replicated it with Olisipo, and compared its performance against a RedBlue consistent version. Our experimental results show that PoR consistency requires fewer restrictions and offers a significantly better performance than RedBlue consistency.

2 Preliminaries

2.1 System model

We assume a geo-distributed system with state fully replicated across k sites denoted by $site_0 \dots site_{k-1}$, where each site hosts a replica, and each replica runs as a deterministic state machine. In the rest of the document, the terms “site” and “replica” are interchangeable.

The system defines a set of operations $\mathscr{U}$ manipulating a set of reachable states $\mathscr{S}$. Each operation u is initially submitted by a user at one site which we call u’s *primary site* and denote $site(u)$. An operation is defined mathematically as a function that receives the current state of the system and returns another function corresponding to its side effects. We refer to the former function as the *generator* function, denoted by g_u; this generator function, when applied to a given state $S \in \mathscr{S}$, returns a *shadow* function or *shadow operation*, denoted $h_u(S)$.

Implementation-wise, the generator function will first execute in a *sandbox* against the current state of the replica at the primary site, without interference from other concurrent operations. In this phase, the execution only identifies what changes u would introduce to state S that is observed by u and will not commit these changes. At the end of executing g_u, the identified side-effect or shadow operation $h_u(S)$ will be sent and applied across all replicas including the primary site.

A desirable property is that all replicas that have applied the same set of shadow operations are in the same state, i.e., the underlying system offers **state convergence**. In addition, the system maintains a set of application-specific **invariants**. For instance, an online shopping service cannot sell more items than those available in stock. To capture this notion, we define the function $valid(S)$ to be *true* if state S satisfies all these invariants and *false* otherwise.

2.2 RedBlue consistency

Our prior proposal called RedBlue consistency [30] is based on a division of shadow operations into blue operations, whose order of execution can vary from site to site, and red operations that must execute in the same relative order at all sites. For guiding developers in making use of RedBlue consistency, this work identified that a condition for ensuring state convergence is that a shadow operation must be labeled red if it is not globally commutative. For ensuring that invariants are maintained, a sufficient condition was identified, stating that all shadow operations that may violate an invariant when being applied against a different state from the one they were generated must be labeled red. For the remaining shadow operations, which have passed the two condition checks, we can safely label them blue.

3 Partial Order-Restrictions consistency

3.1 Motivating example

We illustrate the limitations of coarse-grained labeling schemes like RedBlue consistency through an eBay-like auction service in Fig.1, where an operation `placeBid` (Fig.1(a)) creates a new bid for an item if the corresponding auction is still open, and an operation `closeAuction` (Fig.1(c)) closes an auction and declares a single winner. In this example, the application-specific invariant is that the winner must be associated with the highest bid across all accepted bids. The other two subfigures (Fig.1(b) and Fig.1(d)) depict the commutative shadow operations of these two operations.

When applying RedBlue consistency to replicate such an auction service, we note that the concurrent execution under weak consistency of a `placeBid` with a bid higher than all accepted bids and a `closeAuction` can lead to the violation of the application invariant. This happens because the generation of `closeAuction’` will ignore the highest bid created by the concurrent shadow `placeBid’`. Unfortunately, the only way to address this issue in RedBlue consistency is to label both shadow operations as strongly consistent, i.e., all shadow operations of either type will be totally ordered w.r.t each other, which will incur a high overhead in geo-distributed settings. Intuitively, however, there is no need to order pairs of `placeBid’` shadow operations, since a bid coming before or after another does not affect the winner selection. This highlights that a coarse-grained operation clas-

```
boolean placeBid(int itemId, int clientId, int bid){
 boolean result = false;
 beginTxn();
 if(open(itemId)){
   createShadowOp(placeBid', itemId, clientId, bid);
   result = true;
 }
 commitTxn();
 return result;
}
```

(**a**) Original placeBid operation.

```
placeBid'(int itemId, int clientId, int bid){
  exec(INSERT INTO bidTable VALUES (bid, clientId, itemId));
}
```

(**b**) Shadow placeBid' operation.

```
int closeAuction(int itemId){
 int winner = -1;
 beginTxn();
 close(itemId);
 winner = exec(SELECT userId FROM bidTable WHERE iId = itemId
       ORDER BY bid DESC limit 1);
 createShadowOp(closeAuction', itemId, winner);
 commitTxn();
 return winner;
}
```

(**c**) Original closeAuction operation.

```
closeAuction'(int itemId, int winner){
 close(itemId);
 exec(INSERT INTO winnerTable VALUES (itemId, winner));
}
```

(**d**) Shadow closeAuction' operation.

Figure 1: Pseudocode for the `placeBid` and `closeAuction` operations of an auction site

sification into two levels of consistency can be conservative, and some services could benefit from additional flexibility in terms of the level of coordination.

To overcome these limitations of RedBlue consistency, we next propose Partial Order-Restrictions consistency (or short, PoR consistency), a novel consistency model that allows the developer to reason about various fine-grained consistency requirements in a single system. The key intuition behind our proposal is that this model is generic and can be perceived as a set of restrictions imposed over admissible partial orders across the operations of a replicated system.

3.2 Defining PoR consistency

The definition of PoR consistency includes three important components: (1) a set of restrictions, which specify the visibility relations between pairs of operations; (2) a restricted partial order (or short, R-order), which establishes a (global) partial order of operations respecting operation visibility relations; and (3) a set of site-specific causal serializations, which correspond to total orders in which the operations are locally applied. We define these components formally as follows:

Definition 1 (Restriction). *Given a set of operations U, a* restriction *is a symmetric binary relation on $U \times U$.*

For any two operations u and v in U, if there exists a restriction relation between them, we denote this relation as $r(u,v)$.

Definition 2 (Restricted partial order). *Given a set of operations U, and a set of restrictions R over U, a* restricted partial order *(or short,* R-order*) is a partial order $O = (U, \prec)$ with the following constraint: $\forall u, v \in U$, $r(u,v) \in R \implies u \prec v \vee v \prec u$.*

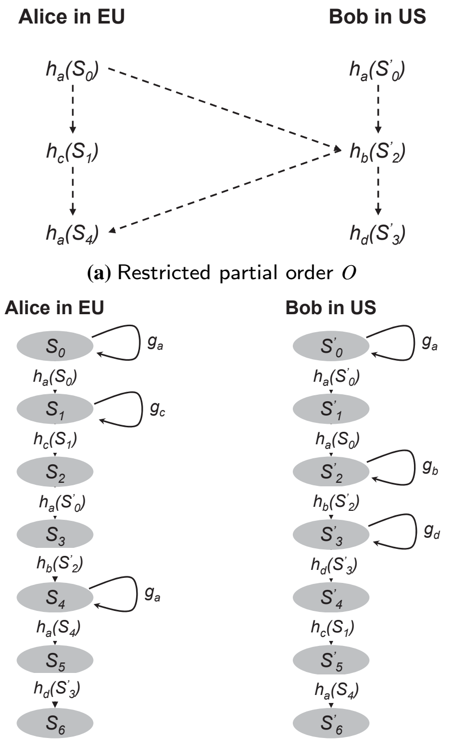
We say that the restrictions in R are met in the corresponding R-order if this order satisfies the above definition. This definition places constraints on a global view of a replicated system; however, it fails to explain how each individual replica at every site will behave according to this global view. When user requests are accepted by any site, that site executes their generator operations and creates corresponding shadow operations which will be replicated across all sites. In addition, every site not only commits shadow operations created by itself, but also applies remote ones shipped from all other sites against its local state. We denote U as the set of shadow operations produced across all sites, while for a site i, we denote V_i as its generator operation set. The following definition models the execution of each site as a growing linear extension of the global R-order, which incorporates a notion of causality, due to the fact that the visibility dependencies that are established when shadow operations are initially generated, are then preserved while the corresponding shadow operations are replicated.

Definition 3 (Causal legal serialization). *Given a site i, an R-order $O = (U, \prec)$ and the set of generator operations V_i received at site i, we say that $O_i = (U \cup V_i, <_i)$ is an* i-causal legal serialization *(or short, a* causal serialization*) of O if*

- *O_i is a total order;*
- *$(U, <_i)$ is a linear extension of O;*
- *For any $h_v(S) \in U$ generated by $g_v \in V_i$, (1) S is the state obtained after applying the sequence of shadow operations preceding g_v in O_i; (2) For any $h_u(S') \in U$, $h_u(S') <_i g_v$ in O_i iff $h_u(S') \prec h_v(S)$ in O.*

Definition 4 (Partial Order-Restrictions consistency). *A replicated system $\mathscr{S}$ spanning k sites with a set of restrictions R is* Partial Order-Restrictions consistent *(or short,* PoR consistent*) if each site i applies shadow operations according to an i-causal serialization of R-order O.*

Fig.2 shows a restricted partial order and its causal legal serializations executed at two sites, namely EU and US, where we restrict pairs of shadow operations where one corresponds to a and the other to b. When the US site executes a generator of b, g_b, it realizes that the shadow operation it would generate may need to be re-



(a) Restricted partial order O

(b) Causal legal serializations of O

Figure 2: Restricted partial order of shadow operations and its causal legal serializations for a system spanning two sites. There exists a restriction $r(h_a(S), h_b(S))$ for all valid S. Dotted arrows in Fig.2a indicate dependencies between shadow operations. Loops in Fig.2b represent generator operations.

stricted w.r.t a concurrent shadow operation initially triggered at the EU site. As a result, g_b at the US site must wait until the respective concurrent shadow operation $h_a(S_0)$ gets propagated from Alice's site to Bob's site. Then g_b will read the state introduced by locally applying $h_a(S_0)$ from Alice, and produce a shadow operation $h_b(S'_2)$. Note that this production will establish a dependency between $h_a(S_0)$ and $h_b(S'_2)$ (as shown in Fig.2a), thus enforcing that they cannot be applied in different relative orders in all causal legal serializations (as shown in Fig.2b). Unlike these two shadow operations, we do not restrict any pair of shadow operations of a; as such, the first operations issued by both Alice and Bob will be concurrently executed without being aware of each other. This example indicates the flexibility and performance benefits of having PoR consistency, compared with RedBlue consistency, since under the latter model all shadow operations of a and b would be serialized w.r.t each other.

4 Restriction inference

When replicating a service under PoR consistency, the first step is to infer restrictions to ensure two important system properties, namely state convergence and invariant preservation. The major challenge we face is to identify a minimal set of restrictions for making the replicated service converge and not violate invariants. With regard to state convergence, we take a similar methodology adopted in prior research [37, 30, 29], which is to check operation commutativity.

To preserve application-specific invariants, instead of totally ordering all *non-invariant safe* shadow operations, i.e., those that potentially transition from a valid state to an invalid one, we try to identify a minimal set of shadow operations that lead to an invariant violation when they are running concurrently in a coordination-free manner. By minimal, we mean that removing any operation from that set would no longer meet that goal. Once this set is identified, adding a restriction between any pair of its operations is sufficient to eliminate the problematic executions.

4.1 State convergence

A PoR consistent replicated system is state convergent if all its replicas reach the same final state when the system becomes quiescent, i.e., for any pair of causal legal serializations of any R-order, L_1 and L_2, we have $S_0(L_1) = S_0(L_2)$, where S_0 is a valid initial state. We state a necessary and sufficient condition to achieve this in the following theorem.

Theorem 5. *A PoR consistent system $\mathscr{S}$ with a set of restrictions R is* ***convergent****, if and only if, for any pair of its shadow operations u and v, $r(u, v) \in R$ if u and v don't commute.*[1]

Unlike RedBlue consistency, under which all operations that are not globally commutative must be totally ordered, PoR consistency only requires that an operation must be ordered w.r.t another one if they do not commute.

4.2 Invariant preservation

In RedBlue consistency, the methodology for identifying restrictions imposed on RedBlue orders for maintaining invariants is to check if a shadow operation is *invariant safe* or not (meaning whether it can potentially violate invariants when executed against a different state from the one that it was generated from). If not, to avoid invariant violations, the generation and replication of all non-invariant safe shadow operations must be coordinated. However, we observed that for some non-invariant safe shadow operations u, the corresponding violation only happens when a particular subset of non-invariant safe shadow operations (including u) are not partially ordered. Therefore, to eliminate all invariant violating executions with a minimal amount of coordination, we need to precisely define, for each violation, the minimal set of non-invariant safe shadow operations that are involved.

[1] All proofs are in a separate technical report [7].

We call this set an `invariant-conflict operation set`, or short, `I-conflict set`. Preserving invariants only requires adding a single restriction over any two shadow operations from each `I-conflict set` so that the concurrent violating executions will be eliminated from all admissible partial orders. We formally define `I-conflict sets` as follows.

Definition 6 (Invariant-conflict operation set)**.** *A set of shadow operations G is an* invariant-conflict operation set *(or* I-conflict set*) if the following conditions are met:*

- *$\forall u \in G$, u is non-invariant safe;*
- *$|G| > 1$;*
- *$\forall u \in G$, $\forall$ sequence P consisting of all shadow operations in G except u, i.e., $P = (G \setminus \{u\}, <)$, $\exists$ a reachable and valid state S, s.t. $S(P)$ is valid, and $S(P+u)$ is invalid.*

In the above definition, the last point asserts that G is minimal, i.e., removing one shadow operation from it will no longer lead to invariant violations. We will use the following example to illustrate the importance of minimality. Imagine that we have an auction on an item i being replicated across three sites such as US, UK and DE, and having initially a 5 dollar bid from *Charlie*. Suppose also that three shadow operations, namely, $placeBid'(i,\ Bob,\ 10)$, $placeBid'(i,\ Alice,\ 15)$, and $closeAuction'(i)$ are accepted concurrently at the three locations, respectively. After applying all of them against the same initial state at every site, we end up with an invalid state, where *Charlie* rather than *Bob* and *Alice* won the auction. This invariant violating execution involves three concurrent shadow operations, but one of the two bid placing shadow operations is not necessary to be included in G, as even after excluding the request from either *Bob* or *Alice*, the violation still remains. This is reflected in Definition 6, according to which $\{placeBid', closeAuction'\}$ is an `I-conflict set`, while $\{placeBid', placeBid', closeAuction'\}$ is not. Intuitively, avoiding invariant violations requires preventing all operations from the `I-conflict set` from running in a coordination-free manner. The minimality property enforced in the `I-conflict set` definition allows us to avoid adding unnecessary restrictions.

Based on the above definition, we formulate the invariant preservation property into the following theorem.

Theorem 7. *Given a PoR consistent system $\mathscr{S}$ with a set of restrictions $R_{\mathscr{S}}$, for any execution of $\mathscr{S}$ that starts from a valid state, no site is ever in an invalid state, if the following conditions are met:*

- *for any of its `I-conflict set` G, there exists a restriction $r(u,v)$ in $R_{\mathscr{S}}$, for at least one pair of shadow operations $u,v \in G$; and*
- *for any pair of shadow operations u and v, $r(u,v)$ in $R_{\mathscr{S}}$ if u and v do not commute.*

Algorithm 1 Find state convergence restrictions

```

   operations of the target system
2:     $R \leftarrow \{\}$                  ▷ $R$: the restriction set
3:     for $i \leftarrow 0$ to $|T|-1$ do
4:         for $j \leftarrow i$ to $|T|-1$ do
5:             if $T_i$ do not commute with $T_j$ then
6:                 $R \leftarrow R \cup \{r(T_i, T_j)\}$
7:     return $R$
```

Algorithm 2 Find invariant preserving restrictions

```
function IPRDISCOVER($T$)
    $R \leftarrow \{\}$                      ▷ $R$: the restriction set
    $Q \leftarrow$ power set of $T$
    for all $Q' \in Q$ do
        if ICONFLICTCHECK($Q'$) then
            if $|Q'| == 1$ then
                $R \leftarrow R \cup \{r(Q'_0, Q'_0)\}$
            else if $\forall u,v \in Q', r(u,v) \notin R$ then
                $R \leftarrow R \cup \{r(u,v)\}$, for an arbitrary
choice of $u,v \in Q'$
    return $R$
function ICONFLICTCHECK($T$)
    if $|T| == 1$ then
        if $\neg(T_0.post \implies T_0.wpre)$ then
            return true
    if $|T| > 1$ then
        $subset\_iconflict \leftarrow$ false
        for $i \leftarrow 2$ to $|T|-1$ do
            for all $R$ s.t. $|R| == i$ and $R \subset T$ do
                if ICONFLICTCHECK(R) then
                    $subset\_iconflict \leftarrow$ true
                    break
        if $!subset\_iconflict$ then
            for all $t \in T$ do
                $post \leftarrow \wedge_{x \in T \setminus \{t\}} x.post$
                if $\neg(post \implies t.wpre)$ then
                    return true
    return false
```

4.3 Identifying restrictions

The key to striking a sensible balance between performance and consistency semantics is to identify a minimal set of restrictions that ensure both state convergence and invariant preservation. With regard to the former property, inspired by Theorem 5, we design a discovery method for finding restrictions to ensure state convergence (Alg. 1). This method systematically performs an operation commutativity analysis between pairs of shadow operations: if two shadow operations do not commute, then a restriction between them is added to the returning restriction set (line 5-6).

To discover restrictions for preserving invariants, we could exhaustively explore all `I-conflict` sets consisting of concurrent shadow operations that trigger violations. However, it is very challenging to achieve this

```
//each permission consists of a set of operations
Permission p;

//receive a set of operations that need to be monitored
Permission getPermission(TxnId tid, String opName);

//wait until the set of operations in p have been applied
void waitForBeingExecuted(TxnId tid, Permission p);

//clean up all required resources occupied
void cleanUp(TxnId tid);
```

Figure 3: Olisipo coordination policy interface

since there might exist a large number of violating executions containing at least one I-conflict set. To make this exploration more efficient, we first collapse many similar executions of a replicated system into a single execution class, and then perform a weakest precondition and postcondition analysis over these classes [23].

In particular, for every shadow operation u, we denote $u.wpre$ as its weakest precondition, a condition on the initial state ensuring that u always preserves invariants. We also denote $u.post$ as the postcondition that captures the side effects of operations through a condition that always holds after the operation is executed. In Alg. 2, we flag a set of shadow operations T as `I-conflicting` if either of the following two conditions is met: (a) T contains a single operation t and t is self-conflicting, i.e., $t.wpre$ is invalidated by $t.post$ (line 12-14); or (b) $|T| > 1$, any subset of T is not `I-conflicting` (but can be self-conflicting) and there exists an operation u from T such that $u.wpre$ can be invalidated by the compound postcondition of all the operations in $T \setminus \{u\}$ (line 16-26).

Once these `I-conflict` sets are determined, then for each such set T, we add a restriction between an arbitrary pair of shadow operations from T if no pair of operations from that set was previously restricted (line 8-9). Otherwise, T will be skipped since the preexisting restriction suffices to preserve invariants. In addition, for shadow operations that are self-conflicting, we have to place a restriction between pairs of shadow operations of that type (line 6-7).

5 Design and Implementation of Olisipo

Several coordination protocols can be used for enforcing a given restriction, such as Paxos, distributed locking, or escrow techniques. However, depending on the observed runtime frequency of operations confined by a restriction, different approaches lead to different performance.

In the previously mentioned auction example, maintaining the invariant that winners always match highest successful bidders requires a restriction between any pair of `placeBid'` and `closeAuction'` operations. A simple scheme would be forcing instances of either operation to pay the same coordination cost. However, since `placeBid'` is likely to be more prevalent than `closeAuction'`, reducing the latency for `placeBid'` and penalizing `closeAuction'` is likely to lead to better performance.

To address this, we propose a coordination service called Olisipo offering a range of coordination policies, each of which presents a trade-off between the cost of each operation and the overall cost. This service allows us to use runtime information about the relative frequency of operations to select an efficient coordination mechanism for a given restriction.

5.1 Coordination protocols

Olisipo supports two built-in protocols, namely `symmetric (Sym)` and `asymmetric (Asym)`, but can be extended with customized coordination policies, which need to be compatible with our interface (Fig. 3). The difference between the two protocols is that, in the case of `Sym`, given a restriction $r(u,v)$ between two operations u and v, the protocol requires both u and v to coordinate with each other for establishing an order between them, whereas the `Asym` protocol allows one of them to proceed by default, while requiring the other to obtain permission before proceeding.

Sym. This protocol requires to set up a logically centralized counter service, which maintains, for each restriction $r(u,v)$, two counters c_u and c_v. Each one represents the total number of operations of the corresponding type that have been accepted by the underlying system. Additionally, every replica at different data centers maintains a local copy of these counters, representing the number of operations of each type that have been executed by that replica. Initially, all local copies, as well as the global counters, have all values set to zero. Whenever an operation is received by a replica, that replica contacts the counter service to increase the corresponding centralized counter and get a fresh copy of the counter maintained for both types of operations. Upon receiving the reply from the counter service, that replica compares the received values with its local copy. If they are the same, then the replica can execute the operation without waiting. Otherwise, the local execution can only take place when all missing operations have been locally replicated. To make the counter service fault tolerant, we leverage a Paxos-like state machine replication library (BFT-SMART [18]) to replicate counters across geo-locations.

Asym. Unlike the above centralized solution, the asymmetric protocol implements distributed barrier in a decentralized manner. Assume, for instance, that u is the barrier. In this case, whenever a replica r receives an operation u it would have to enter the barrier, and contact all other replicas to request participation. This requires all replicas in the system to stop processing operations of type v and enter the barrier. After receiving an acknowledgment of the barrier entrance from all replicas, r can execute the operation, and then notify all replicas that it has left the barrier (while at the same time propagating

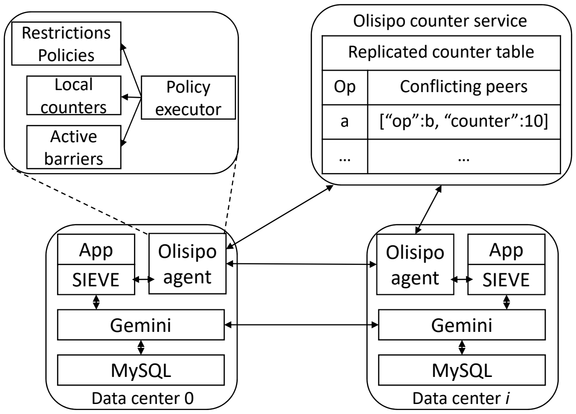

Figure 4: Olisipo architecture

the effects of the operation u it has just executed). Such a coordination strategy might incur a high overhead; however, this is beneficial when one of the two operations in the restriction is rarely submitted to the system.

5.2 Implementation details

As depicted in Fig. 4, the Olisipo architecture consists of a counter service replicated across data centers and a local agent deployed in each data center. The counter service is required only for the `Sym` protocol, whereas the local agent enforces the coordination that is needed by both protocols. To this end, every agent also stores some meta data required for different protocols: for the `Sym` protocol, it maintains a local copy of the replicated counter service, which is used for learning if the local counters lag behind the global counters, which means the corresponding data centers have to wait until all missing operations have been locally incorporated. For the `Asym` protocol, every agent maintains a list of active barriers, which are used for locally deciding if relevant operations blocked on such barriers can proceed. Note that these protocols are not optimized for performance, but nonetheless suffice to demonstrate the benefits of using PoR consistency and enforcing it in a way that takes into account frequency of different operation types.

We implemented Olisipo using Java (2.8k lines of code), linked with BFT-SMART [39] for replicating the centralized counter service and MySQL as the backend storage. We integrated Olisipo with our prior prototypes for Gemini [5] and SIEVE [6], so that Gemini serves as the underlying causally consistent replication tier while SIEVE is used to produce commutative shadow operations at runtime. The code of Olisipo is available at [11].

Workflow. User requests are directed to an application server running at the local data center, which executes the corresponding generator operation. The result is a commutative shadow operation, which is then forwarded to the local Olisipo agent for placing coordination if needed before committing; if the coordination allows for that serialization (which is determined according to the specific protocol for enforcing it) then the shadow operation is sent to Gemini for replicating it across all data centers; otherwise the generator operation must be retried in a new serial order.

6 Evaluation

In our experimental evaluation, we first try to understand if the methodology for inferring restrictions presented in Sec. 4 is effective when applied to real world applications, i.e., it finds a minimal set of restrictions. Finally, we try to assess the impact on latency and system throughput introduced by three factors: adopting PoR consistent replication, using different protocols, and adding more restrictions.

6.1 Case study

Next, we report our experience on discovering restrictions in RUBiS. RUBiS is a fairly simple auction-like benchmark. The original benchmark we used as a starting point contained only 16 transactions and did not include an operation to declare the winner of an auction, so we added a close auction functionality. In the future, we intend to explore other benchmarks with more complex OLTP or OLAP queries.

State convergence. Given that we deploy RUBiS with SIEVE, all shadow operations generated at runtime commute w.r.t. each other by construction, and there is no need modify the application nor restrict any pair of shadow operations for state convergence purposes. All that is required in SIEVE is to specify the desired conflict resolving semantics by choosing from a set of built-in solutions [29].

Invariant preservation. We manually perform the procedure of identifying restrictions to make a geo-replicated RUBiS deployment invariant preserving, as previously presented in Section 4.3. (We leave the automation of this step as future work.) In particular, we determined four invariants of RUBiS, namely (a) identifiers assigned by the system are unique; (b) nicknames chosen by users are unique; (c) item stock must be non-negative; and (d) the auction winner must be associated with the highest bid across all accepted bids. We continued by manually determining the weakest preconditions and postconditions of all RUBiS shadow operations. Those conditions are summarized in Tab. 1 and used by the `I-conflict set` analysis (Alg. 2). With regard to the first invariant, since we take advantage of the coordination-free unique identifier generation method offered by SIEVE, no `I-conflict sets` were found for violating it. In turn, for the remaining three invariants, we identified the following `I-conflict` sets:

- $\{registerUser', registerUser'\}$. Invariant (b) would be violated if the two operations proposed the same *nickname* and were submitted to different sites simultaneously;

$placeBid'$ $(itId, cId, bid)$	wp	$\exists u \in item\_table.\ u.id = itId \wedge u.status = open$	valid auction
	post	$bidTable = bidTable \cup \{< itId, cId, bid >\}$	new bid placed
$closeAuction'$ $(itId, wId)$	wp	$\exists w \in bidTable.\ w.cId = wId \wedge \forall v \in bidTable \setminus \{w\}.\ w.bid > v.bid$	highest accepted bid
	post	$winnerTable = winnerTable \cup \{< itId, wId >\}$	winner declared
$registerUser'$ $(uId, username)$	wp	$\forall u \in user\_table.\ u.name <> username$	username not seen before
	post	$user\_table = user\_table \cup \{< uId, username >\}$	new user added
$storeBuyNow'$ $(itId, delta)$	wp	$\exists u \in item\_table.\ u.id = itId \wedge u.stock >= delta$	enough stock left
	post	$u.stock -= delta$	delta applied

Table 1: Weakest preconditions and postconditions of selected shadow operations of RUBiS

RedBlue consistency	PoR consistency
$r(registerUser', registerUser')$	$r(registerUser', registerUser')$
$r(storeBuyNow', storeBuyNow')$	$r(storeBuyNow', storeBuyNow')$
$r(placeBid', placeBid')$	$r(placeBid', closeAuction')$
$r(closeAuction', closeAuction')$	
$r(placeBid', closeAuction')$	
$r(registerUser', storeBuyNow')$	
$r(registerUser', placeBid')$	
$r(registerUser', closeAuction')$	
$r(storeBuyNow', placeBid')$	
$r(storeBuyNow', closeAuction')$	

Table 2: Restrictions required when replicating the extended RUBiS under RedBlue or PoR consistency

- $\{storeBuyNow', storeBuyNow'\}$. Invariant (c) would be violated if both operations simultaneously subtracted some number of items from *stock*, and the sum of the purchases exceeded the previous *stock* value;
- $\{placeBid', closeAuction'\}$. Invariant (d) would be violated if both operations were submitted at the same time to different sites, and $placeBid'$ carried a higher bid than all accepted bids.

Each `I-conflict set` above covers a class of violating executions of the respective invariant. To eliminate the corresponding violations, we added three restrictions, namely $r(registerUser', registerUser')$, $r(storeBuyNow', storeBuyNow')$ and $r(placeBid', closeAuction')$. In Tab.2 we compare to the PoR consistency solution with using RedBlue consistency. The latter solution would require more restrictions, since the definition states that all non-invariant safe shadow operations must be strongly consistent, i.e., the four shadow operations presented in the above list must be restricted in a pairwise fashion.

We assign the `Sym` protocol to coordinate shadow operations confined by all these restrictions except $r(placeBid', closeAuction')$. This is because $placeBid'$ is significantly more prevalent than $closeAuction'$ in RUBiS, e.g., in a bidding mix workload, the ratio of the number of $closeAuction'$ to the number of $placeBid'$ is only 2.7%. Therefore, we assign the `Asym` protocol to coordinate this restriction and additionally make $closeAuction'$ act as the barrier.

6.2 Experimental setup

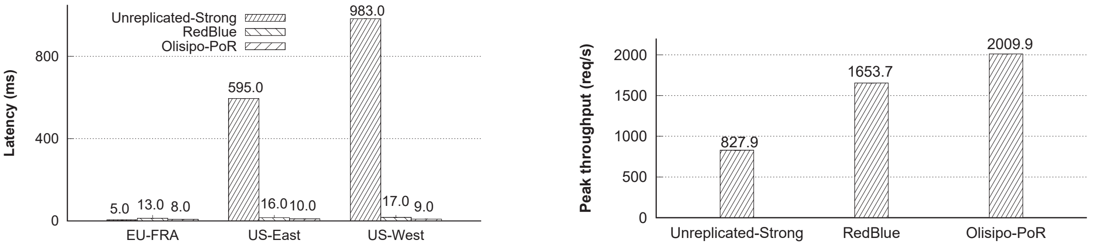
We run experiments on Amazon EC2 [1] using `m4.2xlarge` virtual machine instances located in three sites: US Virginia (US-East), US California (US-West) and EU Frankfurt (EU-FRA). Table 3 shows the average round trip latency and observed bandwidth between every pair of sites. Each VM has 8 virtual cores and 32GB of RAM. VMs run Debian 8 (Jessie) 64 bit, MySQL 5.5.18, Tomcat 6.0.35, and OpenJDK 8 software.

	US-East	US-West	EU-FRA
US-East	0.299 ms 1052.0 Mbps	71.200ms 47.4 Mbps	88.742 ms 29.6 Mbps
US-West	66.365 ms 47.4 Mbps	0.238 ms 1050.7 Mbps	162.156 ms 17.4 Mbps
EU-FRA	88.168 ms 36.2 Mbps	162.163 ms 20.1 Mbps	0.226 ms 1052.0 Mbps

Table 3: Average round trip latency and bandwidth between Amazon data centers

Configuration and workloads. Unless stated otherwise, in all experiments, we deploy the BFT-SMART library under the crash-fault-tolerance model (CFT) with 3 replicas across three sites, and assign the replica at EU-FRA to act as the leader of the consensus protocol. We replicate RUBiS under PoR consistency across three sites using the previously mentioned combination of Olisipo, SIEVE, and Gemini. As additional baselines, we run an unreplicated strongly consistent RUBiS in the EU-FRA site, and a 3 site RedBlue consistency deployment, in which we replicate RUBiS via the PoR consistency framework but with the set of restrictions required by RedBlue consistency (shown in Tab.2). We refer to these three setups as "*Olisipo-PoR*", "*Unreplicated-Strong*", and "*RedBlue*", respectively. For all experiments, emulated clients are equally distributed across three sites and connect to their closest data center according to physical proximity.

We choose to run the bidding mix workload of RUBiS, where 15% of user interactions are updates. To allow the client emulator to issue the newly introduced `closeAuction` requests, we have to slightly change the transition table in the original RUBiS code by assigning a positive probability value for this request. The new transition table can be found here [10]. For all experiments we vary the workload by increasing the number of concurrent client threads in every client emulator, and disable the `thinking time` option so that there is no waiting time between two contiguous requests from the same client thread. We populate the data set via the following parameters: the RUBiS database contains 33,000 items for sale, 1 million users, and 500,000 old items.



(a) Overall average latency

(b) Peak throughput

Figure 5: Performance comparison between three system configurations

6.3 Results

6.3.1 Average user observed latency

The main advantage of adopting PoR consistent replication with Olisipo is to reduce user-perceived latency. To assess this improvement, we start by analyzing the average latency for users at each data center. In this set of experiments, each user issues a single request at a time in a closed loop.

As shown in Fig.5(a), all users except those in EU-FRA observe a lower latency in the *Olisipo-PoR* and *RedBlue* configurations, compared to the users from the same locations in the *Unreplicated-Strong* configurations. This improvement is because, under both PoR and RedBlue consistency, most requests are handled locally within a data center, whereas in the unreplicated setting, requests from users at the two US data centers have to communicate with EU-FRA, which incurs an expensive inter-datacenter communication. At a more detailed level, in the *Unreplicated-Strong* experiment, the raw latency values perceived by users at both US-East and US-West are higher than the round-trip time from the user to the server site (EU-FRA) because processing each request involves sending one or more images to the user.

Compared to *RedBlue*, *Olisipo-PoR* improves the average latency for users at the three sites by 38.5%, 37.5% and 47.1%, respectively. We further observed that users at EU-FRA in the replicated experiments experience a higher latency than users from the same region accessing an unreplicated RUBiS. This is due to the additional work required for incorporating remote shadow operations into the local causal serialization and placing coordination when needed for serializing conflicting requests. Note that although the user observed latency for *Olisipo-PoR* at EU-FRA is almost twice as large as the latency of the unreplicated setup, the absolute number (9 ms) is reasonably low.

6.3.2 Peak throughput

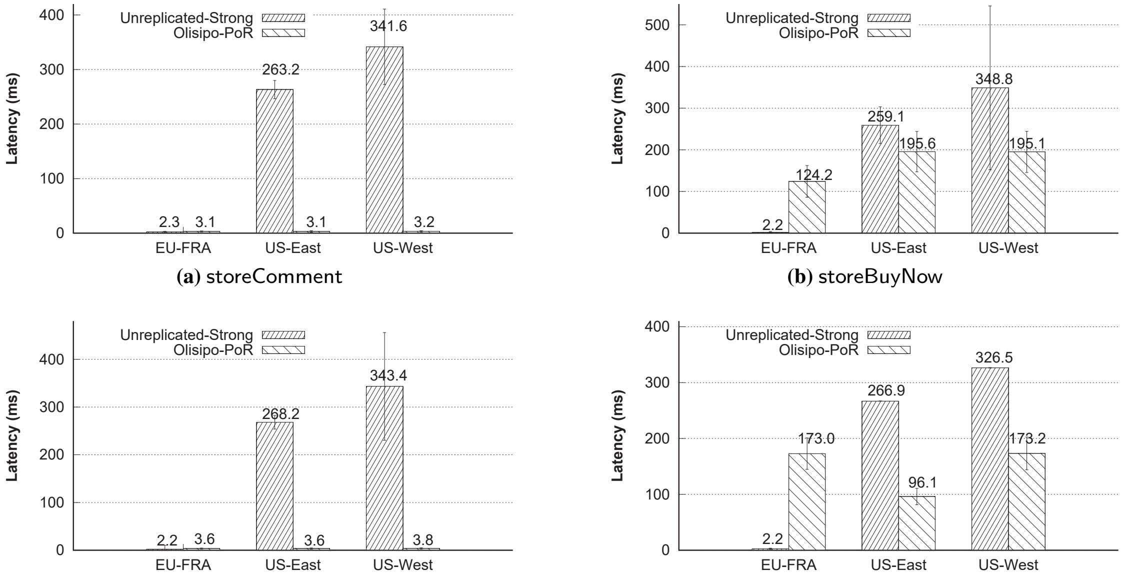
We now focus on the improvement in scalability with the client load achieved by PoR consistency. Fig.5(b) shows the peak throughput achieved by the three configurations, which is measured when the corresponding system is saturated. The improvement of the *Olisipo-PoR* deployment is $1.43X$ when compared to the *Unreplicated-Strong* setup. This increase in throughput is because PoR consistency offers fine-grained consistency so that only a minority of requests need to pay the coordination cost, while the remaining can be processed locally. Compared to a RedBlue consistent RUBiS, the PoR consistent version increases peak throughput by 21.5%, since PoR consistency avoids the cost for coordinating several restrictions required by RedBlue consistency (shown in Tab.2).

6.3.3 Per request latency

Next, we evaluate the per request latency of RUBiS requests. For this round of experiments, each site runs a single user issuing a request at a time.

Latency of non-conflicting requests. Among all RUBiS non-conflicting requests, we chose one representative request called `storeComment`, which places a comment on a user profile, as the illustrating example. Fig.6(a) shows that PoR consistent RUBiS makes users across the three sites observe evenly low latency, and the speedup in the user observed latency for the remote users located at US-East and US-West is 84.9x and 106.8x, respectively, compared to the *unreplicated* strongly consistent deployment. These performance gains happen because, under PoR consistency, the `storeComment` request requires no coordination and can be processed locally. In contrast, in the *unreplicated* experiment, users at the two US sites have to contact the server at EU-FRA and thus perceive a higher latency. We also notice that users from EU-FRA in both experiments have almost identical latency, which is different from the results in Fig.5(a), since the cost of generating and applying the shadow operations of the `storeComment` request is modest.

Latency of conflicting requests. Next, we shift our attention from non-conflicting requests to conflicting ones. As introduced before, Olisipo uses two different protocols (`Sym` and `Asym`) to coordinate conflicting requests. We start by analyzing the latency of requests handled by the `Sym` protocol. The illustrative example we selected is `storeBuyNow`, which produces self-conflicting shadow operations. As shown in Fig.6(b), the user observed latency of the `storeBuyNow` request at all three sites is significantly higher than the latency of `storeComment` (shown in Fig.6(a)), which is a non-conflicting request. This is because most of the lifecycle of these requests was spent asking permission to the centralized counter



(a) storeComment

(b) storeBuyNow

(c) placeBid

(d) closeAuction

Figure 6: Average latency bar graph of four requests for users at three sites. `storeComment` produces non-conflicting shadow operations, while the ones of `storeBuyNow` conflict w.r.t themselves and are regulated by the `Sym` protocol. `placeBid` and `closeAuction` produce two conflicting shadow operations regulated by the `Asym` protocol.

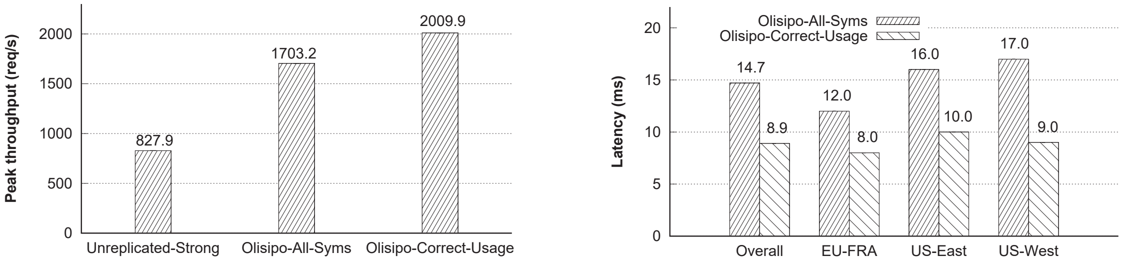
service, which consists of 3 replicas spanning three sites and executing a Paxos-like consensus protocol. Additionally, user observed latency at EU-FRA is lower than the remaining two sites, since the leader of the consensus protocol is co-located with EU-FRA users.

We continue by analyzing the average latency of requests that are coordinated by the `Asym` protocol. Unlike the `Sym` protocol, any pair of operations confined in a restriction will be treated differently by the `Asym` protocol, since one acts as a distributed barrier and the other proceeds if no active barriers are running. In Sect. 6.1, we assigned the `Asym` protocol to regulate the $r(placeBid', closeAuction')$ restriction, while selecting the less frequent shadow operation $closeAuction'$ as a barrier. As shown in Fig.6(c), the average latency measured for the *placeBid* request, which produces $placeBid'$, is very similar to the results obtained for non-conflicting requests shown in Fig.6(a). This is because the ratio of *closeAuction* to *placeBid* is very low and most of the time the *placeBid* request commits immediately without waiting for joining or leaving barriers.

Next, we consider the barrier request *closeAuction* handled by the `Asym` protocol. As expected, Fig.6(d) shows that, compared to *placeBid*, the average latency of *closeAuction* is noticeably higher due to the coordination across sites, through which this request forces all sites not to process incoming *placeBid* requests and collects results of all relevant completed *placeBid* requests. We also notice that users issuing *closeAuction* observed a latency that is slightly higher than the maximum RTT between their primary site and the remaining sites. For example, as shown in Tab.3, the maximum RTT for US-East users to the other two sites is 88.7 ms, while the average latency of *closeAuction* observed by the same group of users is 96.1 ms.

6.3.4 Impact of different protocols

The purpose of offering different coordination protocols is to improve runtime performance by taking into account the workload characteristics. To validate this, we first deploy an experiment denoted by `Olisipo-Correct-Usage`, in which we take into account the runtime information that $closeAuction'$ occurs sparsely and assign the `Asym` protocol to regulate the restriction $r(placeBid', closeAuction')$. We then deploy another experiment denoted by `Olisipo-All-Syms`, in which the restriction $r(placeBid', closeAuction')$ is handled by the `Sym` protocol. Fig. 7 summarizes the comparison of peak throughput and average latency among three experiments, namely `Unreplicated-Strong`, `Olisipo-All-Syms` and `Olisipo-Correct-Usage`. The `Olisipo-All-Syms` setup improves the peak throughput of the unreplicated RUBiS system by 105.7%, because of the coordination-free execution of non-conflicting requests. However, compared to `Olisipo-Correct-Usage`, the performance of `Olisipo-All-Syms` degrades in two dimensions, namely a 15.3% decrease in peak throughput and a 65.2%, 50.0%, 60.0%, 88.9% increase in request latency for all, EU-FRA, US-East, US-West users, respectively. The reason for this performance loss is as follows: every `placeBid'` shadow operation in `Olisipo-All-Syms` requires a communication step between its



(a) Peak throughput

(b) Overall average latency

Figure 7: Peak throughput and overall average latency bar graphs of systems using different protocols.

primary site and the centralized counter service for being coordinated, while most of time `placeBid'` shadow operations in `Olisipo-Correct-Usage` work as non-conflicting requests provided that `closeAuction` requests sparsely arrive in the system.

7 Related work

In the past decades, many consistency proposals focused on reducing coordination among concurrent operations to improve scalability in geo-replicated systems [25, 40, 30, 29, 14, 15, 42, 12, 4, 32]. However, they only allow the programmer to choose from a limited number of consistency levels that they support, such as strong, causal or eventual consistency. Unlike these approaches, PoR consistency offers a fine-grained tunable trade-off between performance and consistency using the visibility restrictions between pairs of operations to express consistency semantics. Some of these proposals for consistency models with reduced coordination also analyzed or even enforced conditions for ensuring state convergence despite the lack of coordination [14, 25, 40, 15, 32, 40]. In addition to state convergence, our solution also analyzes invariant preservation.

In the space of consistency proposals that looked into how to enforce application-specific invariants, Bailis et al. [16] proposed I-confluence, which avoids coordination by determining if a set of transactions are I-confluent, i.e., if the integrity constraints might be violated when they are executing without coordination. Indigo [17] defines consistency as a set of invariants that must hold at any time, and presents a set of mechanisms to enforce these invariants efficiently on top of eventual consistency. Similar to Indigo, warranties [31] map consistency requirements to a set of assertions that must hold in a given period of time, but it needs to periodically invalidate assertions when updates arrive. Roy et al. additionally propose a program analysis against transaction code for producing warranties [35]. In contrast, PoR consistency takes an alternative approach by modeling consistency as restrictions over operations.

A few proposals map consistency semantics to the ordering constraints defined over pairs of operations. Generic Broadcast defines conflict relations between messages for fast message delivery, which are analogous to visibility restrictions used in our solution [34]. However, they do not analyze how to determine the conditions for ensuring invariant preservation. The recent work of Gotsman et al. [24] encodes the concept of a conflict relation into a proof system, which allows for analyzing if consistency choices expressed as conflict relations is sufficient for enforcing application invariants. In comparison, our work makes three contributions. First, our methods allow to find a minimal set of restrictions to be used. Second, we propose a set of coordination methods that adapt to the workloads in order to be more efficient. Third, we present the design and implementation of a complete system that offers PoR consistency.

Some variants of Paxos [26] have explored operation semantics to relax the need to process all operations in the same sequential order. Generalized Paxos allows replicas to execute commutative operations in different orders [27]. EPaxos uses dependencies between pairs of operations to order concurrent conflicting requests [33]. Our work differs from these Paxos variants in that we develop an analysis to extract pairs of conflicting operations by considering the impact of concurrent executions on achieving state convergence and invariant preservation. Furthermore, unlike these protocols, in our work, operations that are not confined by conflicting relations can be first accepted in a single replica and later asynchronously replicated to other replicas.

Finally, our own previous workshop paper described the motivation and a high-level overview of a solution to this problem [28].

8 Conclusion

In this paper, we proposed a technique for achieving convergence and invariant-preservation in geo-replicated systems with a minimal amount of coordination. This combines a new generic consistency model called PoR consistency, an analysis for determining a minimal set of restrictions, and a coordination service called Olisipo for efficiently serializing pairs of operations. Our evaluation of running RUBiS with different setups shows that the joint work of PoR consistency and Olisipo significantly improves the performance of geo-replicated systems.

Log-Free Concurrent Data Structures*

Abstract

Non-volatile RAM (NVRAM) makes it possible for data structures to tolerate transient failures, assuming however that programmers have designed these structures such that their consistency is preserved upon recovery. Previous approaches are typically transactional and inherently make heavy use of logging, resulting in implementations that are significantly slower than their DRAM counterparts. In this paper, we introduce a set of techniques aimed at lock-free data structures that, in the large majority of cases, remove the need for logging (and costly durable store instructions) both in the data structure algorithm and in the associated memory management scheme. Together, these generic techniques enable us to design what we call *log-free concurrent data structures*, which, as we illustrate on linked lists, hash tables, skip lists, and BSTs, can provide several-fold performance improvements over previous transaction-based implementations, with overheads of the order of milliseconds for recovery after a failure. We also highlight how our techniques can be integrated into practical systems, by presenting a durable version of Memcached that maintains the performance of its volatile counterpart.

1 Introduction

Fast, non-volatile memory technologies have been intensively studied over the past years, with various alternatives such as Memristors [53], Phase Change Memory [31, 49], and 3D XPoint [39] being proposed. Nevertheless, these technologies are only now starting to become commercially available. Referred to as *non-volatile RAM (NVRAM)*, they promise byte-addressability and latencies that are comparable to DRAM, yet also non-volatility and higher density than DRAM.

From a programmer's perspective, NVRAM can be read and written using *load* and *store* instructions, identically to DRAM. However, a significant fraction of software needs to be redesigned to work with NVRAM. Unlike DRAM on the one hand, in order to take advantage of NVRAM's non-volatility, the stored data needs to be in a state that allows the resumption of execution after a transient failure (e.g., a power failure). Unlike block-based durable storage on the other hand, the granularity at which data is read and written is much finer, and the latencies much smaller. Thus, strategies that might have yielded the best performance in case of block-based storage might not be appropriate for NVRAM.

In this paper, we focus on adapting to NVRAM the design and implementation of an essential component of modern software systems: concurrent data structures [10, 13, 38, 40, 41, 43]. Ideally, in the NVRAM environment, one would like concurrent data structures that (a) can be recovered in case of a transient failure with states that reflect all completed operations up to the failure, yet (b) whose performance and scalability resemble those of their counterparts designed for DRAM.

This task is challenging because neither data stored in registers, nor in caches, is durable in the face of transient failures. Moreover, by default, the program does not control the order in which cache lines are evicted and written to NVRAM. In order to enforce ordering, specific (and expensive) instructions, which we refer to as *sync* operations, must be used to ensure that a store is written through to NVRAM at the desired point.

Previous approaches [2, 4, 6, 20, 25, 28, 30, 33, 37, 56] to implementing data structures for NVRAM rely mainly on transactions (either explicitly, or implicitly derived from critical sections). With transactions, some form of *logging* is necessary to cope with the possibility of a failure in the middle of a transaction. This log needs to be reliably written before the transaction is executed. This entails waiting for stores to be written to NVRAM before proceeding, which is particularly expensive: whereas when using DRAM, one would at most wait for data to be written to the L1 cache, now one has to wait for data to be written all the way to NVRAM. Logging is thus a major source of expensive sync operations.

We propose three techniques aimed at lock-free data structures that remove logging entirely from data structure operations and dramatically reduce logging in the memory reclamation scheme. We focus on lock-free algorithms, because they always keep the data structure in a consistent state and thus do not inherently require logging in order to maintain consistency across restarts.

The techniques we propose are: (1) the *link-and-persist* technique, which allows atomically changing and persisting a link in a data structure, (2) the *link cache*, which allows persisting entire batches of modified links, thus reducing the number of *sync* operations and (3) *NV-epochs*, a coarse-grained epoch-based memory reclamation scheme. We briefly describe these techniques below.

Link-and-persist applies the pointer marking technique [15] from concurrent programming to ensure atomicity in the face of crashes and recoveries. With link-and-persist, when a data structure link is modified, a mark is

[*] Supported in part by ERC Grant 339539 (AOC).

[†] Work done while the author was at EPFL and MSR Cambridge.

added to the link to signify that the value of the link might not be durable yet. The link can then be persisted, and the mark removed, by the modifying operation or by any other operation (helping).

The *link cache* is an extremely fast, best-effort concurrent hash table stored in volatile memory, which contains data structure links that have not yet been durably written. When modifying the data structure, instead of ensuring updated links are written to NVRAM, we add them to the link cache. Thus, we avoid writing them to NVRAM one at a time. When the durable write of one of them is necessary for correctness, we batch the write-backs of all links stored in our cache, which is significantly faster than waiting for writes to complete one at a time.

Finally, memory allocation and reclamation is also a central concern for concurrent data structures. When working with NVRAM, the traditional approach for avoiding persistent memory leaks or use-after-free problems is again some form of logging. To avoid this, we propose *NV-epochs*, a coarse-grained epoch-based memory reclamation scheme for durable and concurrent data structures. NV-epochs groups memory nodes into memory areas, and reliably and durably keeps track of the active (recently used) memory areas instead of individual allocations. This bookkeeping of active memory areas can be seen as the only form of logging in our approach. However, we make the observation that most of the time, allocation and reclamation exhibit locality[1]. Therefore, logging can be sidestepped entirely in this case, because the memory area an operation accesses will already be marked as active, and thus we do not have to wait for any additional store for memory leak prevention. When recovering after a failure, we simply need to traverse the memory areas that were active at the moment of the crash and detect which objects belonging to these areas are still linked in the data structures. This is significantly faster than generic mark-and-sweep garbage collection for instance [1].

Each of these three techniques is of independent interest, and can be applied individually while maintaining its associated benefits. Together, these techniques can be used to produce what we call by abuse of language *log-free durable concurrent data structures*, namely, durable concurrent data structures that, in the large majority of cases described above, require no logging whatsoever. As we show in the paper, these data structures provide up to an order of magnitude faster updates than a traditional log-based approach, both in single-threaded and in concurrent environments. Moreover, we achieve these benefits while maintaining low recovery times in case of restarts: even for gigabyte-sized structures, the time required to recover the structure is of only a few milliseconds. In terms of correctness, our implementations guarantee durable linearizability [26]. Briefly, all the operations completed before a crash are reflected after recovery.

We also highlight the practicality of our techniques by developing *NV-Memcached*, a durable version of Memcached [38] that is based on a lock-free, durable hash table. NV-Memcached performs similarly to the volatile memory version of Memcached.

Still, our approach is not a silver bullet. While it largely removes the cost of logging for all data structure sizes, this is especially beneficial for small and medium-sized data structures. Indeed, (1) these data structures exhibit high locality in memory allocation/deallocation, as we show in the paper, and (2) the relative cost of sync operations is higher for these data structures, as opposed to larger structures, where other costs, such as traversal, dominate.

To summarize, the contributions of this paper are:

1. *Link-and-persist*: a methodology for designing data structures with no logging in the main operations;
2. *Link cache*: a component that largely eliminates sync operations in durable data structures;
3. *NV-epochs*: a durable memory management scheme in which only a fraction of operations do any logging;
4. *NV-Memcached*, a durable version of Memcached based on our techniques;
5. A library of log-free durable data structures, as well as the link cache, NV-epochs, and NV-Memcached implementations, all available at `go.epfl.ch/nvram`.

The rest of the paper is organized as follows. In § 2 we recall relevant background. We describe our link-and-persist technique in § 3. We discuss our link cache in § 4, and memory management in § 5. We show experimental results in § 6 and discuss related work in § 7.

2 Background

Traditionally, storage has either been fast, but volatile (i.e., data is lost in case of a power failure), as is the case with DRAM, or non-volatile, but slow, as is the case with flash storage for instance. However, more recently, a new class of storage that promises low latency, byte-addressability, and non-volatility is becoming available. NVRAM latencies are expected to be somewhat larger than those of DRAM, with writes being more expensive than reads. Table 1 compares expected PCM and Memristor latencies [51, 54, 59] to those of DRAM and caches.

As highlighted in the introduction, one of the main difficulties when working with NVRAM stems from the fact that, by default, we do not control the order in which cache lines to which we have performed stores are evicted from the caches, and actually written to NVRAM. However, there are current and upcoming instructions [21, 23] on Intel processors[2], which allow us to ensure that a cache line is indeed written to memory. In this paper, we consider

[1] For small and medium sized data structures, as we show, this covers more than 99% of memory operations.

[2] In this work, we assume a TSO-like memory model; our work can be extended to more relaxed memory models as well.

	L1	L2	LLC	DRAM	PCM	Memristor
Read	2	6	15	50	50-70	100
Write	2	6	15	50	150	100

Table 1: *Caches, DRAM, and NVRAM (projected) latencies (ns).*

the *clwb* instruction, because it (a) writes-back a cache line without invalidating it—as opposed to *clflushopt*—and (b) it is only ordered with respect to fences (or to instructions that have an implied store fence, such as, for example, Compare-and-Swap)—as opposed to *clflush*. Property (b) is especially beneficial to performance, since it allows multiple cache-line write-backs to proceed in parallel [22]. We refer to one or more such instructions followed by a store fence as a *sync* operation.

A machine may fail at any point in time (e.g., due to a power failure), but can be expected to restart and resume normal operation (transient failure). We assume, as is commonly done in practice, that only the data stored in durable main memory is still available after a crash. The data that was in a processor's registers or in the write-back caches at the moment of the crash is not available after a restart. Nevertheless, our approach would be highly beneficial and remove the need for logging on an architecture that maintains enough residual energy to flush the register and the caches in case of a power failure as well.

Similar to related work [1], we assume that a region of NVRAM can be mapped to the same region of virtual memory across restarts. Alternatively, if this is not the case, we can update persistent pointers at recovery time.

In the context of concurrent software, it is important to define correctness conditions in the face of restarts. For this purpose, we use the concept of *durable linearizability* introduced by Izraelevitz et al. [26]. Essentially, a durably linearizable implementation guarantees that the state of the data structure after a restart reflects a consistent operation subhistory that includes all the completed operations at the moment of the crash.

3 The Link-and-Persist Technique

In this section, we present our *link-and-persist* technique for designing concurrent and durable data structures. We first argue that such data structures should be lock-free, then we detail the technique itself and how it can be used to obtain correct lock-free data structure implementations for NVRAM. We focus on implementations of linked lists, skip lists, hash tables, and search trees, which are commonly used in practice [10, 13, 38, 40, 41, 43]. Nevertheless, our techniques also apply to other data structures.

The Case for Lock-Free Algorithms. As noted by previous work [7, 26, 29, 46, 47], lock-free algorithms are a good fit for the NVRAM environment. This is because in lock-free algorithms, threads must ensure that the data structure is in a consistent state at all times, so that the failure of any number of threads does not prevent remaining threads from making progress. A beneficial consequence is that, when used with NVRAM, lock-free algorithms ensure that as long as threads' stores are persisted in the order in which they are issued (we show how this can be relaxed), regardless of when a crash occurs, upon a restart the data structure is in a consistent state that allows the execution to resume. Therefore, we remove the need for logging for the data structure itself, as opposed to transactional approaches which inherently require logging.

Our Technique. In linked data structures, a new node becomes visible when a link to it from an existing node is atomically inserted. Once this happens, other operations can see that the new node is present. Furthermore, in many algorithms, a node becomes logically deleted when a mark is atomically inserted on a link to signal deletion. After this, all operations enquiring about the state of this node will consider the node as no longer in the structure. A node becomes unreachable when the last link to it from another node in the data structure is atomically removed.

All these operations change the state of the node, and determine the return value of other operations which depend on the particular node. In the context of NVRAM, in order to ensure durable linearizability, it is therefore essential that all direct dependencies of an operation be durably written before the operation is performed. Otherwise, a scenario in which the user receives a return value, the system restarts, and the stored data no longer reflects the state observed by the user is possible.

In order to deal with this issue, the most straightforward approach is what we call the *link-and-persist* operation. Essentially, when performing a link update that changes the state of a node, the link is atomically updated normally, but contains a mark to signal that there is no guarantee its state is persisted. The updating operation then persists the newly modified link, and once the link is guaranteed to be persisted, it atomically removes the mark. If another operation whose result depends on the marked link occurs before the updating thread can persist it and remove the mark, the second operation will try to do these steps itself. This method involves no blocking, and introduces bounded overhead, thus being suitable for all concurrent algorithm classes, including lock-free and wait-free algorithms [17].

We illustrate our technique through the example of a lock-free linked list that uses the algorithm proposed by Tim Harris [15]. In the original (volatile) algorithm, in the case of inserts, once a node is properly allocated and initialized, we simply have to set the *next* pointer of its predecessor to point to it. In the case of a delete, we must first atomically flag the *next* pointer of the node to be deleted to signal logical deletion, after which the *next* pointer of its predecessor is set such that it bypasses the node to be deleted. Figure 1 shows the extra steps taken when inserting a new node using link-and-persist.

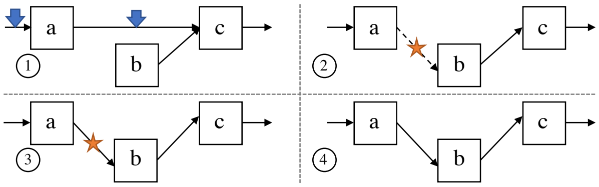

Figure 1: Stages of inserting a node in a linked list using link-and-persist. 1.) The new node (b) is created and its predecessor's (a) adjacent links (indicated by downward arrows) are persisted. 2.) The predecessor node's next pointer is atomically made to point to the new node. A mark (⋆) is added to the link to indicate it is not durable yet. 3.) The new node's incoming link is persisted. 4.) The mark is removed from the incoming link.

Durable Implementations. We have used link-and-persist to implement several durable data structures: linked lists, hash tables, skip lists, and BSTs. These structures model the set abstraction, and have methods to insert, remove, and search for elements identified through a unique key. We consider one implementation per data structure type, starting from the concurrent algorithm that has been shown to provide the best performance and scalability [8]. Our linked list is based on Harris' algorithm [15], the hash table uses one Harris linked list per bucket, the skip list uses the lock-free algorithm by Herlihy et al. [19], while the BST uses the algorithm proposed by Natarajan and Mittal [45]. Other algorithms and data structures can be similarly modified.

Correctness. Our data structures are linearizable, since we start from linearizable algorithms and add only flushes, which do not impact linearization points. We also ensure two additional properties [12]. First, each update operation ensures that its changes are durable before returning. Second, each operation O ensures that all operations O depends on (that involve some of the same nodes and were already linearized) are also durably linearized before O makes changes. Together, these two properties ensure durable linearizability, because they ensure that after a restart, the data structure reflects a consistent cut [26] of the history including all operations that completed before the crash and potentially some operations that were ongoing when the crash occurred.

The first property is easily ensured by durably writing any new edges or nodes introduced by an operation. Making sure an edge e is durably written just means checking if e is marked, and issuing write-backs only if e is not yet durable. The second property is achieved because operations ensure that (1) before an edge is modified, the edge is durably written and (2) incoming and outgoing edges (*adjacent edges*) of nodes involved in the operation are durable before proceeding.

We detail point (2) on a linked list (similar considerations apply for the other linked data structures). For a successful search, we make sure adjacent edges to the returned node are durably written before returning. For a failed search, we make sure the node is durably unreachable before returning (e.g., in the case where a node is marked but not yet durably unlinked). For the parse phase of a modify operation (insert or delete) [8], we take the same steps as for a search. For an insert, we also ensure that adjacent edges to the predecessor are durable before linking the new node. For a delete, we ensure that adjacent edges to the target node T and to T's predecessor are durable before unlinking the target node. In all cases, if an edge e has changed between the time e is read and the time we try to durably write e, then the operation that changed e made sure e was durable.

4 Limiting Write-Backs: the Link Cache

We now introduce our second technique, aimed at further reducing the number of *sync* operations in durable data structures.

4.1 Link Cache Overview

As discussed in § 2, batching multiple cache line write-backs is significantly faster than persisting them one at a time. Therefore, we propose the following scheme: when doing an update, do not immediately persist links, but place them in a fast, *volatile* cache (the *link cache*), and write back all the links in this cache when an operation that directly depends on one of them occurs. Of course, this means that clients which have inserted links into the link cache can only consider the operation completed once the link cache is flushed to NVRAM. The changes of a link and the insertion of a corresponding entry in the link cache must occur atomically (achievable in a non-blocking manner by using hardware transactional memory, or by marking the pointers to be inserted in the link cache while the operation is ongoing). If a restart happens, modified links currently in the link cache might be lost. However, this is not problematic: the fact that these link addresses were in the cache at the moment of restart means that no operation that directly depends on them completed, and thus its outcome may or may not be visible. We thus maintain the durable linearizability property. In addition, an atomic update of an ongoing operation not being durably recorded does not leave the data structure in an incorrect state after a restart. Where ordering of durable updates is necessary, we enforce it in the data structure algorithm (see § 3). The link cache is practical as long as inserting an entry in the cache is faster than waiting for a cache line to be written back to NVRAM.

4.2 Link Cache Implementation

Our main aims for the link cache are small memory footprint, non-blocking operation, and fast insertions. With these requirements in mind, we chose to make insertions in the cache best effort. The cache is only useful if it can improve the time updates spend waiting. Therefore, if an

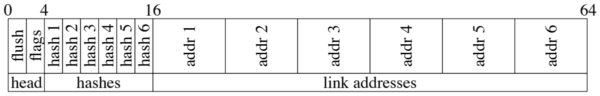

Figure 2: *A bucket in the link cache.*

update attempts to insert an entry in the cache, but does not succeed on the first try, it gives up and persists the modified link itself instead of waiting. Thus, link cache insertions have constant worst case performance.

Our hash table has a configurable (but fixed throughout the execution) number of buckets. Each bucket spans exactly one cache line, and can store up to 6 links. Links concerning a particular key map to one and only one bucket. Figure 2 details the contents of a bucket. The first two bytes are used to signal whether the bucket is currently being flushed. The next two bytes are used to store the current state of each of the entries in the bucket. An entry can be free, pending or busy. We next store the 6 keys associated with the links in the bucket. In order to be able to fit 6 entries in a single cache line, instead of storing the entire key, we only store a 2-byte hash for each of the keys. While this might result in false collisions, they are extremely unlikely. With 32 buckets, we have a hash space of size 2M. Even if false collisions do occur, this is not problematic: we would simply be triggering a flush of the links in the cache when this might not have been strictly necessary. The hashes therefore require 12 bytes in each bucket. The remaining 48 bytes in the cache line are used to store the addresses of the 6 links.

The interface of the link cache has three operations, which we discuss in the following.

Try Link and Add. If there is space in the link cache, this operation atomically modifies the link in the data structure and inserts an entry in the link cache. The operation first tries to reserve an entry in the link cache. To this effect, it tries to atomically change the state of an entry from free to pending. If no free entry exists, the link cache is being flushed, or the attempt to reserve an entry is not successful, the caller is notified that the operation did not succeed and that it should persist the link itself. Once an entry is reserved, we set the corresponding key and link address in the link cache. Next, we try to update the link in the data structure. We insert the new link, but use a bit to mark the fact that for now, this link has been neither persisted, nor has its addition to the link cache been marked as completed. If the link update fails, we set the state of the link cache entry to free and return failure to the caller. We next set the state of the entry in the link cache to busy (to mark the fact that we have added the key and link address, and that the link address in fact contains the value that we want to persist). Finally, we remove the mark from the link in the data structure.

The fact that this operation is best effort, and the fact that we do several atomic updates (link marking, transitioning between multiple states) just in order to be able to handle concurrent readers make this operation an ideal candidate for the use of hardware transactional memory (HTM). In fact, we first try to execute a fast-path HTM-based operation before reverting to the code presented above. In the HTM path, we do not need to insert a marked link into the data structure, and we can avoid going through the pending state in the link cache.

Flush. This operation writes all the finalized entries in a bucket to NVRAM. The operation first atomically increments the corresponding flushing counter to signal that it is in the process of flushing a bucket. The flush operation then issues write-backs for the link addresses in the busy entries in the bucket one by one (without waiting for the write-backs to complete) and sets the state of these entries to free. Next, the operation checks if any of the entries we have not written back have become busy (completed) in the meanwhile, and if yes, issues write-backs for them as well. This is repeated until no new busy entries appear. The thread then waits for the write-backs to complete by issuing a fence, decrements the flushing counter, and returns.

Scan. The scan operation is given a key and searches for any link pertaining to this key in the link cache. If such an entry is found in busy state (i.e., the insertion of the link was finalized), a flush is triggered. If an entry is found but is in pending state, the operation checks whether the new pointer has been inserted into the data structure. If this is the case, the current operation's linearization point should be after that of the operation currently inserting into the link cache, and therefore the current operation triggers a write-back of the new value of the link. Otherwise, the current operation's linearization point is before that of the update, and no further action needs to be taken. In order to guarantee durable linearizability, every data structure operation needs to call the scan method for its key, as well as for its predecessor in the structure in case of updates. However, this is as fast as reading two cache lines.

Illustration: Link Cache Effectiveness. We illustrate the effectiveness of the approach using the same linked list example employed in the previous section. The schedule of operations in our example, as well as the way the link cache is constructed are presented in Figure 3. We assume an initially empty link cache, and we only depict the effects of operations that change the state of the data structure or the link cache. Normally, updates would have to wait for one link to be persisted in the case of the insert operations, and two links in the case of the delete operation (one for marking and one for deletion). However, in this example, by using the link cache, we have replaced writing back 4 cache lines one at a time by a single batch of 3 cache line write-backs.

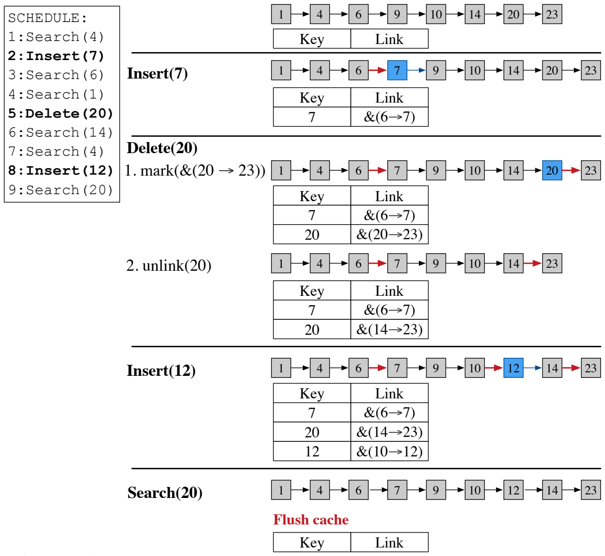

Figure 3: *Example of how the link cache is constructed.*

5 Memory Management with NV-Epochs

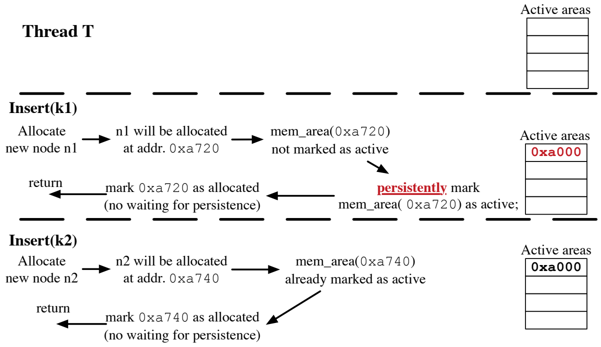
We now address another issue that is unavoidable whenever inserting or removing nodes in a linked concurrent data structure: memory management.

5.1 Overview

Two separate steps need to be performed both when inserting and removing a node: in case of an insertion, memory for the new node is first allocated and initialized, after which the node is linked into the data structure; in case of a deletion, the node is first unlinked from the data structure, and later, when we are sure no references to it exist, its memory is freed. If a restart occurs between these two main steps both in case of an insertion and a removal, a persistent memory leak occurs: we have allocated data that is not linked anywhere in our data structure.

The typical way of addressing the issue in the context of NVRAM is to use some form of logging: before allocating and linking, we log our intention, as we do before unlinking and freeing memory. Once the operation has (durably) completed, the log entry can be removed. However, this entails an extra write to NVRAM per update. In addition, this write needs to complete before we can proceed with the update, thus producing a non-negligible increase in the latency of updates.

In order to avoid waiting for the durable log to be written at each allocation or deallocation, we propose keeping track of coarser-grained active memory areas instead of keeping track of individual allocations/deallocations. Intuitively, when allocating, threads often reserve larger contiguous memory areas from which they serve user requests; thus, consecutive allocations tend to belong to the same memory area. In addition, memory reclamation schemes keep track of which objects have been unlinked, and periodically free those to which no references are held. This reclamation step is only run periodically for performance considerations (typically, when a certain number of unlinked objects have been collected). Therefore, we tend to free multiple nodes at the same time. Out of these, it is usually the case that several of them map to the same memory area. Thus, there is a certain degree of locality in deallocation as well. Hence, if instead of logging every node we unlink from the data structure, we only keep track of the memory areas from which the unlinked nodes come from, we can expect significant savings in term of write-backs to NVRAM: most of the time, the memory area will already be marked as active. We illustrate the potential benefits of the approach in Figure 4.



Thread T
Active areas
Insert(k1)
Allocate new node n1
n1 will be allocated at addr. 0xa720
mem_area(0xa720) not marked as active
persistently mark mem_area(0xa720) as active;
mark 0xa720 as allocated (no waiting for persistence)
return
Active areas
0xa000
Insert(k2)
Allocate new node n2
n2 will be allocated at addr. 0xa740
mem_area(0xa740) already marked as active
mark 0xa740 as allocated (no waiting for persistence)
return
Active areas
0xa000

Figure 4: *Illustration: thread T performs two inserts. While both allocate memory, with our approach, only the first allocation performs a durable write.*

While allowing us important time savings at run time, this method does defer some work for when we need to recover. In particular, we need to go over the allocated memory addresses in the active areas at the time of shutdown, and check if they indeed represent nodes that are linked into the data structure. To be able to do this, we also make the assumption data structure nodes belong to memory areas which store no other type of data. To achieve this, we use an allocator specifically for such nodes.

We first briefly describe the principles of the memory reclamation scheme that we employ, after which we go into more details into how we keep track of the active memory page set, and how we recover after a failure.

5.2 Epoch-Based Memory Reclamation

Epoch-based memory reclamation [11] is based on the following principle: if an object is unlinked, then no references to the object are held after the operations concurrent with the unlink have finished. One method of using this principle in practice (and which we use in our reclamation scheme) is to provide each thread with a local counter, keeping track of the *epoch* the current thread finds itself in. The epoch of a thread is incremented when the thread starts an operation, and when it completes it. Thus, if the current epoch number of a thread is odd, the thread is currently active and in the middle of an operation. We collect multiple objects, and free them when the vector formed by the current epochs of the threads is larger than the one when any of the objects were unlinked (only the epochs of threads that were active at the moment of unlinking need to be larger). We refer to the set of unlinked nodes which we attempt to free together as a *generation*.

5.3 Interface with NVRAM Allocators

Memory allocators usually reserve a large contiguous address space, which is then recursively split into smaller chunks. The chunk from which an object is allocated depends on the object's size. These chunks of contiguous memory are generally referred to as allocator *pages*. Since smaller pages from which data structure nodes are directly allocated are part of larger pages, we can configure the granularity of the pages which we keep track of. High-performance concurrent allocators usually partition the memory space for allocations among threads, such that there is minimal communication necessary between them: pages are assigned to individual threads.

Existing persistent allocators provide the capability of atomically allocating and linking (or unlinking and deallocating) objects, which, as discussed, is generally achieved through some form of logging. We do not require this capability: we only require that the persistent allocator is able to correctly maintain its durable metadata when allocating or deallocating. Moreover, in our case, the last write-back (which marks the memory as allocated or free in a thread's local allocator metadata, and is usually the only write-back the allocator issues) does not have to be completed before proceeding: in the case of an allocation, the data structure algorithm will have to wait for the write-backs to complete after the memory is initialized, while in the case of deallocations the memory reclamation scheme waits for all the deallocations it issues at once to be completed. Thus, in most cases, when the allocator only does one store to thread-local data, we do not have to issue a sync operation for the allocator metadata. Based on its metadata and our structures maintaining active pages, the allocator can recover its state in case of a restart. An existing persistent concurrent allocator can be used with our system, with the small changes we mentioned. We also require the allocator to provide a method that returns the next node address to be allocated. As allocators generally assign larger chunks of memory to individual threads, and threads do not "steal" memory from one another, adding this method is trivial. We use a modified version of jemalloc [27], with write-backs inserted when updates to allocator metadata occur to model the run-time performance of persistent allocators.

5.4 Tracking Active Memory Areas

In our approach, each thread keeps a set of active memory pages in a structure called the *active page table (APT)*. For each memory page, we also store some metadata determining when the page can be considered as no longer active and can thus be removed from the set. This metadata consists of (i) the largest epoch at which this thread has unlinked memory belonging to the page from the data structure, and (ii) the largest epoch at which this thread has allocated memory belonging to this page. The addresses of the memory pages need to be stored durably (meaning that when we insert a new page, we have to wait for the write-back of the address of the page to complete before continuing), while the metadata is only needed for removing table entries, and is not needed in case of a restart.

We attempt to trim a thread's active page table when it exceeds a certain size. For this purpose, the metadata associated with each page is used as follows. A page from which unlinks have happened is active until the epoch-based memory reclamation scheme is guaranteed to have freed all unlinked nodes. This can be verified by having the reclamation scheme keep track of the epoch vector of the most recent generation of objects that were collected. A page from which allocations have happened is active until the insert operation has finished, i.e., while the current epoch of the thread is equal to the last epoch at which a node allocation from this page took place. When using a link cache, we also have to ensure that it contains no entries pertaining to the page under consideration. For this reason, the operation that attempts to trim the active page table issues a link cache flush as well. If all the unlinked nodes have been freed, and all the allocated nodes have been linked, the page can be removed from the table.

We use a separate persistent allocator for the active memory page table. Allocations for the table happen very infrequently (we preallocate a number of entries for each thread at start-up, and allocate multiple entries at once when more space is needed; in addition, tables usually do not grow beyond a certain size, and thus no allocations are needed from a certain point). We require that this second allocator provide the interface previous work on NVRAM memory allocators does [6, 24, 42, 51, 56]. In this instance, we used the allocator provided with `nvml` [24].

5.5 Recovery after Transient Failures

On recovery, we must make sure that there are no nodes that are not linked in the data structure but are allocated.

There are two approaches to verifying this, both of which can be parallelized in order to decrease recovery time. The efficiency of each method depends on the size of the data structure, the complexity of the search method, and the size of the memory space that needs to be verified. In both cases, we assume a well-formed data structure. That is, the recovery procedure should first ensure that the data structure is brought to a consistent state before attempting to remove memory leaks. This step is not necessary for any of the data structures we developed.

The first approach is to go over all the node addresses in the active memory pages at the moment of the crash, and, if an address *n* is allocated, search the data structure for *n*'s key. If (i) the search returns a result and (ii) the

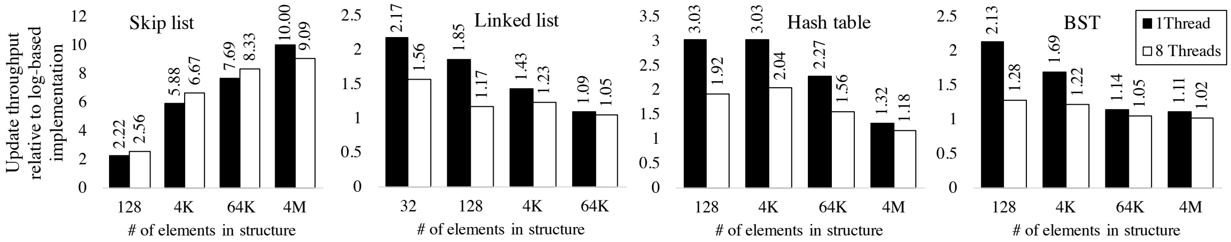


Figure 5: *Update throughput of data structures implemented using our techniques (1 and 8 threads). Values are normalized to throughput of redo log based implementations (1 and 8 threads, respectively).*

address of the returned node is the same as *n*, we leave the node as allocated. Otherwise, we free the node. Condition (ii) is necessary because we might have an allocated but uninitialized node. Therefore, a node with the key that we retrieve from that uninitialized memory might indeed exist in the data structure, but it might not be pointing to this uninitialized memory. The second approach is to traverse the structure only once, and for each node check if its address belongs to the set of active pages. If this is the case, store the address of the node in a volatile memory buffer. Next, go over all the allocated node addresses in the active memory pages, and check if they are in the volatile memory buffer. If they are not, it means they are not linked in the data structure and can be deallocated. Both of these approaches can be parallelized.

We note that in our implementation, it cannot be the case that a node is linked into the data structure, but not marked as allocated. This is because before linking a node in the data structure, we issue a store fence that ensures that the contents of the node, as well as the allocator metadata (for which we issue write-backs, but do not wait for last one to complete when calling the allocation method) are durably written.

6 Evaluation

We now study the impact our proposed techniques have in practice. We look at the overall performance improvements, as well as at the benefits of individual techniques.

6.1 Experimental Setup

We run experiments on an Intel Xeon machine having four E7-4830 v3 12-core processors operating at 2.1–2.7 GHz, with cache sizes of 32KB (L1), 256KB (L2), and 30MB (LLC, per die). We work with key-value pairs, both of which are 8B in size. Nodes are cache-aligned to 64B. Larger values can be accommodated by using indirection instead of directly storing values inside nodes. Shown values are the median of 5 repetitions.

As neither NVRAM with latencies comparable to DRAM, nor processors providing the `clwb` instruction are available yet, we simulate `clwb` by writing data normally, and then pausing for an appropriate number of cycles, similar to previous work [3, 6, 33, 55, 56]. The number of cycles to pause is chosen so as to account for the increased latency of NVRAM (we assume an NVRAM write latency of 125ns, which is an average of the projected values). Intel reports issuing several flushes with `clflushopt` can be up to an order of magnitude faster than flushing them one at a time using `clflush` [22]. We assume similar performance characteristics for the `clwb` instruction. In order to account for the benefit of flushing several cache lines at a time over flushing them one by one, we inject the artifical pause described above only once per batch of cache lines being written to NVRAM (e.g., only once per flush of the link cache).

6.2 Data Structure Performance

We look at the run time behavior of our data structures. We focus on updates, as it is these operations that must be durably recorded in NVRAM. We compare our implementations with alternatives that use lock-based critical sections (and thus use logging). We find that for such data structures, an approach that uses redo logging provides good performance in addition to ensuring durable linearizability. We use the algorithms that we find perform best for each data structure: the lazy linked list [16], a lock-based skip list by Herlihy et al. [18], bst-tk [8], and a hash table with a lazy linked list per bucket. We manually apply logging to each data structure, taking advantage of knowledge of the algorithms so as to minimize the number of *syncs* while maintaining correctness. We do this for fairness of comparison, as the alternative of using a generic transactional/logging framework would have likely resulted in more *syncs* and thus worse performance.

In Figure 5, we show the increase in the number of updates per second obtained by using our structures relative to log-based implementations. We use a workload where 50% of the operations are inserts of random keys, while 50% are removes of random keys, and show results for 1 and 8 concurrent updating threads. We show relative improvements, as the precise latencies are dependent on the assumptions made about `clwb` instruction performance, as well as NVRAM store latencies.

Our method yields important benefits regardless of the data structure type. In particular, for the skip list, where in a log-based implementation a logarithmic number of locks are held while a logarithmic number of updates must be logged, our approach results in an order of magnitude increase in performance. We note that for small

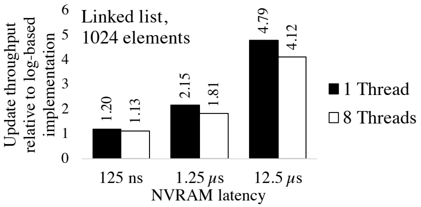

Figure 6: *Update throughput compared to redo log based implementation for various NVRAM write latencies.*

and medium sized data structures, we obtain significant improvements by applying our techniques. For large structures however, our improvements become less impressive. There are two main reasons for this. The first is that as the structure size increases, the latency of an update becomes dominated by the time needed to reach the point in the data structure where the modification needs to be made, both due to the need to traverse more pointers, and because when the structure does not fit in the caches anymore, reads become more expensive. In the case of the linked list in this experiment, it is in fact the only factor that is responsible for the decrease in latency improvement. The second reason has to do with a decrease in the efficiency of our active page tables for deallocations as the structures become large. We discuss why this is, as well as ways of alleviating the issue in § 6.3. In addition, as the number of concurrent updating threads increases, the link cache becomes somewhat less efficient (also discussed in § 6.3). Thus, for high degrees of concurrency, we can turn the link cache off.

In our experiments, we use NVRAM latencies comparable to those of DRAM. Nevertheless, current technologies still have significantly larger latencies. We therefore also perform a simulation where we increase write latency (Figure 6). These measurements are representative of structures which are small enough for reads to be served from cache. As NVRAM write latency increases, our approach becomes much more effective: the ratio between our throughput and that of a log-based implementation becomes inversely proportional to the ratio between the number of *sync* operations in the two approaches.

To summarize, it is important to note that while the precise magnitude of the improvements of our approach may depend on the characteristics of the NVRAM technology being used, these experiments show that our approach is beneficial for all the situations we have considered.

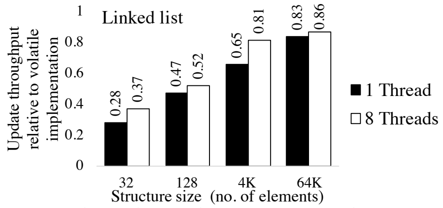

Figure 7: *Update throughput compared to an implementation oblivious of NVRAM.*

We also compare our approach to algorithms aimed at volatile memory, which do not concern themselves with data durability. Briefly, the per-operation overheads related to durability introduced by our approach are constant. While these might account for a non-negligible fraction of the operation latency for small structures, for larger structures, as total operation latency increases, these become less apparent. This is illustrated on a linked list in Figure 7. Thus, in terms of performance, our approach represents a middle ground between volatile data structures and log-based durable approaches.

6.3 Performance: a Closer Look

We now explore the impact each of our techniques has on overall performance.

Link-and-Persist and Link Cache. We evaluate the individual impact on performance of the link-and-persist technique and of the link cache. We measure the throughput of each data structure with the log-based implementation, with a log-free implementation that uses link-and-persist and with a log-free implementation that uses the link cache (all using identical memory management schemes). We then normalize the throughput of the log-free implementations with respect to the log-based implementation to determine the change in performance. We use an update-only workload, with 1024-element data structures. The link cache occupies 32 cache lines.

Figure 8 shows the results. As a result of removing logging, algorithms using link-and-persist outperform log-based alternatives for all structures, both in single-threaded and in concurrent scenarios. Moreover, in most cases, the link cache brings an additional increase in performance with respect to the link-and-persist implementation, due to its batching of write-backs.

NV-Epochs. We evaluate the efficiency of our active page table. The active page table is only efficient if it saves *sync* operations: i.e., if an important fraction of updates do not have to write active page table entries.

We consider 4KB memory pages, and we try to trim an active page table when it exceeds 16 elements. We measure the fraction of allocations and deallocations that

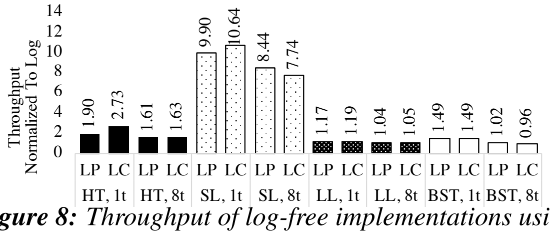

Figure 8: *Throughput of log-free implementations using link-and-persist (LP) and the link cache (LC), normalized to throughput of log-based implementations. Data structures are 1024-element hash table (HT), skip-list (SL), linked list (LL) and binary search tree (BST). Workloads are 100% updates, single-threaded (1t) or with 8 concurrent threads (8t).*

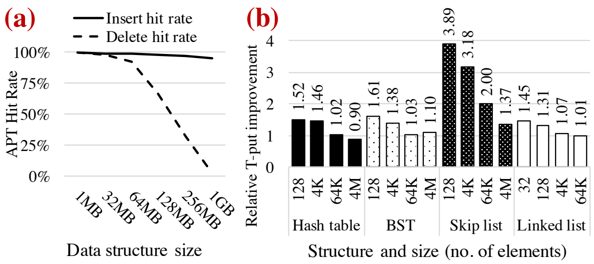

Figure 9: *Active page table hit rates and throughput improvements due to NV-epochs.*

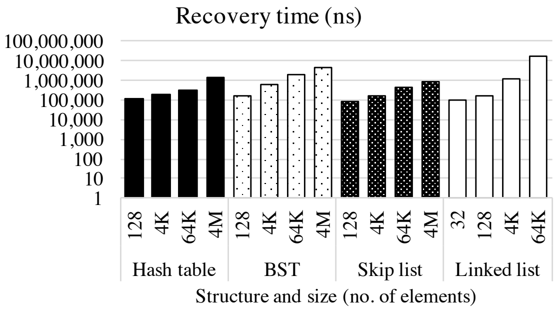

Figure 10: *Data structure recovery times.*

do not need to add an entry to the active page tables (that is, the fraction of hits in the active page table). Results are shown in Figure 9.a. In this experiment, we have used a skip list. Results are similar for other data structures, as the important factor is the data structure size.

We note that the hit rate is close to 100% for allocations, regardless of structure size. In case of deallocations, the hit rate starts decreasing after the structure exceeds 64 MB (more than 1M nodes). This is because as the amount of used memory increases, there is less locality in memory reclamation steps. However, fast memory allocation and deallocation is particularly important for small data structures that fit in the write-back caches, which have small access latencies. In such situations, our approach is effective for both types of operations.

This conclusion is reflected in the throughput observed when using NV-epochs (Figure 9.b): for small and medium-sized structures, NV-epochs can increase throughput several-fold. For large structures, when keeping track of memory at 4KB granularity, NV-epoch's effectiveness decreases. However, the granularity at which we keep track of active memory areas is adjustable. Larger memory areas result in higher hit rates and throughput improvements, at the expense of increased recovery time.

6.4 Recovery

We now measure the time it takes to recover a data structure. We simulate a crash by first stopping execution of the algorithm at an arbitrary point. Then, we ensure the structure's data is not in the write-back caches (by purging the caches). Next, we run the recovery process which first brings the data structure to a consistent state and then traverses its active pages to free allocated-but-not-reachable nodes[3]. We show recovery times for the various structures as a function of their size in Figure 10.

For hash tables, BSTs, and skip-lists, which have fast search methods, recovery is extremely efficient: even in structures with 4M elements, we can recover in less than 5ms. Recovery time for such structures is two orders of magnitude lower than doing a full mark-and-sweep pass in this environment [1]. In the case of the linked list, which has a linear search method, in order to avoid repeated passes over the entire structure, we employ a strategy similar to mark-and-sweep. Recovery in this case is somewhat slower: a linked list with 64K elements can be recovered in 16ms. For all structures, recovery time increases with data structure size. Small structures tend to have a smaller number of active pages at any point in time. In addition, search operations must traverse more pointers for larger structures, and data is less frequently present in the higher-level caches. We believe the observed recovery times are acceptable in case of a reboot.

6.5 NV-Memcached

We now show how our techniques can be applied in a larger context by developing an object caching system for durable memory: *NV-Memcached*. The main idea behind *NV-Memcached* is to make Memcached durable by replacing its core data structures—the hash table and the slab allocator—with durable versions. This transformation entails interesting technical challenges.

First, Memcached uses a lock-protected sequential hash table; thus replacing it with our durable non-blocking hash table would negate the latter's lock-freedom. We solve this challenge by basing *NV-Memcached* on *memcached-clht* [34], a version of Memcached that avoids protecting the hash table with locks by employing a concurrent hash table—CLHT [8], and replacing CLHT with our log-free durable hash table.

The second challenge is related to the recovery of items. With a naive implementation of a durable slab allocator, it is possible for memory leaks to occur after a restart. An item can be allocated, but not yet linked in the hash table, or an item can be unlinked from the hash table but not yet marked as free in the allocator. We address this issue with a similar approach to our active page technique (§ 5): we keep track of active slabs. During recovery, we iterate over each thread's active slab table and free any memory which is marked as allocated but not yet or no longer reachable from the hash table.

We compare the performance of *NV-Memcached* to that of Memcached and memcached-clht using

[3] After recovery, new threads can spawn and resume execution at a "safe" point (a point in the instruction stream from which execution can continue regardless of when the crash occurred). Determining such safe points in general is outside the scope of this paper, but for our specific case, any point in-between two data structure operations is a safe point.

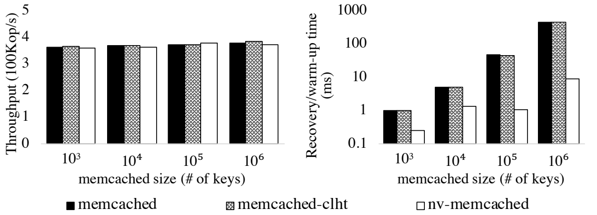

Figure 11: Performance and warm-up time comparison of Memcached and NV-Memcached.

memtier-benchmark [50]. The benchmark runs for a predetermined amount of time, issuing a mix of `get` and `set` operations using keys drawn uniformly at random from a given key range. The key range and the ratio of `get` to `set` operations are configurable. Before each experiment, we warm up the cache by inserting items covering half of the key range. Both the server and the client are run with the default number of threads (4). The results are averaged over 5 runs for each configuration.

The first experiment compares the throughput of the three systems for different key ranges, under a 1:4 `set` to `get` ratio. Figure 11 shows that there is no notable performance drop between Memcached, memcached-clht and *NV-Memcached.* Thus, our techniques remain practical when applied to real-world applications.

The second experiment compares, for three different key range sizes, the warm-up time of Memcached and memcached-clht (the time it takes to populate the cache with half of the key range) to the recovery time of *NV-Memcached* (the time it takes to recover after a restart). Figure 11 shows that populating a (volatile) Memcached or memcached-clht instance with items can take up to three orders of magnitude more time than recovering a *NV-Memcached* instance of the same size. This justifies the practicality of a non-volatile memory caching service—recovering such a service after a machine restart takes just a fraction of the time necessary for its volatile counterpart to get re-populated (and thus be useful again).

7 Related Work

Several approaches have used transactions as a means of interaction with NVRAM [2, 6, 9, 14, 25, 28, 30, 33, 37, 56]. The benefits of transaction-based approaches are generality and ease of use. Yet, their inherent and significant overhead has been recently highlighted (e.g., [52]), and several attempts to alleviate the problem have been proposed. Izraelevitz et al. [25] introduce an approach in which by reliably keeping track of the last executed store instruction at each thread, one is able to simply complete the execution of critical sections after a restart. While efficient if write-back caches are persistent, the approach otherwise requires a write to the log for each store in critical sections. Kolli et al. [30] focus on static transactions in lock-based applications, and attempt to minimize persist dependencies in order to limit waiting time. The authors also show how the commit stage of transactions can be performed while not holding any locks. Similarly, Kamino-Tx [37] uses a copy-on-write technique, and avoids logging in critical sections. DudeTM [33] optimizes redo logging by first executing the transaction and obtaining a redo log in volatile memory, then atomically flushing the redo log to persistent memory, and only then modifying the original data.

In this paper, we go beyond optimizations to logging: we provide a method that in the common case when locality is preserved, allows us to circumvent such logging altogether in the context of concurrent data structures.

A number of efforts [2, 4, 20] have been dedicated to the generation of correct durable applications for NVRAM from existing code. These approaches generally assume lock-based code. Due to their general-purpose nature, they incur additional overheads when compared to our method, in particular due to logging.

Several proposals for indexing trees for NVRAM have been made [5, 32, 48, 54, 58]. However, they either require logging in some form, or do not address potential memory leaks during new node creation. In addition, the techniques cannot be easily generalized to other data structures. Friedman et al. [12] introduce lock-free algorithms for durable queues, but do not go beyond this data structure, or consider memory management. Other work advocating lock-free algorithms either assumes durable caches [46, 47], or automatically generates durable algorithms that issue syncs after each update [26].

The problem of general memory allocation and reclamation for NVRAM has also received attention. Generic persistent memory frameworks [2, 6, 35, 56] handle allocation and reclamation as part of the transaction mechanisms they provide, and thus rely on logging. nvm_malloc [51] provides an interface to allocate and free persistent memory, but because of fine-grained accounting, incurs significant overheads for each allocation and deallocation. Makalu [1] and NVthreads [20] also keep track of allocator metadata at a coarser-grain level. However, they incur higher costs at recovery time, as they require a garbage collection pass over the entire memory. Unlike all these approaches, we propose a method that is highly tuned to concurrent data structures. Thus, we are able to minimize overheads at both run time and recovery time. Our approach in fact builds upon basic memory allocators, and handles concurrent memory reclamation as well. Thus, our scheme can take advantage of an efficient durable memory allocator at its core.

Other Memcached adaptations for NVRAM have been proposed, but they use transactions extensively [6, 36, 44] or they do not guarantee all completed requests are durable [57], whereas *NV-Memcached* ensures all completed requests are durable and limits transactions to the slab allocator code by using our log-free hash table.

Stable and Consistent Membership at Scale with Rapid

Lalith Suresh[†], Dahlia Malkhi[†], Parikshit Gopalan[†], Ivan Porto Carreiro[◇], Zeeshan Lokhandwala[‡]

[†]VMware Research, [‡]VMware, [◇]One Concern

Abstract

We present the design and evaluation of Rapid, a distributed membership service. At Rapid's core is a scheme for *multi-process cut detection* (CD) that revolves around two key insights: (i) it suspects a failure of a process only after alerts arrive from multiple sources, and (ii) when a group of processes experience problems, it detects failures of the entire group, rather than conclude about each process individually. Implementing these insights translates into a simple membership algorithm with low communication overhead.

We present evidence that our strategy suffices to drive unanimous detection almost-everywhere, even when complex network conditions arise, such as one-way reachability problems, firewall misconfigurations, and high packet loss. Furthermore, we present both empirical evidence and analyses that proves that the almost-everywhere detection happens with high probability. To complete the design, Rapid contains a leaderless consensus protocol that converts multi-process cut detections into a view-change decision. The resulting membership service works both in fully decentralized as well as logically centralized modes.

We present an evaluation of Rapid in moderately scalable cloud settings. Rapid bootstraps 2000 node clusters 2-5.8x faster than prevailing tools such as Memberlist and ZooKeeper, remains stable in face of complex failure scenarios, and provides strong consistency guarantees. It is easy to integrate Rapid into existing distributed applications, of which we demonstrate two.

1 Introduction

Large-scale distributed systems today need to be provisioned and resized quickly according to changing demand. Furthermore, at scale, failures are not the exception but the norm [21, 30]. This makes membership management and failure detection a critical component of any distributed system.

Our organization ships standalone products that we do not operate ourselves. These products run in a wide range of enterprise data center environments. In our experience, many failure scenarios are not always crash failures, but commonly involve misconfigured firewalls, one-way connectivity loss, flip-flops in reachability, and some-but-not-all packets being dropped (in line with observations by [49, 19, 37, 67, 41]). We find that existing membership solutions struggle with these common failure scenarios, despite being able to cleanly detect crash faults. In particular, existing tools take long to, or never converge to, a stable state where the faulty processes are removed (§2.1).

We posit that despite several decades of research and production systems, stability and consistency of existing membership maintenance technologies remains a challenge. In this paper, we present the design and implementation of *Rapid*, a scalable, distributed membership system that provides both these properties. We discuss the need for these properties below, and present a formal treatment of the service guarantees we require in §3.

Need for stability. Membership changes in distributed systems trigger expensive recovery operations such as failovers and data migrations. Unstable and flapping membership views therefore cause applications to repeatedly trigger these recovery workflows, thereby severely degrading performance and affecting service availability. This was the case in several production incidents reported in the Cassandra [10, 9] and Consul [26, 25, 27] projects. In an end-to-end experiment, we also observed a 32% increase in throughput when replacing a native system's failure detector with our solution that improved stability (see §7 for details).

Furthermore, failure recovery mechanisms may be faulty *themselves* and can cause catastrophic failures when they run amok [42, 40]. Failure recovery workflows being triggered ad infinitum have led to Amazon EC2 outages [5, 6, 4], Microsoft Azure outages [7, 48], and "killer bugs" in Cassandra and HBase [39].

Given these reasons, we seek to avoid frequent oscillations of the membership view, which we achieve through stable failure detection.

Need for consistent membership views. Many systems require coordinated failure recovery, for example, to correctly handle data re-balancing in storage systems [3, 28]. Consistent changes to the membership view simplify reasoning about system behavior and the development of dynamic reconfiguration mechanisms [65].

Conversely, it is challenging to build reliable clustered services on top of a weakly consistent membership service [11]. Inconsistent view-changes may have detrimental effects. For example, in sharded systems that rely on consistent hashing, an inconsistent view of the cluster leads to clients directing requests to servers that do not host the relevant keys [12, 3]. In Cassandra, the lack of consistent membership causes nodes to duplicate data re-balancing efforts when concurrently adding nodes to a cluster [11] and also affects correctness [12]. To work around the lack of consistent membership, Cassandra ensures that only a single node is joining the cluster at any given point in time, and operators are advised to wait *at least two minutes* between adding each new node to a cluster [11]. As a consequence, bootstrapping a 100 node Cassandra cluster takes three hours and twenty minutes, thereby significantly slowing down provisioning [11].

For these reasons, we seek to provide strict consistency, where membership changes are driven by agreement among processes. Consistency adds a layer of safety above the failure detection layer and guarantees the same membership view to all non-faulty processes.

Our approach

Rapid is based on the following fundamental insights that bring stability and consistency to *both* decentralized and logically centralized membership services:

Expander-based monitoring edge overlay. To scale monitoring load, Rapid organizes a set of processes (a *configuration*) into a stable failure detection topology comprising *observers* that monitor and disseminate reports about their communication *edges* to their *subjects*. The monitoring relationships between processes forms a directed expander graph with strong connectivity properties, which ensures with a high probability that healthy processes detect failures. We interpret multiple reports about a subject's edges as a high-fidelity signal that the subject is faulty.

Multi-process cut detection. For stability, processes in Rapid (i) suspect a faulty process p only upon receiving alerts from multiple observers of p, and (ii) delay acting on alerts about different processes until the churn stabilizes, thereby converging to detect a global, possibly multi-node *cut* of processes to add or remove from the membership. This filter is remarkably simple to implement, yet it suffices by itself to achieve *almost-everywhere agreement* – unanimity among a large fraction of processes about the detected cut.

Practical consensus. For consistency, we show that converting almost-everywhere agreement into full agreement is practical even in large-scale settings. Rapid's consensus protocol drives configuration changes by a low-overhead, leaderless protocol in the common case: every process simply validates consensus by counting the number of identical cut detections. If there is a quorum containing three-quarters of the membership set with the same cut, then without a leader or further communication, this is a safe consensus decision.

Rapid thereby ensures all participating processes see a strongly consistent sequence of membership changes to the cluster, while ensuring that the system is stable in the face of a diverse range of failure scenarios.

In summary, we make the following key contributions:

- Through measurements, we demonstrate that prevailing membership solutions guarantee neither stability nor consistency in the face of complex failure scenarios.
- We present the design of Rapid, a scalable membership service that is robust in the presence of diverse failure scenarios while providing strong consistency. Rapid runs both as a decentralized as well as a logically centralized membership service.
- In system evaluations, we demonstrate how Rapid, despite offering much stronger guarantees, brings up 2000 node clusters 2-5.8x faster than mature alternatives such as Memberlist and ZooKeeper. We demonstrate Rapid's robustness in the face of different failure scenarios such as simultaneous node crashes, asymmetric network partitions and heavy packet loss. Rapid achieves these goals at a similar cost to existing solutions.
- Lastly, we report on our experience running Rapid to power two applications; a distributed transactional data platform and a service discovery use case.

2 Motivation and Related work

Membership solutions today fall into two categories. They are either managed for a cluster through an auxiliary service [15, 43], or they are gossip-based and fully decentralized [45, 44, 8, 69, 62, 59, 70, 64].

We studied how three widely adopted systems behave in the presence of network failure scenarios: *(i)* of the first category, ZooKeeper [15], and of the second, *(ii)* Memberlist [47], the membership library used by Consul [45] and Serf [44] and *(iii)* Akka Cluster [69] (see §7 for the detailed setup). For ZooKeeper and Memberlist, we bootstrap a 1000 process cluster with standalone agents that join and maintain membership using these solutions (for Akka Cluster, we use 400 processes because it began failing for cluster sizes beyond 500). We then drop 80% of packets for 1% of processes, simulating high packet loss scenarios described in the literature [19, 49] that we have also observed in practice.

Figure 1 shows a timeseries of membership sizes, as viewed by each non-faulty process in the cluster (every dot indicates a single measurement by a process). Akka Cluster is unstable as conflicting rumors about processes propagate in the cluster concurrently, even resulting in benign processes being removed from the membership. Memberlist and ZooKeeper resist removal of the faulty processes from the membership set but are unstable over

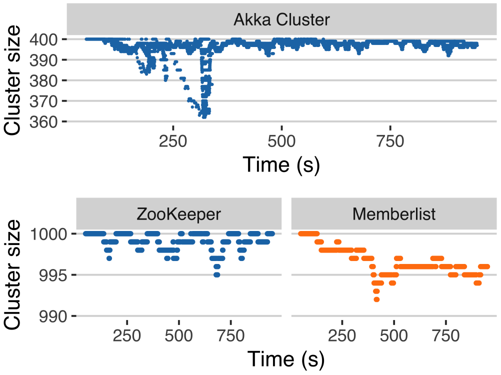

Figure 1: Akka Cluster, ZooKeeper and Memberlist exhibit instabilities and inconsistencies when 1% of processes experience 80% packet loss (similar to scenarios described in [19, 49]). Every process logs its own view of the cluster size every second, shown as one dot along the time (X) axis. Note, the y-axis range does not start at 0. X-axis points (or intervals) with different cluster size values represent inconsistent views among processes at that point (or during the interval).

a longer period of time. We also note extended periods of inconsistencies in the membership view.

Having found existing membership solutions to be unstable in the presence of typical network faults, we now proceed to discuss the broader design space.

2.1 Comparison of existing solutions

There are three membership service designs in use today, each of which provides different degrees of resiliency and consistency.

Logically centralized configuration service. A common approach to membership management in the industry is to store the membership list in an auxiliary service such as ZooKeeper [15], etcd [33], or Chubby [23].

The main advantage of this approach is simplicity: a few processes maintain the ground truth of the membership list with strong consistency semantics, and the remaining processes query this list periodically.

The key shortcoming here is that relying on a small cluster reduces the overall resiliency of the system: connectivity issues to the cluster, or failures among the small set of cluster members themselves, may render the service unavailable (this led Netflix to build solutions like Eureka [58, 61]). As the ZooKeeper developers warn, this also opens up new failure modes for applications that depend on an auxiliary service for membership [17].

Gossip-based membership. van Renesse et al. [72, 71] proposed managing membership by using gossip to spread positive notifications (keepalives) between all processes. If a process p fails, other processes eventually remove p after a timeout. SWIM [29] was proposed as a variant of that approach that reduces the communication overhead; it uses gossip to spread "negative" alerts, rather than regular positive notifications.

Gossip-based membership schemes are widely adopted in deployed systems today, such as Cassandra [8], Akka [69], ScyllaDB [64], Serf [44], Redis Cluster [62], Orleans [59], Uber's Ringpop [70], Netflix's Dynomite [56], and some systems at Twitter [55].

The main advantage of gossip-based membership is resiliency and graceful degradation (they tolerate $N-1$ failures). The key disadvantages include their weak consistency guarantees and the complex emergent behavior that leads to stability problems.

Stability is a key challenge in gossip-based membership: When communication fails between two processes which are otherwise live and correct, there are repeated accusations and refutations that may cause oscillations in the membership views. As our investigation of leading gossip-based solutions showed (Figure 1), these conflicting alerts lead to complex emergent behavior, making it challenging to build reliable clustered services on top of. Indeed, stability related issues with gossip are also observed in production settings (see, e.g., Consul [26, 25, 27] and Cassandra [11, 12, 10]).

Lastly, FireFlies [50] is a decentralized membership service that tolerates Byzantine members. FireFlies organizes monitoring responsibilities via a randomized k-ring topology to provide a robust overlay against Byzantine processes. While the motivation in FireFlies was different, we believe it offers a solution for stability; accusations about a process by a potentially Byzantine monitor are not acted upon until a conservative, fixed delay elapses. If a process does not refute an accusation about it within this delay, it is removed from the membership. However, the FireFlies scheme is based on a gossip-style protocol involving accusations, refutations, rankings, and disabling (where a process p announces that a monitor should not complain about it). Furthermore, FireFlies' refutations resist process removals as much as possible, which is undesirable in non-Byzantine settings. For example, in the 80% packet loss scenario described in Figure 1, a faulty process p may still succeed in disseminating refutations, thereby resisting removal from the membership. As we show in upcoming sections, our scheme is simple in comparison and requires little bookkeeping per process. Unlike FireFlies, we aggregate reports about a process p from multiple sources to decide whether to remove p, enabling timely and coordinated membership changes with low overhead.

Group membership. By themselves, gossip-based membership schemes do not address consistency, and allow the membership views of processes to diverge. In this sense, they may be considered more of failure detectors, than membership services.

Maintaining membership with strict consistency guarantees has been a focus in the field of fault tolerant state-machine replication (SMR), starting with early foundations of SMR [52, 60, 63], and continuing with a variety of group communication systems (see [24] for a survey of GC works). In SMR systems, membership is typically needed for selecting a unique primary and for enabling dynamic service deployment. Recent work on Census [28] scales dynamic membership maintenance to a locality-aware hierarchy of domains. It provides fault tolerance by running the view-change consensus protocol only among a sampled subset of the membership set.

These methods may be harnessed on top of a stable failure detection facility, stability being orthogonal to the consistency they provide. As we show, our solution uses an SMR technique that benefits from stable failure detection to form fast, leaderless consensus.

3 The Rapid Service

Our goal is to create a membership service based on techniques that apply equally well to both decentralized as well as logically centralized designs. For ease of presentation, we first describe the fully decentralized Rapid service and its properties in this section, followed by its design in §4. We then relax the resiliency properties in §5 for the logically centralized design.

API Processes use the membership service by using the Rapid library and invoking a call JOIN(HOST:PORT, SEEDS, VIEW-CHANGE-CALLBACK). Here, HOST:PORT is the process' TCP/IP listen address. Internally, the join call assigns a unique logical identifier for the process (ID). If a process departs from the cluster either due to a failure or by voluntarily leaving, it rejoins with a new ID. This ID is internal to Rapid and is not an identifier of the application that is using Rapid. SEEDS is an initial set of process addresses known to everyone and used to contact for bootstrapping. VIEW-CHANGE-CALLBACK is used to notify applications about membership change events.

Configurations A configuration in Rapid comprises a configuration identifier and a *membership-set* (a list of processes). Each process has a local *view* of the configuration. All processes use the initial seed-list as a bootstrap configuration C_0. Every configuration change decision triggers an invocation of the VIEW-CHANGE-CALLBACK at all processes, that informs processes about a new configuration and membership set.

At time t, if C is the configuration view of a majority of its members, we say that C is the *current configuration*. Initially, once a majority of C_0 start, it becomes current.

Failure model We assume that every pair of correct processes can communicate with each other within a known transmission delay bound (an assumption required for failure detection). When this assumption is violated for a pair of (otherwise live) processes, there is no obvious definition to determine which one of them is faulty (though at least one is). We resolve this using the parameters L and K as follows. Every process p (a *subject*) is monitored by K *observer* processes. If L-of-K correct observers cannot communicate with a subject, then the subject is considered *observably unresponsive*. We consider a process faulty if it is either crashed or observably unresponsive.

Cut Detection Guarantees Let C be the current configuration at time t. Consider a subset of processes $F \subset C$ where $\frac{|F|}{|C|} < \frac{1}{2}$. If all processes in $C \setminus F$ remain non-faulty, we guarantee that the multi-process cut will eventually be detected and a view-change $C \setminus F$ installed [1]:

- Multi-process cut detection: With high probability, every process in $C \setminus F$ receives a multi-process cut detection notification about F. In Rapid, the probability is taken over all the random choices of the observer/subject overlay topology, discussed in §4. The property we use is that with high probability the underlying topology remains an expander at all times, where the expansion is quantified in terms of its second eigenvalue.

A similar guarantee holds for joins. If at time t a set J of processes join the system and remain non-faulty, then every process in $C \cup J$ is notified of J joining.

Joins and removals can be combined: If a set of processes F as above fails, and a set of processes J joins, then $(C \setminus F) \cup J$ is eventually notified of the changes.

- View-Change: Any view-change notification in C is by consensus, maintaining *Agreement* on the view-change membership among all correct processes in C; and *Liveness*, provided a majority of $C \cup J$ ($J = \emptyset$ if there are no joiners) remain correct until the VC configuration becomes current.

Our requirements concerning configuration changes hold when the system has quiesced. During periods of instability, intermediate detection(s) may succeed, but there is no formal guarantee about them.

Hand-off Once a new configuration C_{j+1} becomes current, we abstractly abandon C_j and start afresh: New failures can happen within C_{j+1} (for up to half of the membership set), and the Cut Detection and View Change guarantees must hold.

We note that liveness of the consensus layer depends on a majority of both C_j and C_{j+1} remaining correct to perform the 'hand-off': Between the time when C_j becomes current and until C_{j+1} does, no more than a minority fail in either configuration. This dynamic model

[1] The size of cuts $|F|$ we can detect is a function of the monitoring topology. The proof is summarized in §8, and a full derivation appears in a tech report [51].

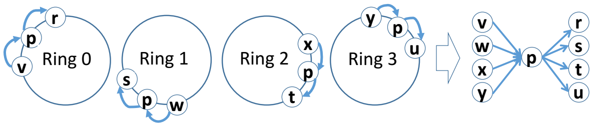

Figure 2: p's neighborhood in a $K = 4$-Ring topology. p's observers are $\{v,w,x,y\}$; p's subjects are $\{r,s,t,u\}$.

borrows the dynamic-interplay framework of [35, 66].

4 Decentralized Design

Rapid forms an immutable sequence of configurations driven through consensus decisions. Each configuration may drive a single configuration-change decision; the next configuration is logically a new system as in the virtual synchrony approach [22]. Here, we describe the algorithm for changing a known current configuration $\mathscr{C}$, consisting of a membership set (a list of process identities). When clear from the context, we omit $\mathscr{C}$ or explicit mentions of the configuration, as they are fixed within one instance of the configuration-change algorithm.

We start with a brief overview of the algorithm, breaking it down to three components: (1) a monitoring overlay; (2) an almost-everywhere multi-process cut detection (CD); and (3) a fast, leaderless view-change (VC) consensus protocol. The response to problems in Rapid evolves through these three components (see Figure 3).

Monitoring We organize processes into a monitoring topology such that every process monitors K peers and is monitored by K peers. A process being monitored is referred to as a *subject* and a process that is monitoring a subject is an *observer* (each process therefore has K subjects and K observers). The particular topology we employ in Rapid is an *expander graph* [38] realized using K pseudo-random rings [34]. Other observer/subject arrangements may be plugged into our framework without changing the rest of the logic.

Importantly, this topology is deterministic over the membership set $\mathscr{C}$; every process that receives a notification about a new configuration locally determines its subjects and creates the required monitoring channels.

There are two types of alerts generated by the monitoring component, REMOVE and JOIN. A REMOVE alert is broadcast by an observer when there are reachability problems to its subject. A JOIN alert is broadcast by an observer when it is informed about a subject joiner request. In this way, both types of alerts are generated by multiple sources about the same subject. Any best-effort broadcast primitive may be used to disseminate alerts (we use gossip-based broadcast).

Multi-process cut detection (CD) REMOVE and JOIN alerts are handled at each process independently by a multi-process cut detection (CD) mechanism. This mechanism collects evidence to support a single, stable multi-process configuration change proposal. It outputs the same cut proposal *almost-everywhere*; i.e., unanimity in the detection among a large fraction of processes.

The CD scheme with a K-degree monitoring topology has a constant per-process per-round communication cost, and provides stable multi-process cut detection with almost-everywhere agreement.

View change (VC) Finally, we use a consensus protocol that has a fast path to agreement on a view-change. If the protocol collects identical CD proposals from a *Fast Paxos quorum* (three quarters) of the membership, then it can decide in one step. Otherwise, it falls back to Paxos to form agreement on some proposal as a view-change.

We note that other consensus solutions could use CD as input and provide view-change consistency. VC has the benefit of a fast path to decision, taking advantage of the identical inputs almost-everywhere.

We now present a detailed description of the system.

4.1 Expander-based Monitoring

Rapid organizes processes into a monitoring topology that is an *expander graph* [38]. Specifically, we use the fact that a random K-regular graph is very likely to be a good expander for $K \geq 3$ [34]. We construct K pseudo-randomly generated rings with each ring containing the full list of members. A pair of processes (o, s) form an observer/subject *edge* if o precedes s in a ring. Duplicate edges are allowed and will have a marginal effect on the behavior. Figure 2 depicts the neighborhood of a single process p in a 4-Ring topology.

Topology properties. Our monitoring topology has three key properties. The first is *expansion*: the number of edges connecting two sets of processes reflects the relative sizes of the set. This means that if a small subset F of processes V are faulty, we should see roughly $\frac{|V|-|F|}{|V|}$ fraction of monitoring edges to F emanating from the set $V \setminus F$ of healthy processes. This ensures with high probability that healthy processes detect failures, as long as the set of failures is not too large. The size of failures we can detect depends on the expansion of the topology as quantified by the value of its second eigenvalue (§ 8). Second, every process monitors K subjects, and is monitored by K observers. Hence, monitoring incurs $O(K)$ overhead

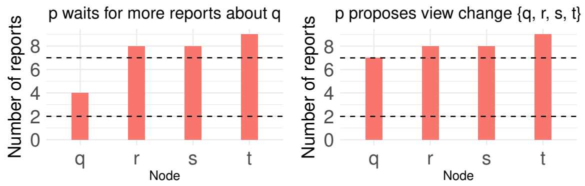

Figure 4: Almost everywhere agreement protocol example at a process p, with tallies about q,r,s,t and $K = 10, H = 7, L = 2$. K is the number of observers per subject. The region between H and L is the unstable region. The region between K and H is the stable region. **Left:** $stable = \{r,s,t\}$; $unstable = \{q\}$. **Right:** q moves from $unstable$ to $stable$; p proposes a view change $\{q,r,s,t\}$.

per process per round, distributing the load across the entire cluster. The fixed observer/subject approach distinguishes Rapid from gossip-based techniques, supporting prolonged monitoring without sacrificing failure detection scalability. At the same time, we compare well with the overhead of gossip-based solutions (§7). Third, every process join or removal results only in $2 \cdot K$ monitoring edges being added or removed.

Joins New processes join by contacting a list of K temporary observers obtained from a seed process (deterministically assigned for each joiner and $\mathscr{C}$ pair, until a configuration change reflects the join). The temporary observers generate independent alerts about joiners. In this way, multiple JOIN alerts are generated from distinct sources, in a similar manner to alerts about failures.

Pluggable edge-monitor. A monitoring edge between an observer and its subject is a pluggable component in Rapid. With this design, Rapid can take advantage of diverse failure detection and monitoring techniques, e.g., history-based adaptive techniques as used by popular frameworks like Hystrix [57] and Finagle [68]; phi-accrual failure detectors [31]; eliciting indirect probes [29]; flooding a suspicion and allowing a timeout period for self-rebuttal [50]; using cross-layer information [54]; application-specific health checks; and others.

Irrevocable Alerts When the edge-monitor of an observer indicates an existing subject is non-responsive, the observer broadcasts a REMOVE alert about the subject. Given the high fidelity made possible with our stable edge monitoring, these alerts are considered *irrevocable*, thus Rapid prevents spreading conflicting reports. When contacted by a subject, a temporary observer broadcasts JOIN alert about the subject.

4.2 Multi-process Cut Detection

Alerts in Rapid may arrive at different orders at each process. Every process independently aggregates these alerts until a stable multi-process cut is detected. Our approach aims to reach agreement *almost everywhere* with regards to this detection. Our mechanism is based on a simple key insight: A process defers a decision on a single process until the alert-count it received on all processes is considered stable. In particular, it waits until there is no process with an alert-count above a low-watermark threshold L and below a high-watermark threshold H.

Our technique is simple to implement; it only requires maintaining integer counters per-process and comparing them against two thresholds. This state is reset after each configuration change.

Processing REMOVE and JOIN alerts Every process ingests broadcast alerts by observers about edges to their subjects. A REMOVE alert reports that an edge to the subject process is faulty; a JOIN alert indicates that an edge to the subject is to be created. By design, a JOIN alert can only be about a process not in the current configuration $\mathscr{C}$, and REMOVE alerts can only be about processes in $\mathscr{C}$. There cannot be JOIN and REMOVE alerts about the same process in $\mathscr{C}$.

Every process p tallies up distinct REMOVE and JOIN alerts in the current configuration view as follows. For each observer/subject pair (o, s), p maintains a value $M(o,\ s)$ which is set to 1 if an alert was received from observer o regarding subject s; and it is set to (default) 0 if no alert was received. A *tally(s)* for a process s is the sum of entries $M(*,\ s)$.

Stable and unstable report modes We use two parameters H and L, $1 \leq L \leq H \leq K$. A process p considers a process s to be in a *stable report mode* if $|\text{tally}(s)| \geq H$ at p. A stable report mode indicates that p has received at least H distinct observer alerts about s, hence we consider it "high fidelity"; A process s is in an *unstable report mode* if $\text{tally}(s)$ is in between L and H. If there are fewer than L distinct observer alerts about s, we consider it noise. Recall that Rapid does not revert alerts; hence, a stable report mode is permanent once it is reached. Note that, the same thresholds are used for REMOVE and JOIN reports; this is not mandatory, and is done for simplicity.

Aggregation Each process follows one simple rule for aggregating tallies towards a proposed configuration change: *delay proposing a configuration change until there is at least one process in stable report mode and there is no process in unstable report mode*. Once this condition holds, the process announces a configuration change proposal consisting of all processes in stable report mode, and the current configuration identifier. The proposed configuration change has the almost-everywhere agreement property, which we analyze in §8 and evaluate in §7. Figure 4 depicts the almost everywhere agreement mechanism at a single process.

Ensuring liveness: implicit detections and reinforcements There are two cases in which a subject process might get stuck in an unstable report mode and not accrue H observer reports. The first is when the observers themselves are faulty. To prevent waiting for stability forever, for each observer o of s, if both o and s are in the unstable report mode, then an *implicit-alert* is applied from o to s (i.e., an implicit REMOVE if s is in $\mathscr{C}$ and a JOIN otherwise; o is by definition always in $\mathscr{C}$).

The second is the case when a subject process has good connections to some observers, and bad connections to others. In this case, after a subject s has been in the unstable reporting mode for a certain timeout period, each observer o of s *reinforces* the detection: if o did not send a REMOVE message about s already, it broadcasts a REMOVE about s to echo existing REMOVEs.

4.3 View-change Agreement

We use the result of each process' CD proposal as input to a consensus protocol that drives agreement on a single view-change.

The consensus protocol in Rapid has a fast, leaderless path in the common case, that has the same overhead as simple gossip. The fast path is built around the Fast Paxos algorithm [53]. In our variation, we use the CD result as initial input to processes, instead of having an explicit proposer populating the processes with a proposal. Fast Paxos reaches a decision if there is a quorum larger than three quarters of the membership set with an identical proposal. Due to our prudent almost-everywhere CD scheme, with high probability, all processes indeed have an identical multi-process cut proposal. In this case, the VC protocol converges simply by counting the number of identical CD proposals.

The counting protocol itself uses gossip to disseminate and aggregate a bitmap of "votes" for each unique proposal. Each process sets a bit in the bitmap of a proposal to reflect its vote. As soon as a process has a proposal for which three quarters of the cluster has voted, it decides on that proposal.

If there is no fast-quorum support for any proposal because there are conflicting proposals, or a timeout is reached, Fast Paxos falls back to a recovery path, where we use classical Paxos [52] to make progress.

In the face of partitions [36], some applications may need to maintain availability everywhere (AP), and others only allow the majority component to remain live to provide strong consistency (CP). Rapid guarantees to reconfigure processes in the majority component. The remaining processes are forced to logically depart the system. They may wait to rejoin the majority component, or choose to form a separate configuration (which Rapid facilitates quickly). The history of the members forming a new configuration will have an explicit indication of these events, which applications can choose to use in any manner that fits them (including ignoring).

5 Logically Centralized Design

We now discuss how Rapid runs as a logically centralized service, where a set of auxiliary nodes S records the membership changes for a cluster $\mathscr{C}$. This is a similar model to how systems use ZooKeeper to manage membership: the centralized service is the ground truth of the membership list.

Only three minor modifications are required to the protocol discussed in §4:

1. Nodes in the current configuration $\mathscr{C}$ continue monitoring each other according to the k-ring topology (to scale the monitoring load). Instead of gossiping these alerts to all nodes in $\mathscr{C}$, they report it only to all nodes in S instead.
2. Nodes in S apply the CD protocol as before to identify a membership change proposal from the incoming alerts. However, they execute the VC protocol only among themselves.
3. Nodes in $\mathscr{C}$ learn about changes in the membership through notifications from S (or by probing nodes in S periodically).

The resulting solution inherits the stability and agreement properties of the decentralized protocol, but with reduced resiliency guarantees; the resiliency of the overall system is now bound to that of S ($F = \frac{S}{2} - 1$) – as with any logically centralized design. For progress, members of $\mathscr{C}$ need to be connected to a majority partition of S.

6 Implementation

Rapid is implemented in Java with 2362 lines of code (excluding comments and blank lines). This includes all the code associated with the membership protocol as well as messaging and failure detection. In addition, there are 2034 lines of code for tests. Our code is open-sourced under an Apache 2 license [2].

Our implementation uses gRPC and Netty for messaging. The counting step for consensus and the gossip-based dissemination of alerts are performed over UDP. Applications interact with Rapid using the APIs for joining and receiving callbacks described in §3. The logical identifier (§3) for each process is generated by the Rapid library using UUIDs. The join method allows users to supply edge failure detectors to use. Similar to APIs of existing systems such as Serf [44] and Akka Cluster [69], users associate application-specific metadata with the process being initialized (e.g., *"role":"backend"*).

Our default failure detector has observers send probes to their subjects and wait for a timeout. Observers mark an edge faulty when the number of communication exceptions they detect exceed a threshold (40% of the last 10 measurement attempts fail). Similar to Memberlist

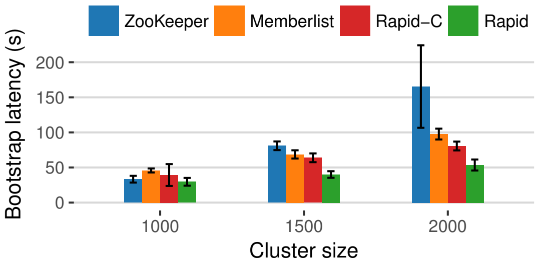

Figure 5: Bootstrap convergence measurements showing the time required for all nodes to report a cluster size of N. Rapid bootstraps a 2000 node cluster 2-2.32x faster than Memberlist, and 3.23-5.81x faster than ZooKeeper.

and Akka Cluster, Rapid batches multiple alerts into a single message before sending them on the wire.

7 Evaluation

Setup We run our experiments on a shared internal cloud service with 200 cores and 800 GB of RAM (100 VMs). We run multiple processes per VM, given that the workloads are not CPU bottlenecked. We vary the number of processes (N) in the cluster from 1000 to 2000.

We compare Rapid against *(i)* ZooKeeper [15] accessed using Apache Curator [13], *(ii)* Memberlist [47], the SWIM implementation used by Serf [44] and Consul [45]. For Rapid, we use the decentralized variant unless specified otherwise (Rapid-C, where a 3-node ensemble manages the membership of N processes).

We also tested Akka Cluster [69] but found its bootstrap process to not stabilize for clusters beyond 500 processes, and therefore do not present further (see §2.1 and Figure 1). All ZooKeeper experiments use a 3-node ensemble, configured according to [16]. For Memberlist, we use the provided configuration for single data center settings (called *DefaultLANConfig*). Rapid uses $\{K,H,L\} = \{10,9,3\}$ for all experiments and we also show a sensitivity analysis. We seek to answer:

- How quickly can Rapid bootstrap a cluster?
- How does Rapid react to different fault scenarios?
- How bandwidth intensive is Rapid?
- How sensitive is the almost-everywhere agreement property to the choice of K,H,L?
- Is Rapid easy to integrate with real applications?

Bootstrap experiments We stress the bootstrap protocols of all three systems under varying cluster sizes. For Memberlist and Rapid, we start each experiment with a single seed process, and after ten seconds, spawn a subsequent group of $N-1$ processes (for ZooKeeper, the 3-node ZooKeeper cluster is brought up first). Every process logs its observed cluster size every second. Every measurement is repeated five times per value of N. We measure the time taken for all processes to converge to a cluster size of N (Figure 5). For $N = 2000$, Rapid improves bootstrap latencies by 2-2.32x over Memberlist, and by 3.23-5.8x over ZooKeeper.

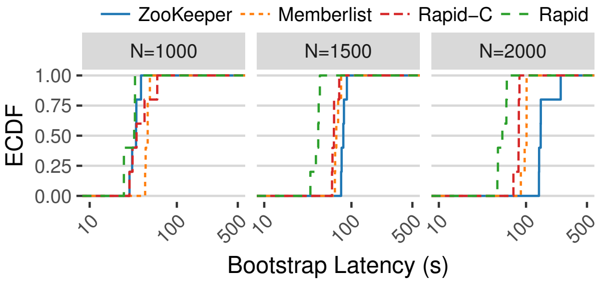

Figure 6: Bootstrap latency distribution for all systems.

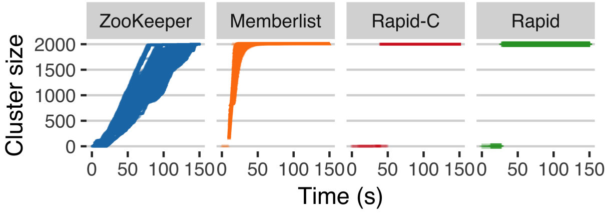

Figure 7: Timeseries showing the first 150 seconds of all three systems bootstrapping a 2000 node cluster.

ZooKeeper suffers from herd behavior during the bootstrap process (as documented in [18]), resulting in its bootstrap latency increasing by 4x from when N=1000 to when N=2000. Group membership with ZooKeeper is done using watches. When the i^{th} process joins the system, it triggers $i-1$ watch notifications, causing $i-1$ processes to re-read the full membership list and register a new watch each. In the interval between a watch having triggered and it being replaced, the client is not notified of updates, leading to clients observing different sequences of membership change events [17]. This behavior with watches leads to the eventually consistent client behavior in Figure 7. Lastly, we emphasize that this is a 3-node ZooKeeper cluster being used *exclusively* to manage membership for a single cluster. Adding even one extra watch per client to the group node at N=2000 inflates bootstrap latencies to 400s on average.

Memberlist processes bootstrap by contacting a seed. The seed thereby learns about every join attempt. However, non-seed processes need to periodically execute a push-pull handshake with each other to synchronize their views (by default, once every 30 seconds). Memberlist's convergence times are thereby as high as 95s on average when $N = 2000$ (Figure 7).

Similar to Memberlist, Rapid processes bootstrap by contacting a seed. The seed aggregates alerts until it bootstraps a cluster large enough to support a Paxos quorum (minimum of three processes). The remaining processes are admitted in a subsequent one or more view

System	N=1000	N=1500	N=2000
ZooKeeper	1000	1500	2000
Memberlist	901	1383	1858
Rapid-C	9	10	7
Rapid	4	8	4

Table 1: Number of unique cluster sizes reported by processes in bootstrapping experiments.

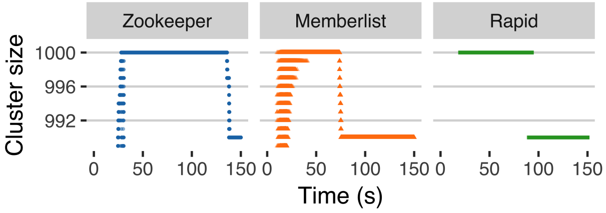

Figure 8: Experiment with 10 concurrent crash failures.

changes. For instance, in Figure 7, Rapid transitions from a single seed to a five node cluster, before forming a cluster of size 2000. We confirm this behavior across runs in Table 1, which shows the number of unique cluster sizes reported for different values of N. In the ZooKeeper and Memberlist experiments, processes report a range of cluster sizes between 1 and N as the cluster bootstraps. Rapid however brings up large clusters with very few intermediate view changes, reporting four and eight unique cluster sizes for each setting. Our logically centralized variant Rapid-C, behaves similarly for the bootstrap process. However, processes in Rapid-C periodically probe the 3-node ensemble for updates to the membership (the probing interval is set to be 5 seconds, the same as with ZooKeeper). This extra step increases bootstrap times over the decentralized variant; in the latter case, all processes participate in the dissemination of votes through aggregate gossip.

Crash faults We now set $N = 1000$ to compare the different systems in the face of crash faults. At this size, we have five processes per-core in the infrastructure, leading to a stable steady state for all three systems. We then fail ten processes and observe the cluster membership size reported by every other process in the system.

Figure 8 shows the cluster size timeseries as recorded by each process. Every dot in the timeseries represents a cluster size recording by a single process. With Memberlist and ZooKeeper, processes record several different cluster sizes when transitioning from N to $N - F$. Rapid on the other hand concurrently detects all ten process failures and removes them from the membership using a 1-step consensus decision. Note, our edge failure detector performs multiple measurements before announcing a fault for stability (§6), thereby reacting roughly 10 seconds later than Memberlist does. The results are identical when the ten processes are partitioned away completely from the cluster (we do not show the plots for brevity).

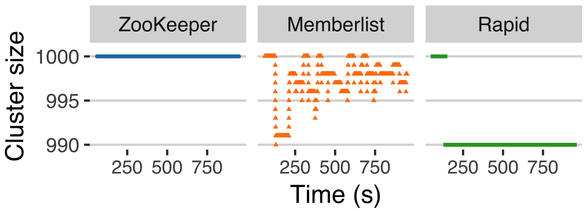

Figure 9: Asymmetric network failure with one-way network partition on the network interface of 1% of processes (ingress path).

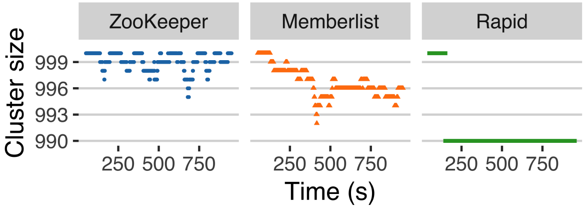

Figure 10: Experiment with 80% ingress packet loss on the network interface of 1% of processes.

Asymmetric network failures We study how each system responds to common network failures that we have seen in practice. These scenarios have also been described in [49, 19, 37, 67, 41].

Flip-flops in one-way connectivity. We enforce a "flip-flopping" asymmetric network failure. Here, 10 processes lose all packets that they receive for a 20 second interval, recover for 20 seconds, and then repeat the packet dropping. We enforce this by dropping packets in the `iptables INPUT` chain. The timeseries of cluster sizes reported by each process is shown in Figure 9.

ZooKeeper does not react to the injected failures because clients do not receive packets on the ingress path, but send heartbeats to the ZooKeeper nodes. Reversing the direction of connectivity loss as in the next experiment does cause ZooKeeper to react. Memberlist never removes all the faulty processes from the membership, and oscillates throughout the duration of the failure scenario. We also find several intervals of inconsistent views among processes. Unlike ZooKeeper and Memberlist, Rapid detects and removes the faulty processes.

High packet loss scenario. We now run an experiment where 80% of outgoing packets from the faulty processes are dropped. We inject the fault at $t = 90s$. Figure 10 shows the resulting membership size timeseries. ZooKeeper reacts to the failures at $t = 200s$, and does not remove all faulty processes from the membership. Figure 10 also shows how Memberlist's failure detector is conservative; even a scenario of sustained high packet loss is insufficient for Memberlist to conclusively remove a set of processes from the network. Further-

	KB/s (received / transmitted)		
System	Mean	p99	max
ZooKeeper	0.43 / 0.01	17.52 / 0.33	38.86 / 0.67
Memberlist	0.54 / 0.64	5.61 / 6.40	7.36 / 8.04
Rapid	0.71 / 0.71	3.66 / 3.72	9.56 / 11.37

Table 2: Mean, 99^{th} percentile and maximum network bandwidth utilization per process.

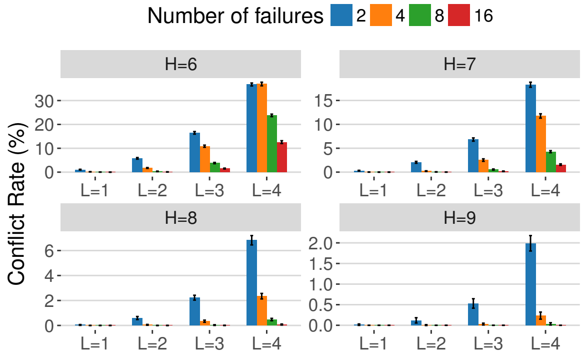

Figure 11: Almost-everywhere agreement conflict probability for different combinations of H, L and failures F when K=10. Note the different y-axis scales.

more, we observe view inconsistencies with Memberlist near $t = 400s$. Rapid, again, correctly identifies and removes only the faulty processes.

Memory utilization. Memberlist (written in Go) used an average of 12MB of resident memory per process. With Rapid and ZooKeeper agents (both Java based), GC events traced using `-XX:+PrintGC` report min/max heap utilization of 10/25MB and 3.5/16MB per process.

Network utilization. Table 2 shows the mean, 99th and 100th percentiles of network utilization per second across processes during the crash fault experiment (1000 processes). Rapid has a peak utilization of 9.56 KB/s received (and 11.37 KB/s transmitted) versus 7.36 KB/s received (8.04 KB/s transmitted) for Memberlist. Rapid therefore provides stronger guarantees than Memberlist for a similar degree of network bandwidth utilization. ZooKeeper clients have a peak ingress utilization of 38.86 KB/s per-process on average to learn the updated view of the membership.

K, H, L sensitivity study We now present the effect of K, H and L on the almost-everywhere agreement property of our multi-process detection technique. We initialize 1000 processes and select F random processes to fail. We generate alert messages from the F processes' observers and deliver these alerts to each process in a uniform random order. We count the number of processes that announce a membership proposal that did not include all F processes (a *conflict*). We run all parameter combinations for $H = \{6,7,8,9\}, L = \{1,2,3,4\}, F = \{2,4,8,16\}$ with 20 repetitions per combination.

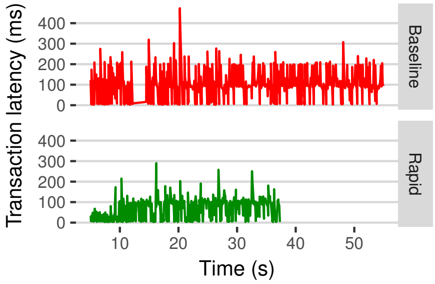

Figure 12: Transaction latency when testing an in-house gossip-style failure detector and Rapid for robustness against a communication fault between two processes. The baseline failure detector triggers repeated failovers that reduce throughput by 32%.

Figure 11 shows the results. As our analysis (§8) predicts, the conflict rate is highest when the gap between H and L is lowest ($H = 6, L = 4$) and the number of failures F is 2. This setting causes processes to arrive at a proposal without waiting long enough. As we increase the gap $H - L$ and increase F, the algorithm at each process waits long enough to gather all the relevant alerts, thereby diminishing the conflict probability. Our system is thereby robust across a range of values; for $H - L = 5$ and $F = 2$, we get a 2% conflict rate for different values of H and L. Increasing to $H - L = 6$ drops the probability of a conflict by a factor of 4.

Experience with end-to-end workloads We integrated Rapid within use cases at our organization that required membership services. Our goal is to understand the ease of integrating and using Rapid.

Distributed transactional data platform. We worked with a team that uses a distributed data platform that supports transactions. We replaced the use of its in-house gossip-based failure detector that uses all-to-all monitoring, with Rapid. The failure detector recommends membership changes to a Paxos-based reconfiguration mechanism, and we let Rapid provide input to the re-configuration management instead. Our integration added 62 and removed 25 lines of code. We also ported the system's failure detection logic such that it could be supplied to Rapid as an edge failure detector, which involved an additional 123 lines of code.

We now describe a use case in the context of this system where stable monitoring is required. For total ordering of requests, the platform has a transaction serialization server, similar to the one used in Google Megastore [20] and Apache Omid [14]. At any moment in time, the system has only one active serialization server, and its failure requires the cluster to identify a new candidate server for a failover. During this interval, workloads are paused and clients do not make progress.

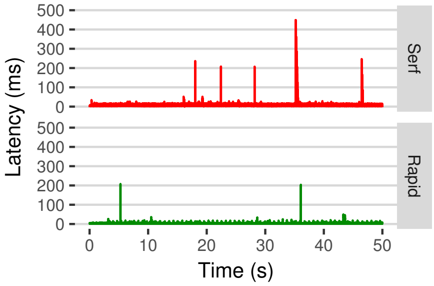

Figure 13: Service discovery experiment. Rapid's batching reduces the number of configuration reloads during a set of failures, thereby reducing tail latency.

We ran an experiment where two update-heavy clients (read-write ratio of 50-50) each submit 500K read/write operations, batched as 500 transactions. We injected a failure that drops all packets between the current serialization server and one other data server (resembling a packet blackhole as observed by [41]). Note, this fault does not affect communication links between clients and data servers. We measured the impact of this fault on the end-to-end latency and throughput.

With the baseline failure detector, the serialization server was repeatedly added and removed from the membership. The repeated failovers caused a degradation of end-to-end latency and a 32% drop in throughput (Figure 12). When using Rapid however, the system continued serving the workload without experiencing any interruption (because no node exceeded L reports).

Service discovery. A common use case for membership is service discovery, where a fleet of servers need to be discovered by dependent services. We worked with a team that uses Terraform [46] to drive deployments where a load balancer discovers a set of backend servers using Serf [44]. We replaced their use of Serf in this workflow with an agent that uses Rapid instead (the Rapid specific code amounted to under 20 lines of code). The setup uses nginx [1] to load balance requests to 50 web servers (also using nginx) that serve a static HTML page. All 51 machines run as t2.micro instances on Amazon EC2. Both membership services update nginx's configuration file with the list of backend servers on every membership change. We then use an HTTP workload generator to generate 1000 requests per-second. 30 seconds into the experiment, we fail ten nodes and observe the impact on the end-to-end latency (Figure 13).

Rapid detects all failures concurrently and triggers a single reconfiguration because of its multi-node membership change detection. Serf, which uses Memberlist, detects multiple independent failures that result in several updates to the nginx configuration file. The load balancer therefore incurs higher latencies when using Serf at multiple intervals (t=35s and t=46s) because nginx is reconfiguring itself. In the steady state where there are no failures, we observe no difference between Rapid and Serf, suggesting that Rapid is well suited for service discovery workloads, despite offering stronger guarantees.

8 Summary of Proofs

In the interest of space, we report the complete proof of correctness in a tech report [51], and only present the key take aways here. Our consensus engine is standard, and borrows from known literature on consensus algorithms [53, 32, 52]. We do not repeat its proof of Agreement and Liveness.

It is left to prove that faced with F failures in a configuration C, the stable failure detector detects and outputs F at all processes with high probability. We divide the proof into two parts.

Detection guarantee For parameters L and K, we can detect a failure of a set F as long as $|F|$ is bounded by the relationship $\frac{|F|}{|C|} \leq (1 - \frac{L}{K} - \frac{\lambda}{2K})$. Here, λ is the second eigenvalue of the underlying monitoring topology, and is tied to the expansion properties of the topology. In our experiments, with $K = 10$, we have observed consistently that $\frac{\lambda}{2K} < 0.45$ (which, for $L = 3$, yields $\frac{|F|}{|C|} \leq 0.25$).

Almost-everywhere agreement Second, we prove the almost-everywhere agreement property about our multi-process cut protocol. We assume that there are t failures, and that nodes receive alerts about these failures in a uniform random order. Let $\Pr[B(z)]$ be the probability that the CD protocol at z outputs a subset of t that differs from the output at other nodes. We show that if multiple processes fail simultaneously, $\Pr[B(z)]$ *exponentially* decreases with increasing K.

9 Conclusions

In this paper, we demonstrated the effectiveness of detecting cluster-wide multi-process cut conditions, as opposed to detecting individual node changes. The high fidelity of the CD output prevents frequent oscillations or incremental changes when faced with multiple failures. It achieves unanimous detection almost-everywhere, enabling a fast, leaderless consensus protocol to drive membership changes. Our implementation successfully bootstraps clusters of 2000 processes 2-5.8x times faster than existing solutions, while being stable against complex network failures. We found Rapid easy to integrate end-to-end within a distributed transactional data platform and a service discovery use case.

Abstract

We study online graph queries that retrieve nearby nodes of a query node in a large network. To answer such queries with high throughput and low latency, we partition the graph and process in parallel across a cluster of servers. Existing distributed graph systems place each partition on a separate server, where query answering over that partition takes place. This design has two major disadvantages. First, the router maintains a fixed routing table (or, policy), thus less flexible for query routing, fault tolerance, and graph updates. Second, the graph must be partitioned so that the workload across servers is balanced, and the inter-machine communication is minimized. To maintain good-quality partitions, it is also required to update the existing partitions based on workload changes. However, graph partitioning, online monitoring of workloads, and dynamically updating the partitions are expensive.

We mitigate these problems by decoupling graph storage from query processors, and by developing smart routing strategies with graph landmarks and embedding. Since a query processor is no longer assigned any fixed part of the graph, it is equally capable of handling any request, thus facilitating load balancing and fault tolerance. Moreover, due to our smart routing strategies, query processors can effectively leverage their cache, reducing the impact of how the graph is partitioned across storage servers. Our experiments with several real-world, large graphs demonstrate that the proposed framework gRouting, even with simple hash partitioning, achieves up to an order of magnitude better query throughput compared to existing distributed graph systems that employ expensive graph partitioning and re-partitioning strategies.

1 INTRODUCTION

Graphs with millions of nodes and billions of edges are ubiquitous to represent highly interconnected structures including the World Wide Web, social networks, knowledge graphs, genome and scientific databases, medical and government records. To support online search and query services (possibly from many clients) with low latency and high throughput, data centers and cloud operators consider scale-out solutions, in which the graph and its data are partitioned horizontally across cheap commodity servers. We assume that the graph topology and the data associated with nodes and edges are co-located, since they are often accessed together [34, 16, 17]. Keeping with the modern database trends to support low-latency operations, we target a fully in-memory system, and use disks only for durability [35, 26, 28]. In this paper, we study online queries that explore a small region of the entire graph, and require fast response time. These queries usually start with a query node, and traverse its neighboring nodes up to a certain number of hops (we shall formally introduce our queries in Section 2). For efficiently answering online queries in a distributed environment, state-of-the-art systems (e.g., [35, 28, 26]) first partition the graph, and then place each partition on a separate server, where query answering over that partition takes place (Figure 1). Since the server which contains the query node can only handle that request, the router maintains a fixed routing table (or, a fixed routing strategy, e.g., modulo hashing). Hence, these systems are less flexible with respect to query routing and fault tol-

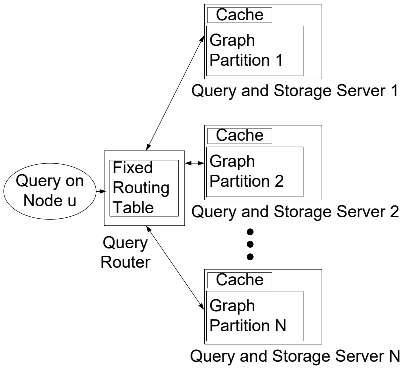

Figure 1: State-of-the-art distributed graph querying systems (e.g., SEDGE [35], Trinity [28], Horton [26])

erance, e.g., adding more machines will require updating the routing table. Besides, an effective graph partitioning in these systems must achieve: (1) workload balancing to maximize parallelism, and (2) locality of data access to minimize network communication. It has been demonstrated [35] that sophisticated partitioning schemes improve the performance of graph querying, compared to an inexpensive hash partitioning.

Due to power-law degree distribution of real-world graphs, it is difficult to get high-quality partitions [6]. Besides, a one-time partitioning cannot cope with later updates to graph structure or variations in query workloads. Several graph re- partitioning and replication-based strategies were proposed, e.g., [35, 18, 16]. However, online monitoring of workload changes, re-partitioning of the graph topology, and migration of graph data across servers are expensive; and they reduce the efficiency and throughput of online querying [25].

Our Contribution. In contrast to existing systems, we consider a different architecture, which relies *less* on an effective graph partitioning. Instead, we decouple query processing and graph storage into two separate tiers (Figure 2). In a decoupled framework, the graph is partitioned across servers allocated to the storage tier, and these storage servers hold the graph data in their main memory. Since a query processor is no longer assigned any fixed part of the graph, it is equally capable of handling any request, thus facilitating load balancing and fault tolerance. At the same time, the query router can send a request to any of the query processors, which adds more flexibility to query routing, e.g., more query processors can be added (or, a query processor that is down can be replaced) without affecting the routing strategy. Another benefit due to decoupled design is that each tier can be scaled-up independently. If a certain workload is processing intensive, more servers could be allocated to the processing tier. On the contrary, if the graph size increases over time, more servers can be added in the storage tier. This decoupled architecture, being generic, can be employed in many existing graph querying systems.

The idea of decoupling, though effective, is not novel. Facebook implemented a fast caching layer, Memcached on top of a graph database that scales the performance of graph query answering [19]. Google's F1 [29] and ScaleDB (http://scaledb.com/pdfs/TechnicalOverview.pdf) are based on a decoupling principle for scalability. Recently, Loesing et. al. [14] and Binnig et. al. [3] demonstrated the benefits of a decoupled, shared-data architecture, together with low latency and high throughput Infiniband network. Shalita et. al. [27] employed de-coupling for an optimal assignment of HTTP requests over a distributed graph storage.

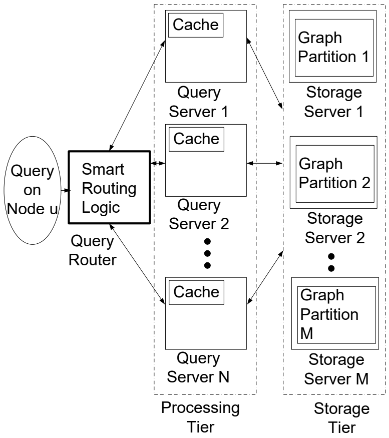

Figure 2: Decoupled architecture for graph querying

Our contribution lies in designing a smart query routing logic to utilize the cache of query processors over such decoupled architecture. Achieving more cache hits is critical in a decoupled architecture – otherwise, the query processors need to retrieve the data from storage servers, which will incur extra communication costs. This is a non-trivial problem, e.g., exploiting cache locality and balancing workloads are conflicting in nature. For example, to achieve maximum cache locality, the router can send all the queries to the same processor (assuming no cache eviction happens). However, the workload of the processors will be highly imbalanced, resulting in lower throughput. In addition, graph workloads are significantly different from traditional database applications. The interconnected nature of graph data results in poor locality, and each query usually accesses multiple neighboring nodes spreading across the distributed storage. Therefore, to maximize cache hit rates at query processors, it is not sufficient to only route the queries on same nodes to the same processor. Rather, successive queries on *neighboring* nodes should also be routed to the same processor, since the neighborhoods of two nearby nodes may significantly overlap. To the best of our knowledge, such smart query routing schemes for effectively leveraging the cache contents were not considered in existing graph querying systems.

We summarize our contributions as follows.

1. We study for the first time the problem of *smart query routing* aimed at improving the throughput and efficiency of distributed graph querying.
2. In contrast to many distributed graph querying systems [35, 28, 26], we consider a different architecture that *decouples* query processors from storage layer, thereby achieving flexibility in system deployment, query routing, scaling up, load balancing, and fault tolerance.
3. We develop smart, lightweight, and adaptive *query routing algorithms* that improve cache hit rates at query processors, thus reducing communication

with storage layer, and making our design less reliant on a sophisticated graph partitioning scheme across storage layer.

4. We empirically demonstrate throughput and efficiency of our framework, gRouting on three real-life graphs, while also comparing with two existing distributed graph processing systems (SEDGE/Giraph [35] and PowerGraph [6]). Our decoupled implementation, even with its simple hash partitioning, achieves up to an order of magnitude higher throughput compared to existing systems with expensive graph partitioning schemes.

2 PRELIMINARIES

2.1 Graph Data Model

A heterogeneous network can be modeled as a labeled, directed graph $G = (V, E, \mathscr{L})$ with node set V, edge set E, and label set $\mathscr{L}$, where (1) each node $u \in V$ represents an entity in the network, (2) each directed edge $e \in E$ denotes the relationship between two entities, and (3) $\mathscr{L}$ is a function which assigns to each node u and every edge e a label $\mathscr{L}(u)$ (and $\mathscr{L}(e)$, respectively) from a finite alphabet. The node labels represent the attributes of the entities, e.g., name, job, location, etc, and edge labels the type of relationships, e.g., founder, place founded, etc.

We store the graph as an adjacency list. Every node in the graph is added as an entry in the storage where the key is the node id and the value is an array of 1-hop neighbors. If the nodes and edges have labels, they are stored in the corresponding value entry. For each node, we store both incoming and outgoing edges. Both incoming and outgoing edges of a node can be important from the context of different queries. As an example, if there is an edge *founded* from *Jerry Yang* to *Yahoo!* in a knowledge graph, there also exists a reverse relation *founded_by* from *Yahoo!* to *Jerry Yang*. Such information could be useful in answering queries about *Yahoo!*.

2.2 h-Hop Traversal Queries

We discuss various h-hop queries over heterogeneous, directed graphs in the following.

1. **h-hop Neighbor Aggregation**: Count the number of h-hop neighbors of a query node.
2. **h-step Random Walk with Restart**: The query starts at a node, and runs for h-steps — at each step, jumps to one of its neighbors with equal probability, or returns to the query node with a small probability.
3. **h-hop Reachability**: Find if a given target node is reachable from a given source node within h-hops.

The aforementioned queries are often used as the basis for more complex graph operations. For example, neighborhood aggregation is critical for node labeling and classification, that is, the label of an unlabeled node could be assigned as the most frequent label which is present within its h-hop neighborhood. The h-step random walk is useful in expert finding, ranking, discovering functional modules, complexes, and pathways. Our third query can be employed in distance-constrained and label-constrained reachability search, as well as in approximate graph pattern matching queries [16].

2.3 Decoupled Design

We decouple query processing from graph storage. This decoupling happens at a *logical* level. As an example, query processors can be different physical machines than storage servers. On the other hand, the same physical machine can also run a query processing daemon, together with storing a graph partition in its main memory as a storage server. However, the logical separation between the two layers is critical in our design.

The advantages of this separation are more flexibility in query routing, system deployment, and scaling up, as well as achieving better load balancing and fault tolerance. However, we must also consider the drawbacks of having the graph storage apart. First, query processors may need to communicate with the storage tier via the network. This includes an additional penalty to the response time for answering a query. Second, it is possible that this design causes high contention rates on either the network, storage tier, or both.

To mitigate these issues, we design smart routing schemes that route queries to processors which are likely to have the relevant data in their cache, thereby reducing the communication overhead between processing and storage tiers. Below, we discuss various components of our design, including storage, processing tier, and router.

Graph Storage Tier. The storage tier holds all graph data by horizontally partitioning it across cheap commodity servers. Sophisticated graph partitioning will benefit our decoupled architecture as follows. Let us assume that the neighboring nodes can be stored in a page within the same storage server, and the granularity of transfer from storage to processing tier is a page containing several nodes. Then, we could actually ship a set of relevant nodes with a single request if the graph is partitioned well. This will reduce the number of times data are transferred between the processing and storage tier.

However, our lightweight and smart query routing techniques exploit the notion of graph landmarks [12] and embedding [36], thereby effectively utilizing the cache of query processors that stores recently used graph data. As demonstrated in our experiments, due to our smart routing, many neighbors up to 2∼3-hops of a query node can be found locally in the query processors' cache. Therefore, the partitioning scheme employed across storage servers becomes less important.

Query Processing Tier. The processing tier consists of servers where the actual query processing takes place. These servers do not communicate with each other [14]. They only receive queries from the query router, and also request graph data from the storage tier if necessary.

To reduce the amount of calls made to the storage tier, we utilize the cache of the query processors. Whenever some data is retrieved from the storage, it is saved in cache, so that the same request can be avoided in the near future. However, it imposes a constraint on the maximum storage capacity. When the addition of a new entry surpasses this storage limit, one or more old entries are evicted from the cache. We select the LRU (i.e., Least Recently Used) eviction policy because of its simplicity. LRU is usually implemented as the default cache replacement policy, and it favors recent queries. Thus, it performs well with our smart routing schemes.

Query Router. The router creates a thread for each processor, and opens a connection to send queries by following the routing schemes which we shall describe next.

3 QUERY ROUTING STRATEGIES

When a query arrives at the router, the router decides the appropriate query processor to which the request could be sent. For existing graph querying systems, e.g., SEDGE [35] and Horton [26], where each query processor is assigned a graph partition, this decision is fixed and defined in the routing table; the processor which contains the query node handles the request. With a decoupled architecture, no such mapping exists. Hence, we design novel routing schemes with the following objectives.

3.1 Routing Algorithm Objectives

1. Leverage each processor's cached data. Let us consider t successive queries received by the router. The router will send them to query processors in a way such that the average number of *cache hits* at the processors is maximized. This, in turn, reduces the average query processing latency. However, as stated earlier, to achieve maximum cache hits, it will not be sufficient to only route the queries on same nodes to the same processor. Rather, successive queries on *neighboring* nodes should also be routed to the same processor, since the neighborhoods of two nearby nodes may significantly overlap. This will be discussed shortly in Requirement 1.

2. Balance workload even if skewed or contains hotspot. As earlier, let us consider a set of t successive queries. A naïve approach will be to ensure that each query processor receives equal number of queries, e.g., a round-robin way of query dispatching by the router. However, each query might have a different workload, and would require a different processing time. We, therefore, aim at maximizing the overall *throughput* via query stealing (explained in Requirement 2), which automatically balances the workload across query processors.

3. Make fast routing decisions. The average time at the router to dispatch a query should be minimized, ideally a small constant time, or much smaller than $\mathcal{O}(n)$, where n is the number of nodes in the input graph. This reduces the query processing latency.

4. Have low storage overhead in the router. The router may store auxiliary data to enable fast routing decisions. However, this additional storage overhead must be a small fraction compared to the graph size.

3.2 Challenges in Query Routing

It is important to note that our routing objectives are not in harmony; in fact, they are often conflicting with each other. First, in order to achieve maximum cache locality, the router can send all the queries to the same processor (assuming no cache eviction happens). However, the workload of the processors will be highly imbalanced in this case, resulting in lower throughput. Second, the router could inspect the cache of each processor before making a good routing decision, but this will add network communication delay. Hence, the router must *infer* what is likely to be in each processor's cache.

In the following, we introduce two concepts that are directly related to our routing objectives, and will be useful in designing smart routing algorithms.

Topology-Aware Locality. To understand the notion of cache locality for graph queries (i.e., routing objective 1), we define a concept called *topology-aware locality*. If u and v are nearby nodes, then successive queries on u and v must be sent to the same processor. It is very likely that the h-hop neighborhoods of u and v significantly overlap.

But, how will the router know that u and v are nearby nodes? One option is to store the entire graph topology in the router; but this could have a high storage overhead. For example, the *WebGraph* dataset that we experimented with has a topology of size 60GB. Ideally, a graph with 10^7 nodes can have up to 10^{14} edges, and in such cases, storing only the topology itself requires petabytes of memory. Thus, we impose a requirement on our smart routing schemes as follows.

Requirement 1 *The additional storage at the router for enabling smart routing should not be asymptotically larger than $\mathcal{O}(n)$, n being the number of nodes; however, the routing schemes should still be able to exploit topology-aware locality.*

Achieving this goal is non-trivial, as the topology size can be $\mathcal{O}(n^2)$, and we provision for only $\mathcal{O}(n)$ space to approximately preserve such information.

Query Stealing. Routing queries to processors that have the most useful cache data might not always be the best strategy. Due to power-law degree distribution of real-world graphs, processing queries on different nodes might require different amount of time. Therefore, the processors dealing with high-degree nodes will have more workloads. Load imbalance can also happen if queries are concentrated in one specific region of the graph. When that happens, all queries will be sent to one processor, while other processors remain idle. To rectify such scenarios, we implement *query stealing* in our routing schemes as stated next.

Requirement 2 *Whenever a processor is idle and is ready to handle a new query, if it does not have any other requests assigned to it, it may "steal" a request that was originally intended for another processor.*

Query stealing is a well established technique for load balancing that is prevalently used by the HPC community, and there are several ways how one can implement it. *We perform query stealing at the router level.* In particular, the router sends the next query to a processor only when it receives an acknowledgement for the previous query from that processor. The router also keeps a *queue* for each connection in order to store the future queries that need to be delivered to the corresponding processor. By monitoring the length of these queues, it can estimate how busy a processor is, and this enables the router to rearrange the future queries for load balancing. We demonstrate the effectiveness of query stealing in our experiments (Section 4.6).

We next design four routing schemes — the first two are naïve and do not meet all the objectives of smart routing. On the other hand, the last two algorithms follow the requirements of a smart routing strategy.

3.3 Baseline Methods

3.3.1 Next Ready Routing

Next Ready routing is our first baseline strategy. The router decides where to send a query by choosing the next processor that has finished computing and is ready for a new request. The main advantages are: (1) It is easy to implement. (2) Routing decisions are made in constant time. (3) No preprocessing or storage overhead is required. (4) The workload is well balanced. However, this scheme fails to leverage processors' cache.

3.3.2 Hash Routing

The second routing scheme that we implement is *hash*, and it also serves as a baseline to compare against our smart routing techniques. The router applies a fixed hash function on each query node's id to determine the processor where it sends the request. In our implementation, we apply a modulo hash function.

In order to facilitate load balancing in the presence of workload skew, we implement *query stealing* mechanism. Whenever a processor is idle and is ready to handle a new query, if it does not have any other requests assigned to it, it steals a request that was originally intended for another processor. Since queries are queued in the router, the router is able to take this decision, and ensures that there are no idle processors when there is still some work to be done. Our hash routing has all the benefits of next ready, and very likely it sends a repeated query to the same processor, thereby getting better locality out of the cache. However, hash routing cannot capture topology-aware locality.

3.4 Proposed Methods

3.4.1 Landmark Routing

Our first smart routing scheme is based on landmark nodes [12]. One may recall that we store both incoming and outgoing edges of every node, thus we consider a *bi-directed* version of the input graph in our smart routing algorithms. We select a small set L of nodes as landmarks, and also pre-compute the distance of every node to these landmarks. We determine the optimal number of landmarks based on empirical results. Given some landmark node $l \in L$, the distance $d(u,v)$ between any two nodes u and v are bounded as follows:

$$|d(u,l) - d(l,v)| \leq d(u,v) \leq d(u,l) + d(l,v) \qquad (1)$$

Intuitively, if two nodes are close to a given landmark, they are likely to be close themselves. Our landmark routing is based on the above principle. We first select a set of landmarks that partitions the graph into P regions, where P is the total number of processors. We then decide a one-to-one mapping between those regions and processors. Now, if a query belongs to a specific region (decided based on its distance to landmarks), it is routed to the corresponding processor. Clearly, this routing strategy requires a preprocessing phase as follows.

Preprocessing. We select landmarks based on their node degree and how well they spread over the graph [1]. Our first step is to find a certain number of landmarks considering the highest degree nodes, and then compute their distance to every node in the graph by performing breadth first searches (BFS). If we find two landmarks to be closer than a pre-defined threshold, the one with the lower degree is discarded. The complexity of this step is $\mathcal{O}(|L|e)$, due to $|L|$ number of BFS, where $|L|$ is the number of landmarks, and e is the number of edges.

Next, we assign the landmarks to query processors as follows. First, every processor is assigned a "pivot" landmark with the intent that pivot landmarks are as far from each other as possible. The first two pivot landmarks are the two that are farthest apart considering all other landmark pairs. Each next pivot is selected as the landmark that is farthest from all previously selected pivot landmarks. Each remaining landmark is assigned to the processor which contains its closest pivot landmark. The complexity of this step is $\mathcal{O}(|L|^2 + |L|P)$, where P is the number of processors.

Finally, we define a "distance" metric d between the graph nodes and query processors. The distance of a node u to a processor p is defined as the minimum distance of u to any landmark that is assigned to processor p. This information is stored in the router, which requires $\mathscr{O}(nP)$ space and $\mathscr{O}(nL)$ time to compute, where n is the number of nodes. Therefore, *the storage requirement at the router is linear in the number of nodes*.

Routing. To decide where to send a query on node u, the router verifies the pre-computed distance $d(u,p)$ for every processor p, and selects the one with the smallest $d(u,p)$ value. As a consequence, the routing decision time is linear in the number of processors: $\mathscr{O}(P)$. This is very efficient since the number of processors is small.

In contrast to our earlier baseline routings, this method is able to leverage topology-aware locality. It is likely that query nodes that are in the neighborhood of each other will have similar distances to the processors; hence, they will be routed in a similar fashion. On the other hand, the landmark routing scheme is less flexible with respect to addition or removal of processors, since the assignment of landmarks to processors, as well as the distances $d(u,p)$ for every node u and each processor p needs to be recomputed.

The distance metric $d(u,p)$ is useful not only in finding the best processor for a certain query, but it can also be used for load balancing, fault tolerance, dealing with workload skew, and hotspots. As an example, let us assume that the closest processor for a certain query is very busy, or is currently down. Since the distance metric gives us distances to all processors, the router is able to select the second, third, or so on closest processor. This form of load balancing will impact the nearby query nodes in the same way; and therefore, the modified routing scheme will still be able to capture topology-aware locality. In practice, it can be complex to define exactly when a query should be routed to its next best query processor. We propose a formula that calculates the *load-balanced distance* $d^{LB}(u,p)$ as given below.

$$d^{LB}(u,p) = d(u,p) + \frac{\text{Processor Load}}{\text{Load Factor}} \tag{2}$$

Thus, the query is always routed to the processor with the smallest $d^{LB}(u,p)$. The router uses the number of queries in the queue corresponding to a processor as the measure of its load. The load factor is a tunable parameter, which allows us to decide how much load would result in the query to be routed to another processor. We find its optimal value empirically.

Dealing with Graph Updates. During addition/ deletion of nodes and edges, one needs to recompute the distances from every node to each of the landmarks. This can be performed efficiently by keeping an additional *shortest-path-tree* data structure [31]. However, to avoid the additional space and time complexity of maintaining a shortest-path-tree, we follow a simpler approach. When a new node u is added, we compute the distance of this node to every landmark, and also its distance $d(u,p)$ to every processor p. In case of an edge addition or deletion between two existing nodes, for these two end-nodes and their neighbors up to a certain number of hops (e.g., 2-hops), we recompute their distances to every landmark, as well as to every processor. Finally, in case of a node deletion, we handle it by considering deletion of multiple edges that are incident on it. After a significant number of updates, previously selected landmark nodes become less effective; thus, we recompute the entire preprocessing step periodically in an off-line manner.

3.4.2 Embed Routing

Our second smart routing scheme is the *Embed* routing, which is based on graph embedding [36, 4]. We embed a graph into a lower dimensional Euclidean space such that the hop-count distance between graph nodes are approximately preserved via their Euclidean distance (Figure 3). We then use the resulting node co-ordinates to determine how far a query node is from the recent history of queries that were sent to a specific processor. Clearly, embed routing also requires a preprocessing step.

Preprocessing. For efficiently embedding a large graph in a D-dimensional Euclidean plane, we first select a set L of landmarks and find their distances from each node in the graph. We then assign co-ordinates to landmark nodes such that the distance between each pair of landmarks is approximately preserved. We, in fact, minimize the *relative error* in distance for each pair of landmarks, defined below.

$$f_{error}(v_1,v_2) = \frac{|d(v_1,v_2) - \text{EuclideanDist}(v_1,v_2)|}{d(v_1,v_2)} \tag{3}$$

Here, $d(v_1,v_2)$ is the hop-count distance between v_1 and v_2 in the original graph, and EuclideanDist(v_1,v_2) is their Euclidean distance after the graph is embedded. We minimize the relative error since we are more interested in preserving the distances between nearby node pairs. Our problem is to minimize the aggregate of such errors over all landmark pairs — this can be cast as a generic multi-dimensional global minimization problem, and could be approximately solved by many off-the-shelf techniques, e.g., the *Simplex Downhill* algorithm that we apply in this work. Next, every other node's co-ordinates are found also by applying the Simplex Downhill algorithm that minimizes the aggregate relative distance error between the node and all the landmarks. The overall graph embedding procedure consumes a modest preprocessing time: $\mathscr{O}(|L|e)$ due to BFS from $|L|$ landmarks, $\mathscr{O}(|L|^2D)$ for embedding the landmarks, and $\mathscr{O}(n|L|D)$ for embedding the remaining nodes. In addition, the second step is completely parallelizable per node. Since each node receives D co-ordinates, it requires total $\mathscr{O}(nD)$ space in the router, which is linear in the number of nodes. Unlike landmark routing, *a benefit*

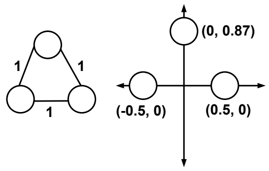

Figure 3: Example of graph embedding in 2D Euclidean plane

of embed routing is that the preprocessing is independent of the system topology, allowing more processors to be easily added at a later time.

Routing. The router has access to each node's co-ordinates. By keeping an average of the query nodes' co-ordinates that it sent to each processor, it is able to infer the cache contents in these processors. As a consequence, the router finds the distance between a query node u and a processor p, denoted as $d_1(u,p)$, and defined as the distance of the query node's co-ordinates to the historical mean of the processor's cache contents. As recent queries are more likely to influence the cache contents due to LRU eviction policy, we use the exponential moving average to compute the mean of the processor's cache contents. Initially, the mean co-ordinates for each processor are assigned uniformly at random. Next, assuming that the last query on node v was sent to processor p, its updated mean co-ordinates are:

$$\text{MeanCo-ordinates}(p) = \alpha \cdot \text{MeanCo-ordinates}(p) + (1-\alpha) \cdot \text{Co-ordinates}(v) \quad (4)$$

The smoothing parameter $\alpha \in (0,1)$ in the above Equation determines the degree of decay used to discard older queries. For example, α close to 0 assigns more weight only to the last query, and α close to 1 decreases the weight on the last query. We determine the optimal value of α based on experimental results. Finally, the distance between a query node u and a processor p is computed as given below.

$$d_1(u,p) = ||\text{MeanCo-ordinates}(p) - \text{Co-ordinates}(u)|| \quad (5)$$

Since we embed in an Euclidean plane, we use the L_2 norm to compute distances. We select the processor with the smallest $d_1(u,p)$ distance. One may observe that the routing decision time is only $\mathcal{O}(PD)$, P being the number of processors and D the number of dimensions.

Analogous to landmark routing, we now have a distance to each processor for a query; and hence, we are able to make routing decisions taking into account the processors' workloads and faults. As earlier, we define a *load-balanced distance* $d_1^{LB}(u,p)$ between a query node u and a processor p, and the query is always routed to the processor with the smallest $d_1^{LB}(u,p)$ value.

$$d_1^{LB}(u,p) = d_1(u,p) + \frac{\text{Processor Load}}{\text{Load Factor}} \quad (6)$$

The embed routing has all the benefits of smart routing. This routing scheme divides the active regions (based on workloads) of the graph into P partitions in an overlapping manner, and assigns them to the processors' cache. Moreover, it dynamically adapts the partitions with new workloads. Therefore, *it bypasses the expensive graph partitioning and re-partitioning problems to the existing cache replacement policy of the query processors*. This shows the effectiveness of embed routing.

Dataset	# Nodes	# Edges	Size on Disk (Adj. List)
WebGraph	105 896 555	3 738 733 648	60.3 GB
Memetracker	96 608 034	418 237 269	8.2 GB
Freebase	49 731 389	46 708 421	1.3 GB

Table 1: Graph datasets

Dealing with Graph Updates. Due to pre-assignment of node co-ordinates, embed routing is less flexible with respect to graph updates. When a new node is added, we compute its distance from the landmarks, and then assign co-ordinates to the node by applying the Simplex Downhill algorithm. Edge updates and node deletions are handled in a similar method as discussed for landmark routing. We recompute the entire preprocessing step periodically in an off-line manner to deal with a significant number of graph updates.

4 EVALUATION

4.1 Experiment Setup

• **Cluster Configuration.** We perform experiments on a cluster of 12 servers having 2.4 GHz Intel Xeon processors, and interconnected by 40 Gbps Infiniband, and also by 10 Gbps Ethernet. Most experiments use a single core of each server with the following configuration: 1 server as router, 7 servers in the processing tier, 4 servers in the storage tier; and communication over Infiniband with remote direct memory access (RDMA). Infiniband allows RDMA in a few microseconds. We use a limited main memory (0∼4GB) as the cache of processors. Our codes are implemented in C++.

To implement our storage tier, we use RAMCloud [20], which provides high throughput and very low read/write latency, in the order of 5-10 μs for every put/ get operation. It is able to achieve this efficiency because it keeps all stored values in memory as a distributed key-value store, where a key is hashed to determine on which server the corresponding key-value pair will be stored.

• **Datasets.** We summarize our data sets in Table 1. As explained in Section 2, we store both in- and out-neighbors. The graph is stored as an adjacency list — every node-id in the graph is the key, and the corresponding value is an array of its 1-hop neighbors. The graph is partitioned across storage servers via RAMCloud's default and inexpensive hash partitioning scheme, MurmurHash3 over graph nodes.

WebGraph: The uk-2007-05 web graph (http://law.di.unimi.it/ datasets.php) is a collection of web pages, which are represented as nodes, and their hyperlinks as edges. **Memetracker:** This dataset (snap.stanford.edu) tracks quotes and phrases that appeared from August 1 to October 31, 2008 across online news spectrum. We consider documents as nodes and hyper-links as edges. **Freebase:** We download the *Freebase* knowledge graph from http://www.freebase.com/. Nodes are named entities (e.g., Google) or abstract concepts (e.g., Asian people), and edges denote relations (e.g., founder).

• **Online Query Workloads.** We consider three online graph queries [35], discussed in Section 2.2 — all require traversals up to h hops: (1) h-hop neighbor aggregation, (2) h-step random walk with restart, and (3) h-hop reachability. We consider a uniform mixture of above queries. We simulate a scenario when queries are drawn from a hotspot region; and the hotspots change over time. In particular, we select 100 nodes from the graph uniformly at random. Then, for each of these nodes, we select 10 different query nodes which are at most r-hops away from that node. Thus, we generate 1000 queries; every 10 of them are from one hotspot region, and the pairwise distance between any two nodes from the same hotspot is at most $2r$. Finally, all queries from the same hotspot are grouped together and sent consecutively. We report our results averaged over 1000 queries.

To realize the effect of topology-aware locality, we consider smaller values of r and h, e.g., $r = 2$ and $h = 2$.

• **Evaluation Metrics.**
Query Response Time measures the average time required to answer one query.
Query Processing Throughput measures the number of queries that can be processed per unit time.
Cache Hit Rate: We report cache hit rates, since higher cache hit rates reduce the query response time. Consider t queries $q_1, q_2, \ldots, q_t$ received successively by the router. For simplicity, let us assume that each query retrieves all h-hop neighbors of that query node (i.e., h-hop neighborhood aggregation). We denote by $|N_h(q_i)|$ the number of nodes within h-hops from q_i. Among them, we assume that $|N_h^c(q_i)|$ number of nodes are found in the query processors' cache.

$$\text{Cache Hit Rates} := \sum_{i=1}^{t} |N_h^c(q_i)| \tag{7}$$

$$\text{Cache Miss Rates} := \sum_{i=1}^{t} \left(|N_h(q_i)| - |N_h^c(q_i)|\right) \tag{8}$$

• **Parameter Setting.** We find that *embed routing performs the best compared to three other routing strategies*. We also set the following parameter values since they perform the best in our implementation. We shall, however, demonstrate sensitivity of our routing algorithms with these parameters in Section 4.6.

We use maximum 4GB cache in each query processor. All experiments are performed with the cache initially empty (cold cache). The number of landmarks $|L|$ is set as 96 with at least 3 hops of separation from each other. For graph embedding, 10 dimensions are used. Load Factor (which impacts query stealing) is set as 20, and the smoothing parameter $\alpha = 0.5$.

In order to realize how our routing schemes perform when there is no cache in processors, we consider an additional "no-cache" scheme. In this mode, all queries are routed following the next ready technique; however, as there is no cache in query processors, there will be no overhead due to cache lookup and maintenance.

• **Compared Systems.** Decoupled architecture and our smart routing logic, being generic, can benefit many graph querying systems. Nevertheless, we compare gRouting with two distributed graph processing systems: SEDGE/Giraph [35] and PowerGraph [6]. Other recent graph querying systems, e.g., [26, 19] are not publicly available for a direct comparison.

SEDGE [35] was developed for h-hop traversal queries on top of Giraph or Google's Pregel system [15]. It follows in-memory, vertex-centric, bulk-synchronous parallel model. SEDGE employs ParMETIS software [9] for graph partitioning and re-partitioning. PowerGraph [6] follows in-memory, vertex-centric, asynchronous gather-apply-scatter model. In the beginning, only the query node is active, and each active node then activates its neighbors, until all the h-hop neighbors from the query nodes are activated. PowerGraph also employs a sophisticated node-cut based graph partitioning method.

4.2 Comparison with Graph Systems

We compare gRouting (embed routing is used) with two distributed graph processing systems, SEDGE/Giraph [35] and PowerGraph [6]. As these systems run on Ethernet, we consider a version of gRouting on Ethernet (gRouting-E). We consider 12 machines configuration of SEDGE and PowerGraph, since query processing and graph storage in them are coupled on same machines. In contrast, we fix the number of routing, processing, and storage servers as 1, 7 and 4, respectively. The average 2-hop neighborhood size varies from 10K∼60K nodes over our datasets.

In Figure 4, we find that our throughput, with hash partitioning and over Ethernet, is 5∼10 times better than SEDGE and PowerGraph that employ expensive graph partitioning and re- partitioning. The re-partitioning in SEDGE requires around 1 hour and also apriori information on future queries, whereas PowerGraph graph partitioning finishes in 30 min. On the contrary, gRouting performs lightweight hash partitioning over graph nodes, and does not require any prior knowledge of the future workloads. Moreover, our throughput over Infiniband is 10∼35 higher than these systems. *These results show the usefulness of smart query routing over expensive graph partitioning and re-partitioning schemes.*

Next, we report scalability, impact of cache sizes, and graph updates over our largest *Webgraph* dataset, and using Infiniband network.

4.3 Scalability and Deployment Flexibility

One of the main benefits of separating processing and storage tiers is deployment flexibility — they can be scaled-up independently, which we investigate below.

Processing Tier: We vary the number of processing servers from 1 to 7, while using 1 router and 4 storage servers. In Figure 5(a), we show throughput with varying number of processing servers. Corresponding cache hit rates are presented in Figure 5(b). For these experiments, we assume that each query processor has sufficient cache capacity (4GB) to store the results of all 1000 queries (i.e, adjacency lists of 52M nodes, shown in Figure 5(b)). Since, for every experiment, we start with an empty cache, and then send the same 1000 queries in order, maximum cache hit happens when there is only one query processor. As we increase the number of query processors, these queries get distributed and processed by different processors, thus cache hit rate generally decreases. This is more evident for our baseline routing schemes, and we find that their throughput saturates with 3$\sim$5 servers. These findings demonstrate the usefulness of smart query routing: *To maintain same cache hit rate, queries must be routed intelligently. Since Embed routing is able to sustain almost same cache hit rate with many query processors (Figure 5(b)), its throughput scales linearly with query processors.*

Storage Tier: We next vary the number of storage servers from 1 to 7, whereas 1 server is used as the router and 4 servers as query processors (Figure 5(c)). When we use 1 storage server, we can still load the entire 60GB *Webgraph* on the main memory of that server, since each of our servers has sufficient RAM. The throughput is the least when there is only one storage server. We observe that 1$\sim$2 storage servers are insufficient to handle the demand created by 4 query processors. However, with 4 storage servers, the throughput saturates, since the bottleneck is transferred to query processors. This is evident from our previous results — the throughput with 4 query processors was about 120 queries per second (Figure 5(a)), which is the same throughput achieved with 4 storage servers in the current experiments.

4.4 Impact of Cache Sizes

In previous experiments, we assign 4GB cache to each processor, which was large enough for our queries; and we never discarded anything from the cache. We next perform experiments when it needs to evict cache entries. In Figure 6, we present average response times with various cache capacities. At the largest, with 4GB cache per processor, no eviction occurs. Therefore, there is no additional performance gain by increasing the cache capacity. On the other extreme, having cache with less than

Landmark	Embed	
	embed per landmark	embed per node
35 sec	36 sec	1 sec

Table 2: Preprocess times

Landmark	Embed	Input graph
2.8 GB	4GB	60.3GB

Table 3: Preprocess storage

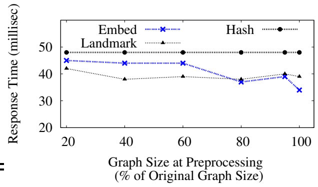

Figure 7: Robustness with graph updates

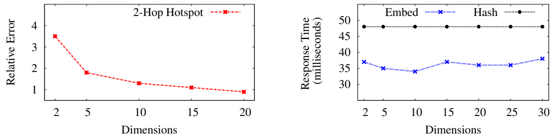

(a) Relative error

(b) Response time

Figure 8: Impact of embedding dimensionality

64MB per processor results in worse response times than what was obtained with no-cache scheme, represented by the horizontal red line (86ms in Figure 6). When the cache does not have much space, it ends up evicting entries that might have been useful in the future. Hence, there are not enough cache hits to justify its maintenance and lookup costs when cache size $<$ 64MB/ processor.

We also evaluate our routing strategies in terms of minimum cache requirement to achieve a response time of 86ms, the break-even point of deciding whether or not to add a cache. Figure 6(c) shows that smart routing schemes achieve this response time with a much lower cache, as compared to that of the baselines. These results illustrate that *our smart routings utilize the cache well; and for the same amount of cache, they achieve lower response time compared to baseline routings*.

4.5 Preprocessing and Graph Updates

Preprocessing Time and Storage: For landmarks routing, we compute the distance of every node to all landmarks, which can be evaluated by performing a BFS from each landmark. This takes about 35 sec for one landmark in *Webgraph* (Table 2), and can be parallelized per landmark. For embed routing, in addition, we need to embed every node with respect to landmarks, which requires about 1 sec per node in *Webgraph*, and is again parallelizable per node.

The preprocessed landmark routing information consumes about 2.8GB storage space in case of *Webgraph*. On the contrary, with embedding dimensionality 10, the *Webgraph* embedding size is only 4GB. Both these preprocessed information are modest compared to the original *Webgraph* size, which is around 60GB (Table 3).

Graph Updates: In these experiments, we preprocess a reduced subgraph of the original dataset. For example, at 20% of the original dataset (Figure 7), we select only 20% of all nodes uniformly at random, and compute preprocessed information over the subgraph induced by these selected nodes. However, we always run our query over the complete *Webgraph*. We incrementally compute the necessary information for the new nodes, as they are being added, without changing anything on the preprocessed information of the earlier nodes. As an example, in case of embed routing, we only compute the distance of a new node to the landmarks, and thereby find the coordinates of that new node. However, one may note that with the addition of every new node and its adjacent edges, the preprocessed information becomes outdated (e.g., the distance between two earlier nodes might decrease). Since we do not change anything on the preprocessed information, this experiment demonstrates the robustness of our method with respect to graph updates.

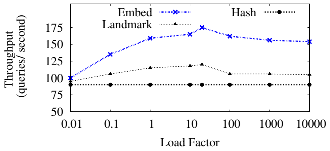

Figure 9: Impact of load factor

Figure 7 depicts that *our smart routing schemes are robust for a small number of graph updates*. With embed routing, preprocessed information over the whole graph results in response time of 34 ms, whereas preprocessed information at 80% of the graph results in response time of 37 ms (i.e., response time increases by only 3 ms). As expected, the response time deteriorates when preprocessing is performed on a smaller amount of graph data, e.g., with only 20% graph data, response time increases to 44 ms, which is comparable to the response time of baseline hash routing (48 ms).

4.6 Sensitivity Analysis

We find that gRouting is more sensitive towards load factor (due to *query stealing*) and embedding dimensionality, compared to other parameters, e.g., number of landmarks and smoothing factor (α). Due to lack of space, we present sensitivity analysis with respect to load factor and embedding dimensionality in Figures 8 and 9. Sensitivity results with other parameters can be found in our extended version [10]. In all figures, we also show our best baseline — hash routing, for comparison.

Embedding Dimensionality: We consider the performance implications of the number of dimensions on embed routing. For these experiments, we create several embeddings, with dimensionality from 2 to 30. While the relative error in distance between node pairs decreases with higher dimensions, it almost saturates after 10 dimensions (Figure 8(a)). On the other hand, we observe that the average response time reduces until dimension 10, and then it slowly increases with more dimensions (Figure 8(b)). This is because with higher dimensions, we reduce the distance prediction error, thereby correctly routing the queries and getting more cache hits. However, a large number of dimensions also increases the routing decision making time at the router. Hence, the least response time is achieved at dimensionality 10.

Load Factor: This parameter impacts both of our smart routing schemes. We find from Equations 3 and 7 that smaller values of load factor diminish the impact of "smart" routing (i.e., landmarks and node co-ordinates), instead queries will be routed to the processor having the minimum workload. On the other hand, higher values of load factor reduces the impact of load balancing (i.e., query stealing) — queries would be routed solely based on landmarks and node co-ordinates. Therefore, in these experiments, we expect that the throughput will initially increase with higher values of load factor, until it reaches a maximum, and then it would start decreasing. Indeed, it can be observed in Figure 9 that with load factor between 10$\sim$20, the best throughput is achieved.

5 Related Work

We studied *smart query routing* for distributed graph querying — a problem for which we are not aware of any prior work. In the following we, however, provide a brief overview of work in neighborhood areas.

Landmarks and Graph Embedding. Landmarks were used in path finding, shortest path estimation, and in estimating network properties [12, 24, 1, 23]. Graph embedding [36] was employed in internet routing, such as predicting internet network distances and estimating minimum round trip time between hosts [4]. To the best of our knowledge, ours is the first study that applies graph embedding and landmarks to design effective routing algorithms for distributed graph querying.

Graph Partitioning, Re-partitioning, Replication. The balanced, minimum-edge-cut graph partitioning divides a graph into k partitions such that each partition contains same number of nodes, and the number of cut-edges is minimized. Even for $k = 2$, the problem is **NP**-hard, and there is no approximation algorithm with a constant approximation ratio unless **P =NP** [18]. Therefore, efforts were made in developing polynomial-time heuristics — METIS, Chaco, SCOTCH, to name a few. More sophisticated graph partitioning schemes were also proposed, e.g., node-cut [6], complementary partitioning [35], and label propagation [33], among many others.

Graph re-partitioning is critical for online queries, since the graph topology and workload change over time [16]. The methods in [35, 18, 11] perform re-partitioning based on past workloads. Incremental partitioning was developed for dynamic and stream graphs [37, 32, 30]. With the proposed embed routing, we bypass these expensive graph partitioning and re-partitioning challenges to the existing cache replacement policy.

Replication was used for graph partitioning, re-partitioning, load balancing, and fault tolerance. In earlier works, [22, 8] proposed one extreme version by replicating the graph sufficiently so that, for every node in the graph, all of its neighbors are present locally. Mondal et. al. designed an overlapping graph re-partitioning scheme [16], which updates its partitions based on the past read/ write patterns. Huang et. al. [7] designed a lightweight re- partitioning and replication scheme considering access locality, fault tolerance, and dynamic updates. While we also replicate the graph data at query processors' cache in an overlapping manner, we *only replicate the active regions* of the graph based on recent workloads. Unlike [16, 7] we do not explicitly run any graph replication strategy at our processors or storage servers. Instead, our *smart routing algorithms* automatically perform replications at processors' cache.

Graph Caching, De-coupling, Multi-Query Optimization. Facebook uses a fast caching layer, Memcached on top of a graph database to scale the performance of graph querying [19]. Graph-structure-aware and workload-adaptive caching techniques were also proposed, e.g., [2, 21]. There are other works on view-based graph query answering [5] and multi-query optimizations [13]. Unlike ours, these approaches require the workload to be known in advance.

Recently, Shalita et. al. [27] employed decoupling for an optimal assignment of HTTP requests over a distributed graph storage. First, they perform a static partition of the graph in storage servers based on co-access patterns. Next, they find past workloads on each partition, and dynamically assign these partitions to query processors such that load balancing can be achieved. While their decoupling principle and dynamic assignment at query processors are similar to ours, they still explicitly perform a sophisticated graph partitioning at storage servers, and update such partitions in an offline manner. In contrast, our smart routing algorithms automatically partition the active regions of the graph in a dynamic manner and store them in the query processors' cache, thereby achieving both load balancing and improved cache hit rates.

6 CONCLUSIONS

We studied h-hop traversal queries – a generalized form of various online graph queries that access a small region of the graph, and require fast response time. To answer such queries with low latency and high throughput, we follow the principle of decoupling query processors from graph storage. Our work emphasized *less* on the requirements for an expensive graph partitioning and re-partitioning technique, instead we developed smart query routing strategies for effectively leveraging the query processors' cache contents, thereby improving the throughput and reducing latency of distributed graph querying. In addition to workload balancing and deployment flexibility, gRouting is able to provide linear scalability in throughput with more number of query processors, works well in the presence of query hotspots, and is also adaptive to workload changes and graph updates.

Abstract

This paper tackles the cache thrashing problem caused by the non-deterministic scheduling feature of bulk synchronous parallel (BSP) execution in GPUs. In the BSP model, threads can be executed and interleaved in any order before reaching a barrier synchronization point, which requires the entire working set to be in cache for maximum data reuse over time. However, it is not always possible to fit all the data in cache at once. Thus, we propose a locality-aware software throttling framework that throttles the number of active execution tasks, prevents cache thrashing, and enhances data reuse over time. Our locality-aware software throttling framework focuses on an important class of applications that operate on sparse matrices (graphs). These applications come from the domains of linear algebra, graph processing, machine learning and scientific simulation. Evaluated on over 200 real sparse matrices and graphs that suffer from cache thrashing in the Florida sparse matrix collection, our technique achieves an average of 2.01X speedup, a maximum of 6.45X speedup, and a maximum performance loss $\leq$5%.

1 Introduction

Operations on sparse matrix and graph are important for solving linear algebra and optimization problems that arise in data science, machine learning, and physics-based simulation. In this paper we focus on a fundamental sparse matrix operation that relates an input vector x with an output vector y. Let $\mathbf{x}$ be an $n \times 1$ vector, $\mathbf{y}$ be an $m \times 1$ vector, and A be a $m \times n$ matrix, the relation between y and x is defined as $\mathbf{y}$ = A$\mathbf{x}$, where

$$y_i = reduce\_op\{A_{ik} \odot x_k\},\ 1 \leq k \leq n.$$

When the operator *reduce_op* is *sum* and the binary operator $\odot$ is multiplication, the operation is sparse matrix vector multiplication (SpMV). When the operator *reduce_op* is *min* and the binary operator $\odot$ is $+$, the operation is an iterative step in the single source shortest path (SSSP) problem [13]. An example is shown in Figure 1.

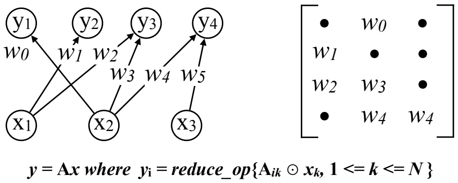

Figure 1: A Fundamental Sparse Matrix Operation

However, poor data reuse is often a problem when running sparse applications on GPUs. Throttling is a useful technique to improve data reuse. Unlike other locality enhancement techniques that focus on spatial data reuse on many-core, for instance, the memory coalescing techniques [33], throttling improves data reuse over time by limiting the number of actively executed tasks.

Throttling prioritizes the execution of the tasks that reuse the data in the cache over those that do not reuse the data in the cache. Figure 2 shows an example of how throttling improves cache data reuse. Assuming the cache capacity is 4, in the original case, the cache cannot hold all the data elements in the execution list which will inevitably cause cache (capacity) misses. Throttling helps by dividing the execution into two phases and scheduling one phase after another. Data elements in each phase can now fit into cache and be fully reused so that no cache (capacity) misses will occur.

Throttling for GPU has been studied extensively in the hardware context. Rogers and others [27] discovered that limiting the number of active wavefronts (warps) enhances cache data reuse over time and alleviates cache thrashing. The DYNCTA framework [19] limits the number of CTAs for memory intensive applications and results in better cache performance. The work by Chen and others [8] augmented cache bypassing with a dy-

[*] First authors Chen and Hayes have made equal contributions to this work and are listed alphabetically.

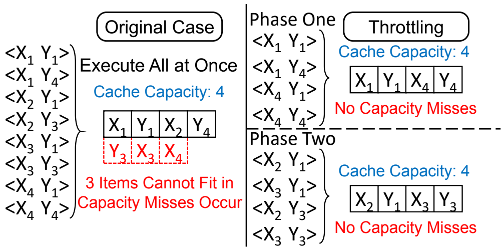

Figure 2: Throttling Example

namic warp-throttling technique to improve both cache performance and energy efficiency. However, all these prior throttling techniques on GPUs have been developed as hardware modifications.

In this paper, we present a software throttling framework that targets irregular applications operating on sparse data. Our software throttling framework will first divide the entire workload into multiple partitions such that the working set of each partition fits into the cache and the data communication between different partitions is minimum (we will refer to each partition as *cache-fit partition* or *cache-fit work group* throughout this paper). Then we schedule the cache-fit partitions and let each of them be processed independently to ensure throttling.

There are three main challenges for realizing software throttling. First, the traditional work partition models focus on minimizing data reuse among different partitions with load-balancing constraints [2, 6, 29]. However, cache-fit work partitioning is not necessarily load-balanced, it should be data-balanced across different partitions. Second, inappropriate scheduling of cache-fit partitions might result in low execution pipeline utilization. For each of the cache-fit partitions that have low data reuse, there may not be enough tasks running concurrently, which will make the execution pipeline units not fully utilized and degrade the computation throughput. Last, reducing the overhead of software throttling is important and yet challenging, especially for finding minimum communication *cache-fit* partitions, which is the most time-consuming step in software throttling.

To tackle these challenges, we propose the three following techniques. To obtain *cache-fit* partitions, we develop an efficient **data-balanced** work partition model. Our partition model can balance data while minimizing the communication cost among different partitions. We also introduce a **split-join** scheduling model to take advantage of the trade-off between throttling and throughput. The *split-join* scheduling model adaptively merges partitions to avoid low execution pipeline utilization and/or use a concurrent queue based implementation for relaxed barrier synchronization. We reduce the partition overhead by a coarse-grained partition model which was built upon a multi-level partition paradigm. Instead of partitioning the original work matrix (graph), our model partitions a coarsened matrix (graph) which can significantly reduce the partition overhead while maintaining similarly good partition quality.

Our throttling technique is a pure software based implementation. It is readily deployable and highly efficient. Evaluated over 228 sparse matrices and graphs from Florida matrix collection [11] - the set of matrices which suffer from cache thrashing (their working set cannot entirely fit into the L2 cache on the Maxwell GPU and Pascal GPU we tested), our software throttling method can achieve an average 2.01X speedup (maximal 6.45X speedup).

As far as we know, this is the first work that systematically investigates **software throttling** techniques for GPUs and is extensively evaluated on real sparse matrices and graphs. The contribution and the outline of our paper is summarized as follows:

- We introduce an analytical model named *data-balanced* work partition for locality-aware software throttling. Efficient heuristics are developed to achieve (near-)minimum communication *cache-fit* work partitions that can be further scheduled to alleviate GPU cache thrashing (Section 2).

- We exploit the trade-off between cache locality and execution pipeline utilization and provide a set of practical *cache-fit* work group scheduling policies based on *adaptive merging* and *concurrent dequeuing*. We discuss the advantages/disadvantages, the applicability, and the effectiveness of each scheduling policy in different settings. (Section 3).

- Our method requires *no hardware modification*. It is low overhead and readily deployable. We introduce efficient overhead control mechanisms for graph(matrix)-based work partition. (Section 4).

- We conduct a *comprehensive data analysis* for over 200 large real sparse matrices(graphs). Our framework in particular works well for the set of sparse matrices that have large working sets and suffer from high GPU cache contention (Section 5).

2 Data-Balanced Work Partition

Our software throttling framework first divides the entire workload into cache-fit partitions. A cache-fit partition's working set fits into the cache such that it will not cause any cache capacity miss. This section presents the concept and methodology of data-balanced work partition.

2.1 Graph Representation

In this paper, we focus on a fundamental operation in sparse linear algebra and optimization applications. It is defined as follows. Assume we have an $m \times n$ matrix A, an $n \times 1$ vector x, and an $m \times 1$ vector y such that:

$$y_i = reduce\_op\{A_{ik} \bigodot x_k\}, 1 \leq k \leq n \qquad (1)$$

The operator $\odot$ is a binary operator, and the operator *reduce_op* is a reduction operator. When $\odot$ is product $\times$ and *reduce_op* is *sum*, the operation is a sparse matrix vector multiplication (SpMV). When $\odot$ is plus $+$ and *reduce_op* is *min*, the operation is a *min/product* step in the single source shortest path (SSSP) problem.

We represent a computation unit as a 2-tuple (x_j, y_i) which represents (1) one binary $\odot$ operation between x_j and A_{ij} , and (2) one step in the reduction operation *reduce_op* for obtaining y_i. We only focus on vector x and y, since the matrix entries will be used only once in Equation (1).

We represent the entire workload as a *2-tuple* list. Using a graph representation, each data element in the *2-tuple* is modeled as a vertex and each tuple is modeled as an edge that connects the corresponding two vertices. Performing a work partition is essentially performing an edge partition on the graph, as illustrated in Figure 3.

2.2 Data-Balanced v.s. Load-Balanced

We formally define the **data-balanced** *work partition* model. The input is a list of *2-tuple* modeled as a work graph and the output is a set of minimum-interaction work partitions such that the number of unique vertices, which represent data elements, in every work partition is less than or equal to the cache capacity.

In contrast to prior load-balanced work partition, we perform data-balanced work partition. We denote this problem as a *Vertex-balanced Edge-Partition (V-EP)* model and we give the definition below:

Definition 2.1.
Vertex-balanced Edge-Partition (V-EP) Problem *Given a graph $G = (V,E)$ with the set of vertices V and the set of edges E, and vertex capacity constraint T. Let $x = \{e_1, e_2, ...e_k\}$ denote a partition of the edges of G into k disjoint subsets, and let $V(e_i)$ denote the set of unique vertices in e_i. $\forall n \in V$, let $P(n)$ denote the number of subsets that n's incident edges fall into. We optimize the total vertex replication cost:*

$$\begin{aligned} \underset{x}{minimize} \quad & R(x) = \sum_{n \in V} (P(n) - 1) \\ subject\ to \quad & \forall i \in [1..k], |V(e_i)| \leq T \end{aligned} \qquad (2)$$

In prior work, the *Edge-balanced Edge-Partition* (E-EP) problem has been well studied particularly in the distributed graph processing setting [6, 14] and also for balancing workloads in GPU [25, 26]. However, the V-EP problem is not. Both the V-EP and E-EP problems minimize vertex replication cost, while the E-EP model aims to balance the load among processors in space, and the V-EP model aims to alleviate cache thrashing and maximize data reuse over time.

Figure 3: Data-Balanced v.s. Load-Balanced

We use an example in Figure 3 to illustrate the difference between the V-EP work partition and the E-EP work partition. Assuming the cache capacity is 4, Figure 3 (a) shows a 2-way V-EP work partition: one partition has 4 edges and the other has 2, the unique vertices of both (4 vertices) fit into cache. Figure 3 (b) shows another 2-way E-EP partition: Each partition has 3 edges, however *partition 2* has 6 unique vertices and do not fit into cache. Thus the E-EP model might exacerbate rather than alleviate the cache thrashing problem.

2.3 Partition Framework

We propose a data-balanced work partition framework that ensure the working set of each partition is of the same size and in the meantime the data reuse across different partitions is reduced as much as possible.

Our partition framework is a recursive *bisection* framework. Bisection is a *2-way* balanced edge partition that ensures minimum vertex replica between two equal-size edge partitions. The optimal *bisection* is a well studied problem [25]. We take the advantage of the *bisection* method and perform hierarchical partitioning.

During the recursive partition process, the framework bisects a sub-graph that has more unique vertices than specified by the capacity constraint. It keeps bisecting until no such sub-graph exists.

We use a tree data structure to keep track of the obtained sub-graphs. Starting from the root node that represents the entire work graph, the framework bisects the corresponding graph and generates two children nodes: each of the child nodes corresponds to a sub-graph that contains half of the edges from the parent node. If either or both children nodes violate the capacity constraint, either or both will be added to the list of sub-graphs that need to be further bisected. The process repeats until all leaf nodes become cache-fit work partitions.

The detailed algorithm is listed below in Algorithm 1. The *data-balanced work partition* (DBWP) procedure takes the work graph G and the cache capacity constraint T as input, and generates a set of cache-fit partitions P as output. The *bisect* function in Algorithm 1 we adopted is based on the best existing balanced edge partition algorithm named SPAC [26, 24] by Li and others. We will discuss the implementation details and the overhead control mechanisms of the *bisect* function in Section 4.

Algorithm 1 Data-Balanced Work-Partition (DBWP)

```
Input: work graph G, cache capacity T
Output: cache-fit partition set P
procedure DBWP(G, T, P)
    if $|G.data\_elements| > T$ then
        (lchild, rchild) = bisect(G)
        DBWP(lchild, T, P)
        DBWP(rchild, T, P)
    else
        add G to P
    end if
end procedure
```

We use an example to illustrate the *DBWP* procedure in Figure 4. In this example, the graph has 8 edges and 8 vertices, and the cache capacity constraint is 4. Performing *bisect* for the sub-graph represented by the tree root node, we obtain two sub-graphs each of which has 4 edges. The vertex replica cost is optimum: 2, since two nodes y_2 and x_2 appear in both partitions.

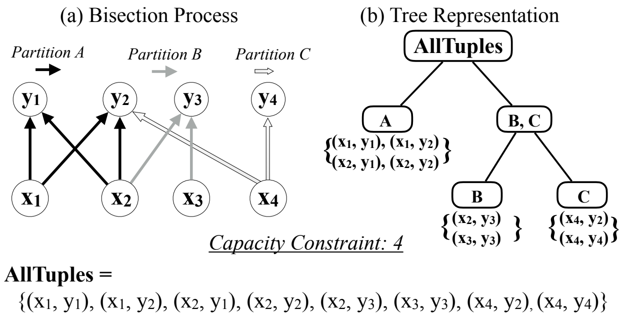

Figure 4: Hierarchical Bisection Example

The first sub-graph A in Figure 4 (a) has 4 unique vertices and does not violate the capacity constraint, we do not perform further bisection on sub-graph A. The other sub-graph, however, has 6 unique vertices and does not fit into the cache. Therefore we perform the second bisection and obtain partitions B and C where the vertex replica cost is optimum (0 in this case). At this point, there is no sub-graph that does not fit into the cache, therefore we terminate the bisection process. The tree representation is shown in Figure 4 (b).

3 Cache-Fit Partitions Scheduling

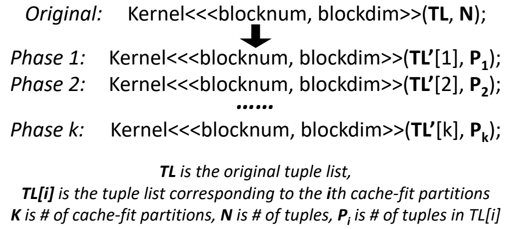
DBWP model outputs a set of *cache-fit* partitions. All these partitions need to be processed independently to minimize cache-thrashing interference. However, naive scheduling of these partitions might result in low execution pipeline utilization. In this section, we introduce four different *Cache-Fit Partitions* Scheduling methods: *Cache-Fit* Scheduling (**CF**), *Cache-Fit Queue* Scheduling (**CF-Q**), *Split-Join* Scheduling (**SJ**) and *Split-Join Queue* Scheduling (**SJ-Q**).

CF works well when all cache-fit partitions have high data reuse. **SJ** is good for cases when the sparsity structure is already known, for instance, pruned deep leaning neural networks. Both **CF-Q** and **SJ-Q** can loosely enforce throttling and provide a better performance.

3.1 Cache-Fit Scheduling

A straightforward way to isolate the computation of different cache-fit partitions is to assign each partition a single *kernel* function and execute these kernels one by one. A *kernel* is a function that is executed on GPU. All threads within a GPU kernel will need to finish before the entire kernel complete – there is a strict barrier between different GPU kernels. Moreover, between two consecutive kernels, the data in the cache will be invalidated.

Here, we propose **CF** which separates the original kernel functions into multiple kernels, while the number of which is determined by the number of cache-fit partitions given by **DBWP** model. The code of the kernel function for each cache-fit partition is the same. The only difference is the input to each kernel. **CF** ensures that the data in the cache is fully reused before it was evicted from the cache within each cache-fit partition.



```
Original:   Kernel<<<blocknum, blockdim>>(TL, N);
                          ⬇
Phase 1:    Kernel<<<blocknum, blockdim>>(TL'[1], P1);
Phase 2:    Kernel<<<blocknum, blockdim>>(TL'[2], P2);
                        ……
Phase k:    Kernel<<<blocknum, blockdim>>(TL'[k], Pk);
```

TL is the original tuple list,
TL[i] is the tuple list corresponding to the ith cache-fit partitions
K is # of cache-fit partitions, N is # of tuples, P_i is # of tuples in TL[i]

Figure 5: Kernel Splitting for Cache-Fit Scheduling

We show the idea of **CF** in Figure 5. The input *2-tuple* task list TL is split into k *2-tuple* lists TL', which corresponds to each of the cache-fit partitions. Each new tuple list will be processed by a single kernel.

3.2 Cache-Fit Queue Scheduling

CF makes sure that each cache-fit partition will be processed by one kernel. Although **CF** can provide good throttling performance for a lot of matrices, this scheduling method may cause low execution pipeline utilization for the type of matrices whose data reuse is low. For example, for a given cache size T and average data reuse ratio r for a cache-fit partition, the total work is $T * r/2$ using our work graph model. The variable T is fixed for a given architecture. If r is low, the number of concurrent tasks in one cache-fit partition p is low and may not keep the execution pipeline busy.

To avoid this problem, we propose **CF-Q**, which processes the whole tuple list in a single kernel instead of one invocation per cache-fit partition. However, using a single kernel means that elements in one cache-fit partition have no guarantee to be executed without any interference. To enable throttling, we set up a FIFO queue before launching the kernel. Each queue entry corresponds to a chunk of tuples so that adjacent chunks are from the same cache-fit partition. A warp automatically fetches a chunk from the queue and process the tuples from that chunk. We show an example of how **CF-Q** works in Figure 6.

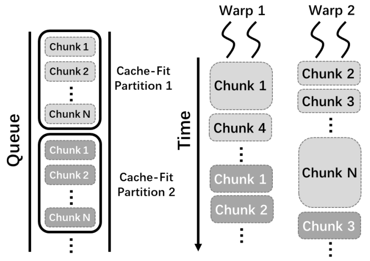


Figure 6: Queue Based Scheduling Example

Unlike **CF** which has explicit barriers to strictly enforce the independent execution of different cache-fit partitions, **CF-Q** uses no barrier. It is possible that the last chunk in one partition and the first chunk in the next partition are fetched within a very short time period. In Figure 6, chunk 1 and chunk 2 from partition 2 will be running concurrently with chunk N from partition 1. However, **CF-Q** can still provide relaxed barriers between different partitions since chunks from the same cache-fit partition in the queue will always be retrieved in consecutive time periods so that no following partitions can be executed before previous one starts. The pseudo code of **CF-Q** is provided in Algorithm 2.

Algorithm 2 Cache-Fit Queue Scheduling

```
Input: cache-fit partition set $P$
procedure CF-Q($P$)
    for each partition $p$ in $P$ do
        insert $p$ into queue $Q$
    end for
    Kernel($Q$)
end procedure
procedure KERNEL($Q$)
    while Q is not empty do
        $I \leftarrow$ next queue item (chunk) from $Q$
        process $I$[laneID]
    end while
end procedure
```

3.3 Split-Join Scheduling

Split-Join (**SJ**) is another method that exploits the tradeoff between locality and execution pipeline utilization. **SJ** dynamically merges the *cache-fit* partitions that has low data reuse or combines low data reuse partitions with a high data reuse partition that is less likely to be interfered. **SJ** first constructs the tree structure that represents the hierarchical cache-fit partitions which we discussed in Section 2.3, we will refer to this as *SJ-tree*. **SJ** merges sibling nodes in the *SJ-tree* conditionally in a bottom-up manner. We only consider recombining sibling nodes as the sibling nodes have better data sharing than non-sibling nodes and the merging is logarithmic time.

SJ is performed with a fast online profiling process. We define a *profiling pass* as a profiling of all the nodes at one level of the *SJ-tree* which comprises one traversal of the entire work graph. So, the entire profiling process will take d profiling passes, where d is the depth of the *SJ-tree*. It takes at least $log(k)$ and up to k profiling passes for any given *SJ-tree*, where k is the number of leaf nodes in the tree. The lower bound $log(k)$ is reached when the binary tree is balanced and has $log(k)$ levels. Moreover, in the worst case scenario, when the tree is not balanced and at every level there is at most one leaf node, k profiling passes are needed. We run every work partition that corresponds to a leaf node in the *SJ-tree* in *stand-alone* mode and record the running time.

We use the first d iterations of the linear algebra and optimization applications to collect information for profiling. Since those applications we tested take between 50 and 22,000 iterations to converge, the overhead of profiling can be amortized. For example, *G3_circuit* need 5 iterations for profiling, and the total profiling time for Conjugate Gradient (CG) solver takes 0.017 s. The running time for CG with 22824 iterations is 94.331 s which gives us 0.018% profiling overhead. In practice, among all the matrices we used in the experiment, we found that the SJ-tree had at most 8 levels and thus required at most 8 passes for profiling.

The tree node merging problem can be defined as a tree-based weighted set cover problem. Merging two sibling nodes is as if choosing their parent node. The problem becomes how to find a subset of tree nodes $\boldsymbol{P}$ that will cover all possible cache-fit partitions (leaf nodes) while minimizing the overall running time:

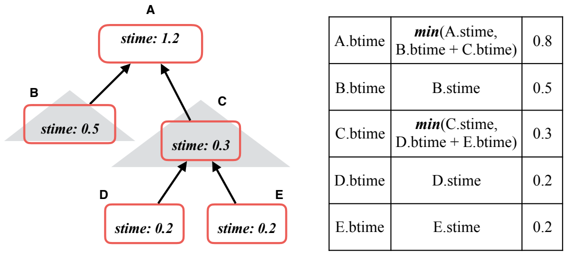
$$\begin{aligned} \text{minimize} \quad & \sum_{x \in P} c(x) \\ \text{subject to} \quad & \bigcup_{x \in P} S(x) = L \end{aligned} \tag{3}$$

where L is the set of all leaf nodes, P is the subset of the tree nodes (both leaf and non-leaf nodes) we want to find, $c(x)$ is a cost function that denotes the standalone running time of node x and S(x) is a set function that returns all leaf nodes of the subtree under node x.

Algorithm 3 Tree Recombination

```
Input: SJ-tree root
Output: optimal running time of SJ-tree root
procedure TREERECOMB(root)
    return BESTCONFIG(root)
end procedure
procedure BESTCONFIG(r)
    left_t = BESTCONFIG(r.leftChild)
    right_t = BESTCONFIG(r.rightChild)
    this_node_t = r.stime
    r.btime = min(left_t + right_t, this_node_t)
    return r.btime
end procedure
```

We develop a linear time algorithm that is capable of finding the optimum solution for the *tree-based set cover* problem. The algorithm processes the tree in post-topological order. Every node is associated with an attribute *btime* and an attribute *stime*. A sub tree's optimum time *btime* (annotated as an attribute of its root node) is the minimum of the two items: its root node's standalone running time *stime* and the summation of its two children subtree's *btime*. For a leaf node, its *btime* is the same as its standalone running time *stime*. The pseudo code is provided in Algorithm 3 together with an example in Figure 7. This process identifies the best set cover of the SJ-tree and determines how to recombine cache-fit partitions into every GPU kernel. **SJ** can achieve high execution pipeline utilization without sacrificing cache benefits (as data reuse is low for these low pipeline utilization cases).



A.btime	*min*(A.stime, B.btime + C.btime)	0.8
B.btime	B.stime	0.5
C.btime	*min*(C.stime, D.btime + E.btime)	0.3
D.btime	D.stime	0.2
E.btime	E.stime	0.2

{B, C} is chosen as the best configuration.

Figure 7: Tree Node Recombination Example

3.4 Split-Join Queue Scheduling

SJ dynamically merges cache-fit partitions that has low data reuse to ensure high execution pipeline utilization and good throttling performance. However, although **SJ** can provide Strict Barriers between different (merged) partitions, **SJ** cannot guarantee the execution order of those cache-fit partitions inside the merged partitions.

We propose **SJ-Q** which uses the idea of **CF-Q** that places cache-fit partitions in one merged work group (kernel) into a queue and each kernel will be using one independent queue. **SJ-Q** can provide both strict barriers between different merged partitions and also relaxed barriers between cache-fit partitions from the same merged partition. In the mean time, it inherits the advantage of **SJ** that avoids low execution pipeline utilization.

Sched.	Pipeline Util.	Prof.	Barrier	Queue	Code Change
CF	Low	No	Strict (S)	No	No
CF-Q	High	No	Relaxed (R)	Yes	Yes
SJ	High	Yes	Strict	No	No
SJ-Q	High	Yes	S/R	Yes	Yes

Table 1: Comparison of Four Scheduling Methods: Sched. refers to Scheduling Method, Prof. refers to if profiling is needed, and Util. refers to utilization.

Summary CF enforces strict barriers between different cache-fit partitions to ensure throttling. However, low execution pipeline utilization may happen which can degrade the computation performance; **CF-Q** uses a queue based method that can fully utilize the execution pipeline and loosely enforce barriers between consecutive cache-fit partitions; **SJ** merges those low data reuse partitions into one based on a tree set cover algorithm and online profiling; **SJ-Q** enforces strict barriers between different merged partitions and relaxed barriers between different cache-fit partitions within one merged partition.

We summarize the features of four scheduling methods in Table 1. All methods ensure good throttling performance while different methods impose different levels of barrier synchronization and code change overhead.

4 Implementation

We perform the adaptive overhead control mechanisms and data reorganization to make our software throttling method more efficient. We reduce the overhead of bisection in the **DBWP** Model, which is the most time-consuming part. In particular, we focus on two bisection algorithms: 1) Coarsened Bisection built upon the SPAC model by Li and others [25], and 2) K-D tiling built upon the k-d tree geometric space partitioning method [5].

We also use CPU-GPU pipelining to make the scheduling overhead transparent [33]: the CPU determines the best schedule while GPU is doing the actual computation. We improve the kernel performance by transforming data layout after we get cache-fit partitions such that the data access within the same kernel is coalesced as much as possible.

4.1 Adaptive Overhead Control

Coarsened Bisection *Coarsened Bisection* is based on SPAC [25] an effective sequential edge partition model. SPAC relies on a multi-level partition paradigm, in which, a graph is coarsened, partitioned, and refined/uncoarsened level by level. In *Coarsened Bisection*, we reduce the overhead of SPAC by eliminating the last few levels of refinement steps. We discovered that the last few coarsened levels (five to seven levels) of refinement stages in the multilevel partitioning scheme, if omitted, do not lead to much performance difference for our software throttling methods. While at the same time, a large amount of partition over can be saved.

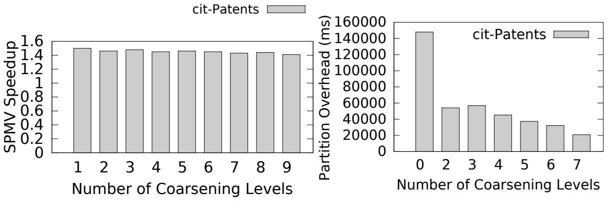


Figure 8: Trade-off between Eliminated Refinement Levels and Scheduling Overhead/Benefits

We show the trade-off between the number of levels where the refinement step is eliminated, and the SPAC partition overhead, and the *SpMV* speedup when applying the SPAC for scheduling, for the sparse matrix cit-patents [11] in Figure 8. It can be seen from the figure that by eliminating the last five to seven levels of refinement, the overhead is reduced by up to 7.5x, while the *SpMV* speedup only changed from 1.5x to 1.4x.

The detailed algorithm is showed in Algorithm 4. Notice that the input graph is already an coarsened graph, since we can perform first level coarsening while reading data from file. We also parallelize the merging phase in the coarsening phase to further reduce overhead. The merging phase is mainly for reconstructing the coarsened graph in each level and is amenable to parallelization.

Algorithm 4 Coarsened Bisection

```
Input: Coarsened Graph $G$
Output: Partition $P$
procedure COARSENBISECT($G$)
    // we call a set of edges - an entity
    build entity based adjacent list $L$ of $G$
    for $level \in \{1, \ldots, maxLevel\}$ do
        sort $L$ by entity degree
        for each entity $e$ do
            merge $e$ with its heaviest avaliable neighbor $ne$
        end for
        build coarsened $L$ by results from above step
    end for
    build coarsened graph $G'$ from $L$
    $P \leftarrow$graphPartition($G'$)
end procedure
```

K-D Tiling Another bisection method we adopted is a tiling based method: *K-D Tiling*. Since any graph can be converted into a sparse matrix representation, we treat the partition as a partition in a geometric two-dimensional space. This method is similar to the k-d tree structure [5] used for partitioning a k-dimensional space. Every non-leaf node in a k-d tree represents a division point along a single spatial dimension, recursively splitting the space's points into two groups.

This partitioning method has even lower overhead than *Coarsened Bisection*. Each split can be performed in O(n) average time via the *quickselect* algorithm [16], and the number of rounds of splitting is logarithmic. However, unlike *Coarsened Bisection*, the tiling approach does not consider connectivity of the graph, and so it generates inferior results. This trade-off makes *Coarsened Bisection* preferable in applications where its overhead can be hidden via amortization, for instance, in optimization problems, and the K-D tiling method is better for overhead-sensitive applications.

4.2 Data Reorganization

After we perform *Data-Balanced Work-Partition* on the work graph, we reorganize the data in memory according to cache-fit partitions for efficient memory coalescing. We prioritize the partition that has the smallest amount of unique data – indicating a high data reuse if the amount of work in each partition is the same. We iterate over each partition's tuple list, and place all their non-boundary vertices (vertices that only appear in one kernel) consecutively in memory using *data packing* [12]. After non-boundary vertices for each partition have been processed, we process boundary vertices. The data reordering algorithm is briefly described in Algorithm 5.

5 Evaluation

We perform experiments on two platforms: an NVIDIA *GTX 745* GPU with Intel Core i7-4790 CPU and an NVIDIA *TITAN X* GPU with Intel Xeon CPU E5-2620. The GPU configurations are detailed in Table 2. We evaluate our techniques using important real-world workloads including sparse linear algebra, neural networks, and graph analytics.

Table 2: Experimental Environment

GPU Model	Titan X	GTX 745
Architecture	Pascal	Maxwell
Core #	5376	576
L2 Cache	3MB	2MB
CUDA version	CUDA 8.0	CUDA 8.0

Algorithm 5 Data Remapping

```
Input: Original Partition Set $P$, Boundary Vertex Set $B$
Output: Reordered Data $D$
procedure DATAREMAPPING($P, D$)
    for each vertex $v$ in partition $p$ of $P$ do
        if $v \notin B$ then
            $unique[p]$++
        end if
    end for
    P' = rank(P, $unique$[P]); // Rank $P$ by $unique$[]
    // Assign non-boundary nodes
    for each vertex $v$ in partition $p$ of $P'$ do
        if !$boundary[v]$ and $v$ is not in $D$ then
            append $v$ to $D$
        end if
    end for
    // Assign boundary nodes
    for each vertex $v$ in partition $p$ of $P'$ do
        if $boundary[v]$ and $v$ is not in $D$ then
            append $v$ to $D$
        end if
    end for
end procedure
```

Sparse Linear Algebra Workloads We use sparse matrix vector multiplication (SpMV) and the conjugate gradient solver (CG). We present performance and sensitivity analysis, as well as the effectiveness of overhead control.

Neural Networks We use a pruned form of AlexNet [15]. The pruned neural network is essentially sparse matrix operation.

Graph Processing Workloads We use two graph processing benchmarks: the Bellman-Ford (BMF) and PageRank (PR) programs [21]. Bellman-Ford takes a weighted graph as input and iteratively calculates every node's distance – an important, basic operation used in path and network analysis applications. PageRank takes a weighted graph as input and calculates the importance of every node based on its incoming links.

Computational Fluid Dynamics Workloads We use the CFD benchmark from the Rodinia benchmark suite [7]. The CFD solver is an unstructured grid finite volume solver for the three-dimensional Euler equations for compressible flow. The CFD benchmark is already highly optimized in terms of data layout [9]. We use three mesh input sets from Rodinia [7].

5.1 Sparse Linear Algebra

SpMV We treat the sparse matrix as a bipartite graph, as described in Section 2.1, and then apply our techniques . We use the SpMV kernel function from the cusp library[10] and the matrix format is COO.

Of the 2757 matrices in the University of Florida collection [11], we extract those where the working set cannot fit entirely into the L2 (last-level) cache, which leaves us with 228 matrices on GTX 745, and 192 on Titan X. Though we optimize for the L2 cache, our techniques can be generalized to other caches.

The performance summary for *SpMV* across these matrices is shown in Figure 9. We also include Org+R, which applies the data reorganization scheme described in Section 4.2 to the original program to optimize memory coalescing. Memory coalescing is a technique for enhancing spatial locality [33], which is orthogonal to our technique proposed in this paper. As our work also performs memory coalescing after obtaining and scheduling cache-fit partitions, we show the performance of *memory coalescing only* (Org+R) versus our technique + *memory coalescing* for fair comparison and for demonstrating the significant performance improvement from our technique.

Among the other methods shown, first is CF, the Cache-Fit method described in Section 3.1. This splits the kernel to run each of the cache-fit partitions in standalone mode. Second is SJ, the Split-Join method described in Section 3.3 and uses tree-based set cover algorithm to merge cache-fit partitions. Third is CF-Q from Section 3.2, which applies the concurrent queue for loosely enforcing cache-fit partition ordering within a single kernel invocation. Finally we show SJ-Q from Section 3.4, which applies the concurrent queue to merged partitions in SJ. We use our Coarsened Bisection partitioner for all four of these methods. The baseline is the original program performance.

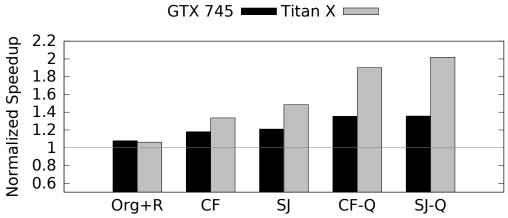

Figure 9: Average Speedup for SpMV

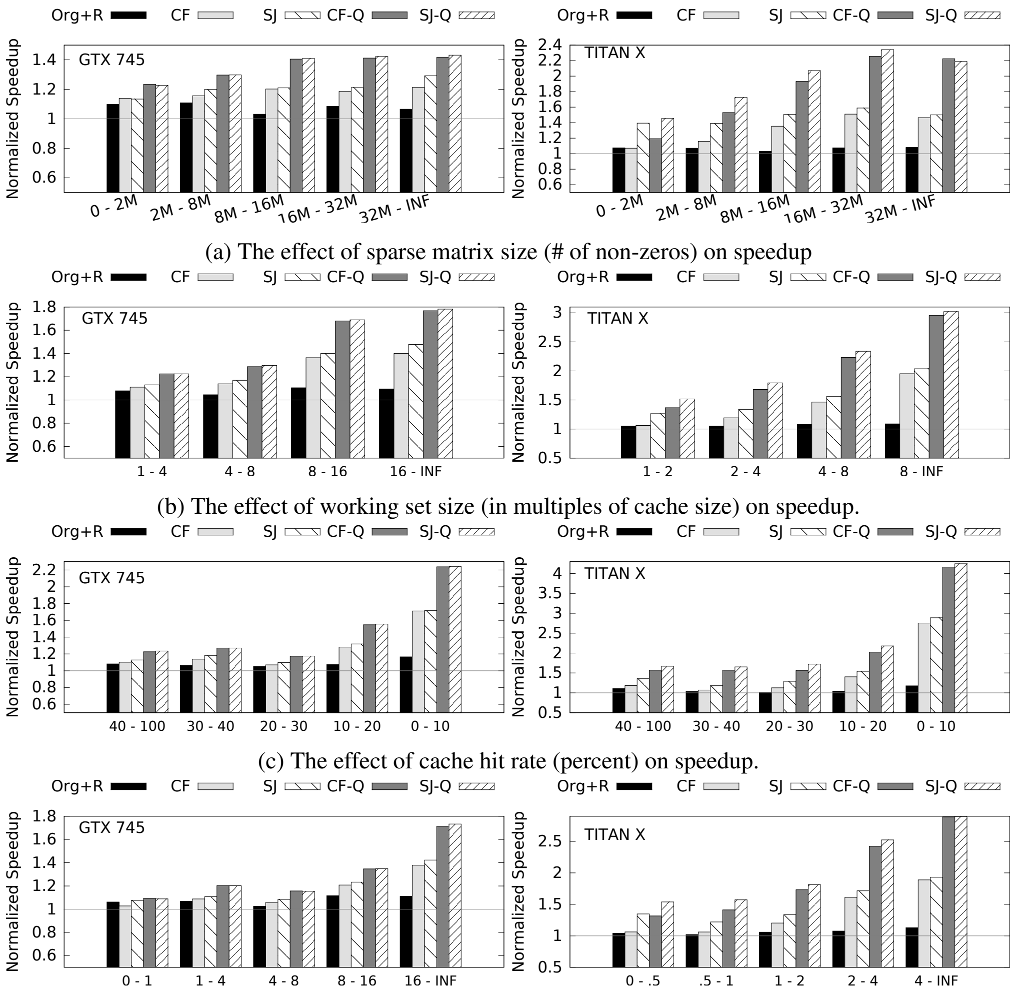
All four methods provide significant speedup compared to the original case and the Org+R case. But each method has trade-offs. The SJ and SJ-Q methods both require runtime profiling, whereas CF and CF-Q do not need runtime profiling. CF and SJ are easier to incorporate to a program as the kernel code does not change (only the input to each kernel invocation changes), whereas CF-Q and SJ-Q require code modification in order to implement the queue.

We find that our techniques provide significantly more improvement in the high contention environments of larger matrices with lower hit rates. We demonstrate the effectiveness of these methods with respect to matrix size, working set size, cache hit rate, and original running time.

Matrix Size In Figure 10 (a), each group of bars shows average speedup for sparse matrices with the specified amounts of non-zeros. Every method except Org+R is



(a) The effect of sparse matrix size (# of non-zeros) on speedup

(b) The effect of working set size (in multiples of cache size) on speedup.

(c) The effect of cache hit rate (percent) on speedup.

(d) The effect of original runtime (milliseconds) on speedup.

Figure 10: SpMV Speedup on GTX 745 and Titan X

much more effective on larger matrices than on smaller ones, but we do see speedup in every group.

Working Set Our techniques become more effective as the working set grows, alleviating the increased cache contention. In Figure 10 (b), each group of bars shows average speedup for matrices with a working set of specified size. The unit used for the x-axis is the number of times the working set can completely fill the cache.

We see speedup improve as the working set grows, just as it tends to do when the matrix size grows. But the effects are more pronounced, with higher speedup. This shows working set size is more useful than matrix size for determining whether we should use locality-aware software throttling optimization.

Cache Hit Rate Our techniques are designed to improve matrices that suffer from low hit rates due to cache thrashing. As such, a lower original hit rate allows us to achieve higher speedup. In Figure 10 (c), each group of bars shows average speedup for matrices with a specified range of cache hit rates for the original case.

For matrices with lowest hit rates, the speedup for the queue-based approaches is particularly extreme. This shows that the queue-based approach is especially effective in environments that have high cache contention. The implicit communication between thread warps competing for queue reservations allows warps to achieve higher temporal locality with each other.

Run Time In Figure 10 (d), each group of bars shows the average speedup for matrices with the specified original runtime, measured in milliseconds. Since the Titan X device is much faster than the GTX 745, we use smaller thresholds for it. In general we can expect that the runtime correlates highly with the number of non-zeros, and so this figure shows a similar curve to the others.

CG We show the performance of conjugate gradient (CG) using SJ-Q. The major computation component is sparse matrix vector multiplication (SpMV). It calls *SpMV* iteratively until convergence. Therefore the overhead is amortized across different iterations. We show the overall performance in Figure 11 for a representative set of inputs. We find the performance improvement of CG with overhead is similar to that of *SpMV* without overhead. The overhead of Coarsened Bisection and SJ-Q profiling is well amortized.

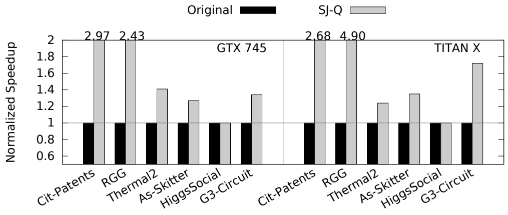


Figure 11: CG Speedup on GTX 745 and Titan X

We also show the L2 cache hit rates for CG in Figure 12. The changes to cache hit rates correlate with the performance improvement. The matrix rgg_n_2_23_s0 (RGG) has a much smaller cache hit rate on Titan X (0.44%) than on GTX 745 (36.75%), despite its larger cache size. There is more cache contention on Titan X since it uses more cores. We are able to improve the hit rate to 62.92% without changing the thread number or the implementation of the kernel code. Only the set of non-zero elements processed by each kernel is changed.

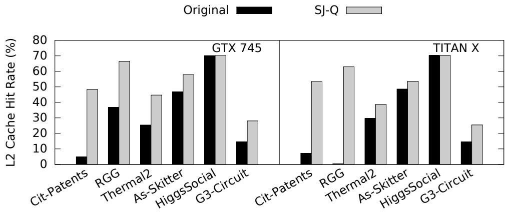

Figure 12: CG Cache Hit Rate on GTX 745 and Titan X

5.2 Neural Networks

We explore the effectiveness of our techniques on the AlexNet neural network, achieving an overall speedup of up to 54% on the Titan X device, which is suited for deep learning. Each fully connected layer of the neural network AlexNet operates as a matrix-vector operation; the matrix is a weight matrix. The work by Han and others [15] prunes the AlexNet network to remove elements of low weight and result in sparse matrices.

Since AlexNet is designed for smaller, embedded devices, we run multiple instances in parallel, allowing the neural network to analyze 150 different images at once for our Titan X GPU. This provides a reasonable amount of computation and data for our more powerful hardware.

In Figure 13, we show the speedup achieved by our technique on each of the three pruned *fc* layers of AlexNet. We include the alternate baseline of the original case plus data reorganization, as well as the Cache-Fit and Split-Join strategies both with and without the queue-based implementation.

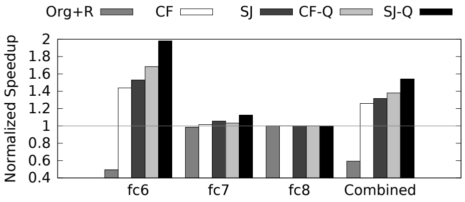

Figure 13: Speedup for AlexNet layers on Titan X

When only applying data reorganization, we see no improvement or even some slowdown. But when we apply any of our partitioning techniques we see speedup up to 98%, and no degradation on the smaller layers. The reason for less-speedup in the smaller layers (fc 7 and fc 8) is that their vector size is smaller and can fit into last level cache entirely in our Titan X GPU. We believe the performance improvement will be more pronounced for Alexnet if we test with embedded devices.

5.3 Graph Applications

We show the performance of the Bellman-Ford and PageRank programs on a set of graphs from the University of Florida Sparse Matrix Collection [11], Stanford Large Network Dataset Collection [23], and DIMACS implementation challenge [1]. Information for each graph is listed in Table 3.

We demonstrate the efficiency of the K-D tiling (SJ-kdtiling) approach, since both BMF and PR take fewer iterations to converge compared with sparse linear system solvers. Thus we need a fast and approximate partitioner so that the overhead can be amortized. We use SJ rather than SJ-Q, since it still provides good speedup while avoiding the overhead of the queue.

We summarize the performance with overhead in Table 3. We see that our approach improves performance for both BMF and PR. *RoadCal* benefits least, due to small size, but sees improvement in some cases.

Table 3: BMF and PR Performance Summary

Graph	GTX 745		TITAN X	
	BMF	PR	BMF	PR
Pokec [23]	1.62	2.98	1.88	3.17
WebGoogle [23]	2	3.29	1.8	3.37
Wikipedia-051105 [11]	1.24	1.99	1.43	1.97
WikiTalk [11]	1.74	2.57	2.09	2.75
IMDB [11]	2.16	3.22	1.59	2.62
RoadCentral [11]	1.19	1.6	1.69	2.18
RoadCal [1]	1	1	1	1.22

We observe that the speedup for PR is greater than for BMF. There are more memory accesses in the PR algorithm than in the BMF algorithm, and so it benefits more from our locality-aware software throttling.

We show cache hit rates for each program in Figure 14 and Figure 15. We show speedup with and without overhead for PR on Titan X in Table 4. PR has fewer iterations than CG so cannot improve performance with Coarsened Bisection if overhead is considered. However, the KD-Tiling method is fast enough that for SJ-kdtiling's performance to remain high with overhead.

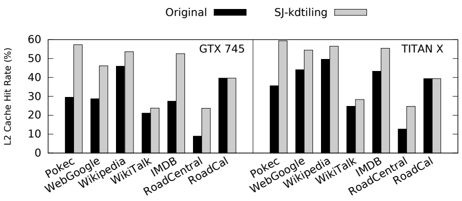

Figure 14: Cache Hit Rates for Bellman-Ford

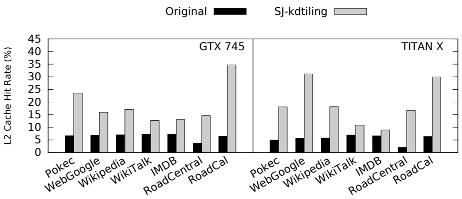

Figure 15: Cache Hit Rates for PageRank

Table 4: PageRank Speedup with and without Overhead

Graph	SJ-kdtiling w/ Overhead	SJ-kdtiling w/o Overhead
Pokec	3.17	3.34
WebGoogle	3.37	3.43
Wikipedia	1.97	1.98
WikiTalk	2.75	2.81
IMDB	2.62	2.27
RoadCentral	2.18	2.48
RoadCal	1.22	1.21

5.4 Computational Fluid Dynamics

The graph structure for CFD is a mesh in which every node has up to four neighbors. Since these meshes are small, We use SJ instead of SJ-Q for throttling. In Figure 16 we show the performance on GTX 745. We achieve speedup of up to 10%. Input *fvcorr_097* has the smallest number of nodes, thus the smallest improvement. CFD already has an optimized data layout [9]. With our throttling method, we nonetheless see some speedup. This demonstrates the effectiveness of our approach.

6 Related Work

Modern GPUs are equipped with massive amounts of parallelism and significant computing horsepower. However, this also results in higher levels of cache contention. To achieve high performance, reusing data in cache is critical. Both software and hardware approaches have been proposed to address the cache contention problem.

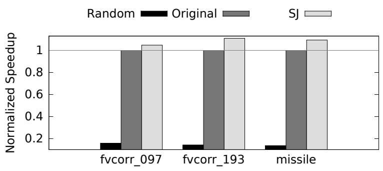

Figure 16: CFD Speedup

Warp Scheduling Policy Recent works focus on modifying GPU warp scheduling policy to reduce cache contention by throttling threads [18] [27] [20, 19] or to prioritize thread execution based on criticality [22]. However, all those approaches require hardware modification and require fine-grained thread scheduling which is complicated in a massively parallel system.

Our approach does not require hardware modification or fine-grained thread scheduling. Moreover, most warp scheduling policies aim to reduce the number of active warps for better performance. However, as we discovered in this paper, it is not always good to reduce the number of simultaneously running tasks for better cache performance. In some scenarios, i.e., when data reuse is low, having higher concurrency actually helps.

Computation and Data Layout Transformation On GPUs, Baskaran et al. [3] developed a compile-time transformation scheme coalescing loop nest accesses to achieve efficient global memory access. Zhang et al. [32] focused on reducing irregular memory accesses and enhancing memory coalescing to improve GPU program performance. These and other works [28, 31, 8, 17, 30, 4] all focus on improving memory coalescing for spatial locality. Our method is orthogonal to these approaches, as we optimize temporal locality.

7 Conclusion

This paper proposes a locality-aware software throttling framework that targets irregular sparse matrix applications on GPUs. We perform data-balanced *work partition* on the entire workload to get **cache-fit** partitions and use scheduling to exploit the trade-off between cache locality and execution pipeline utilization. Our framework is practical and effective. It requires no hardware modification and achieves an average 2.01X (maximal 6.45X) speedup on more than 200 real sparse matrices.

Abstract

PageRank is a fundamental link analysis algorithm that also functions as a key representative of the performance of Sparse Matrix-Vector (SpMV) multiplication. The traditional PageRank implementation generates fine granularity random memory accesses resulting in large amount of wasteful DRAM traffic and poor bandwidth utilization. In this paper, we present a novel Partition-Centric Processing Methodology (PCPM) to compute PageRank, that drastically reduces the amount of DRAM communication while achieving high sustained memory bandwidth. PCPM uses a Partition-centric abstraction coupled with the Gather-Apply-Scatter (GAS) programming model. By carefully examining how a PCPM based implementation impacts communication characteristics of the algorithm, we propose several system optimizations that improve the execution time substantially. More specifically, we develop (1) a new data layout that significantly reduces communication and random DRAM accesses, and (2) branch avoidance mechanisms to get rid of unpredictable data-dependent branches.

We perform detailed analytical and experimental evaluation of our approach using 6 large graphs and demonstrate an average 2.7× speedup in execution time and 1.7× reduction in communication volume, compared to the state-of-the-art. We also show that unlike other GAS based implementations, PCPM is able to further reduce main memory traffic by taking advantage of intelligent node labeling that enhances locality. Although we use PageRank as the target application in this paper, our approach can be applied to generic SpMV computation.

1 Introduction

Graphs are the preferred choice of data representation in many fields such as web and social network analysis [9, 3, 29, 10], biology [17], transportation [15, 4] etc. The growing scale of problems in these areas has generated substantial research interest in high performance graph analytics. A large fraction of this research is focused on shared memory platforms because of their low communication overhead compared to distributed systems [26]. High DRAM capacity in modern systems further allows in-memory processing of large graphs on a single server [35, 33, 37]. However, efficient utilization of compute power is challenging even on a single node because of the (1) low computation-to-communication ratio and, (2) irregular memory access patterns of graph algorithms. The growing disparity between CPU speed and DRAM bandwidth, termed memory wall [42], has become a key issue in high performance graph analytics.

PageRank is a quintessential algorithm that exemplifies the performance challenges posed by graph computations. It iteratively performs Sparse Matrix-Vector (SpMV) multiplication over the adjacency matrix of the target graph and the current PageRank vector $\overrightarrow{PR}$ to generate new PageRank values. The irregularity in adjacency matrices leads to random accesses to $\overrightarrow{PR}$ with poor *spatial* and *temporal* locality. The resulting cache misses and communication volume become the performance bottleneck for PageRank computation. Since many graph algorithms can be similarly modeled as a series of SpMV operations [37], optimizations on PageRank can be easily generalized to other algorithms.

Recent works have proposed the use of Gather-Apply-Scatter (GAS) model to improve locality and reduce communication for SpMV and PageRank [43, 11, 5]. This model splits computation into two phases: *scatter* current source node values on edges and *gather* propagated values on edges to compute new values for destination nodes. The 2-phased approach restricts access to either the current $\overrightarrow{PR}$ or new $\overrightarrow{PR}$ at a time. This provides opportunities for cache-efficient and lock-free parallelization of the algorithm.

We observe that although this approach exhibits several attractive features, it also has some drawbacks leading to inefficient memory accesses, both quantitative as well as qualitative. First, we note that while scattering, a vertex *repeatedly* writes its value on all outgoing edges, resulting in large number of reads and writes. We also observe that the Vertex-centric graph traversal in [11, 5] results in *random* DRAM accesses and the Edge-centric traversal in [34, 43] scans edge list in coordinate format which increases the number of reads.

Our premise is that by changing the focus of computation from a single vertex or edge to a *cacheable* group of vertices (partition), we can effectively identify and reduce redundant edge traversals as well as avoid random accesses to DRAM, while still retaining the benefits of GAS model. Based on these insights, we develop a new

Partition-Centric approach to compute PageRank. The major contributions of our work are:

1. We propose a Partition-Centric Processing Methodology (PCPM) that propagates updates from nodes to partitions and reduces the redundancy associated with GAS model.
2. By carefully evaluating how a PCPM based implementation impacts algorithm behavior, we develop several system optimizations that substantially accelerate the computation, namely, (a) a new data layout that drastically reduces communication and random memory accesses, (b) branch avoidance mechanisms to remove unpredictable branches.
3. We demonstrate that PCPM can take advantage of intelligent node labeling to further reduce the communication volume. Thus, PCPM is suitable even for high locality graphs.
4. We conduct extensive analytical and experimental evaluation of our approach using 6 large datasets. On a 16-core shared memory system, PCPM achieves $2.1\times - 3.8\times$ speedup in execution time and $1.3\times - 2.5\times$ reduction in main memory communication over state-of-the-art.
5. We show that PCPM can be easily extended to weighted graphs and generic SpMV computation (section 3.5) even though it is described in the context of PageRank algorithm in this paper.

2 Background and Related Work

2.1 PageRank Computation

In this section, we describe how PageRank is calculated and what makes it challenging for the conventional implementation to achieve high performance. Table 1 lists a set of notations that we use to mathematically represent the algorithm.

Table 1: List of graph notations

$G(V,E)$	Input directed graph
A	adjacency matrix of $G(V,E)$
$N_i(v)$	in-neighbors of vertex v
$N_o(v)$	out-neighbors of vertex v
$\overrightarrow{PR}_i$	PageRank value vector after i^{th} iteration
$\overrightarrow{SPR}$	scaled PageRank vector $\left(SPR(v) = \frac{PR_i(v)}{\lvert N_o(v)\rvert}\right)$
d	damping factor in PageRank algorithm

PageRank is computed iteratively. In each iteration, all vertex values are updated by the new weighted sum of their in-neighbors' PageRank, as shown in equation 1.

$$PR_{i+1}(v) = \frac{1-d}{|V|} + d \sum_{u \in N_i(v)} \frac{PR_i(u)}{\lvert N_o(u)\rvert} \tag{1}$$

PageRank is typically computed in pull direction [35, 38, 37, 30] where each vertex pulls the value of its in-neighbors and accumulates into its own value, as shown in algorithm 1. This corresponds to traversing A in a column-major order and computing the dot product of each column with the scaled PageRank vector $\overrightarrow{SPR}$.

Algorithm 1 Pull Direction PageRank (PDPR) Iteration

```
for $v \in V$ do
    $temp = 0$
    for all $u \in N_i(v)$ do
        $temp += PR[u]$
    $PR_{next}[v] = \frac{(1-d)\times|V|^{-1} + d\times temp}{|N_o(v)|}$
swap($PR, PR_{next}$)
```

In the pull direction implementation, each column completely owns the computation of the corresponding element in the output vector. This enables all columns of A to be traversed asynchronously in parallel without the need to store partial sums in memory. On the contrary, in the push direction, each node updates its out-neighbors by adding its own value to them. This requires a row-major traversal of A and storage for partial sums since each row contributes partially to multiple elements in the output vector. Further, synchronization is needed to ensure conflict-free processing of multiple rows that update the same output element.

Performance Challenges: Sparse matrix layouts like Compressed Sparse Column (CSC) store all non-zero elements of a column sequentially in memory allowing fast column-major traversal of A [36]. However, the neighbors of a node can be scattered anywhere in the graph and reading their values results in random accesses (single or double word) to $\overrightarrow{SPR}$ in pull direction computation. Similarly, the push direction implementation uses a Compressed Sparse Row (CSR) format for fast row-major traversal of A but suffers from random accesses to the partial sums vector. These low locality and fine granularity accesses incur high cache miss ratio and contribute a large fraction to the overall memory traffic as shown in fig. 1.

2.2 Related Work

The performance of PageRank depends heavily on the locality in memory access patterns of the graph (which we refer to as *graph locality*). Since node labeling has significant impact on graph locality, many prior works have investigated the use of node reordering or clustering [7, 22, 6, 2] to improve the performance of graph algorithms. Reordering based on spatial and temporal locality aware placement of neighbors [39, 20] has

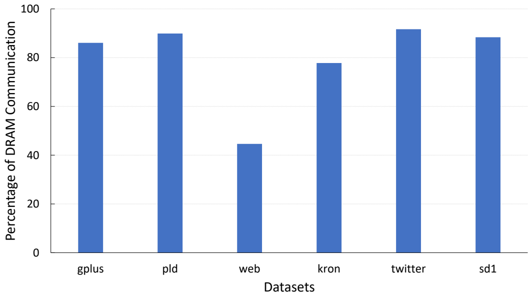

Figure 1: Percentage contribution of vertex value accesses to the total DRAM traffic in a PageRank iteration.

been shown to further outperform the well known clustering and tree-based techniques. However, such sophisticated algorithms also introduce substantial pre-processing overhead which limits their practicability. In addition, scale-free graphs like social networks are less tractable by reordering transformations because of their skewed degree distribution.

Cache Blocking (CB) is another technique used to accelerate graph processing [41, 32, 45]. CB induces locality by restricting the range of randomly accessed nodes and has been shown to reduce cache misses [24]. CB partitions A along rows, columns or both into multiple block matrices. However, SpMV computation with CB requires the partial sums to be re-read for each block. The extremely sparse nature of these block matrices also reduces the reuse of cached vertex data [31].

Gather-Apply-Scatter (GAS) is another popular model incorporated in many graph analytics frameworks [23, 34, 13]. It splits the analytic computation into *scatter* and *gather* phases. In the *scatter* phase, source vertices transmit updates on all of their outgoing edges and in the *gather* phase, these updates are processed to compute new values for corresponding destination vertices. The *updates* for PageRank algorithm correspond to *scaled PageRank values* defined earlier in section 2.1.

Binning exploits the 2-phased computation model by storing the updates in a semi-sorted manner. This induces *spatio-temporal* locality in access patterns of the algorithm. Binning can be used in conjunction with both Vertex-centric or Edge-centric paradigms. Zhou et al. [43, 44] use a custom sorted edge list with Edge-centric processing to reduce DRAM row activations and improve memory performance. However, their sorting mechanism introduces a non-trivial pre-processing cost and imposes the use of COO format. This results in larger communication volume and execution time than the CSR based Vertex-centric implementations [5, 11].

GAS model is also *inherently sub-optimal* when used with either Vertex-centric or Edge-centric abstractions. This is because it traverses the entire graph twice in each iteration. Nevertheless, Binning with Vertex-centric GAS (BVGAS) is the state-of-the-art methodology on shared memory platforms [5, 11] and we use it as baseline for comparison in this paper.

3 Partition-Centric Processing

We propose a new Partition-Centric Processing Methodology (PCPM) that significantly improves the efficiency of processor-memory communication over that achievable with current Vertex-centric or Edge-centric methods. We define *partitions* as disjoint sets of contiguously labeled nodes. The Partition-Centric abstraction then perceives the graph as a set of links from each node to the partitions corresponding to the neighbors of the node. We use this abstraction in conjunction with the 2-phased Gather-Apply-Scatter (GAS) model.

During the PCPM scatter phase, each thread processes one partition at a time. Processing a partition p means propagating messages from nodes in p to the neighboring partitions. A message to a partition p' comprises of the update value of source node ($PR[v]$) and the list of out-neighbors of v that lie in p'. PCPM caches the vertex data of p and streams the messages to the main memory. The messages from p are generated in a Partition-centric manner i.e. messages from all nodes in p to a neighboring partition p' are generated consecutively and are not interleaved with messages to any other partition.

During the gather phase, each thread scans all messages destined to one partition p at a time. A message scan applies the update value to all nodes in the neighbor list of that message. Partial sums of nodes in p are cached and messages are streamed from the main memory. After all messages to p are scanned, the partial sums (new PageRank values) are written back to DRAM.

With static pre-allocation of distinct memory spaces for each partition to write messages, PCPM can asynchronously scatter or gather multiple partitions in parallel. In this section, we provide a detailed discussion on PCPM based computation and the required data layout.

3.1 Graph Partitioning

We employ a simple approach to divide the vertex set V into partitions. We create equisized partitions of size q where partition P_i owns all the vertices with index $\in [i*q,(i+1)*q)$ as shown in fig. 2a. As discussed later, the PCPM abstraction is built to easily take advantage of more sophisticated partitioning schemes and deliver further performance improvements (the trade-off is time complexity of partitioning versus performance gains). As we show in the results section, even the simple partitioning approach described above delivers significant performance gains over state-of-the-art methods.

Each partition is also allocated a contiguous memory space called *bin* to store updates (*update_bins*) and corresponding list of destination nodes (*destID_bins*) in the incoming messages. Since each thread in PCPM scatters or gathers only one partition at a time, the random accesses to vertex values or partial sums are limited to address range equal to the partition size. This improves temporal locality in access pattern and in turn, overall cache performance of the algorithm.
